Development of Retinal Ganglion Cell Dendritic Structure and Synaptic Connections

Ning Tian, MD-PhD[1]

Created: June 13, 2012.

1 Introduction

The neuronal information of the visual scene that is processed by the retina is conducted to the brain by a set of separate spatio-temporal synaptic pathways. The morphological basis for the formation of these parallel synaptic pathways is the laminar-specific structure of the retina, in which specific subtypes of retinal neurons form synapses only with highly selective presynaptic and postsynaptic cells (1-3).

Retinal ganglion cells (RGCs) are the output neurons of the retina. In the retina, RGCs synapse with bipolar and amacrine cells in the inner plexiform layer (IPL) to receive excitatory and inhibitory synaptic inputs respectively. The axons of RGCs travel through the optic nerve to retinorecipient structures in the brain, where they transfer their specific aspects of visual information to the higher centers (3). Because different subtypes of bipolar cells (Fig 1) (4) and amacrine cells (Fig. 2) (5) have their axonal/dendritic terminals in the specific sublaminae of the IPL, it is crucial that dendrites of individual RGCs are also confined to specific strata in order to synapses with them.

Thus, the synaptic circuitries processing distinct visual features, the so called "parallel pathways" (1, 2, 6-10), start in the retina. In most mammals, RGCs can be divided into about 20 morphological subtypes based on their distinctive dendritic structure and synaptic connections (11-19). The wholemount drawings of mouse RGCs (Fig. 3) illustrate the diversity of morphologies present in mammalian RGCs ((19). See also RGCs of human, cat and rabbit retinas in the ganglion cell chapter in Webvision).

Most of these RGCs have specific dendritic distribution in the IPL in adult retina as exemplified by the schematic (Fig. 4) showing the branching patterns of mouse RGCs. In most mammals, these lamina-restricted distributions of RGC dendrites and synaptic connections are formed during pre- and post-natal development. The question is how this lamination arises.

2 Neurogenesis and synaptogenesis of retina

The neurogenesis and synaptogenesis of mammalian retina is an orderly process. Figure 5 shows an overview drawing of the development of mouse retinal neurons. RGCs differentiate first followed by amacrine cells, cones and horizontal cells. Rod photoreceptors differentiate shortly afterward. Bipolar cells are the last neurons to differentiate. In mammals most retinal neurons differentiate before birth (20-22).

The order of synaptogenesis of retinal neurons is somewhat different from the order of neurogenesis. The synapses of amacrine cells in the IPL appear first. These are followed by the synaptic formation between photoreceptors and horizontal cells in the OPL. The last synaptic element to link photoreceptors in the outer retina and RGCs in the inner retina is the synaptic connection between bipolar cells and RGCs (Fig. 5A) (23, 24). In mouse, the density of both ribbons and conventional synapses in the IPL continuously increases after eye opening and reaches the peak level by the age of P21 (Fig. 5B). Functionally, the strength of RGC synaptic inputs measured by the frequency of spontaneous synaptic activity is low before eye opening in mice. After eye

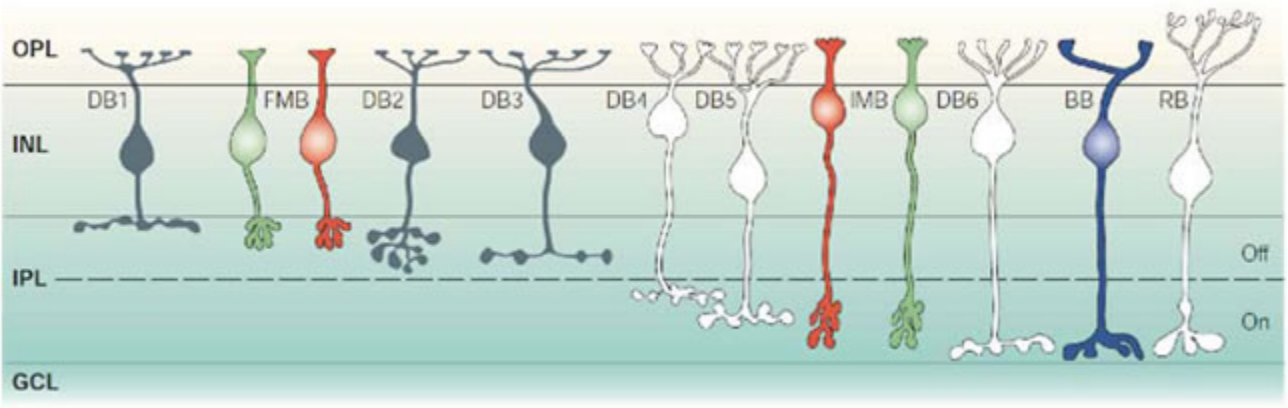

Figure 1: The major subtypes of bipolar cells of primate retina (Adapted from Wässle, 2004 (10)). Similar types have been observed in the rats (4), rabbit, cat (15, 74), monkey (75) and human (76).

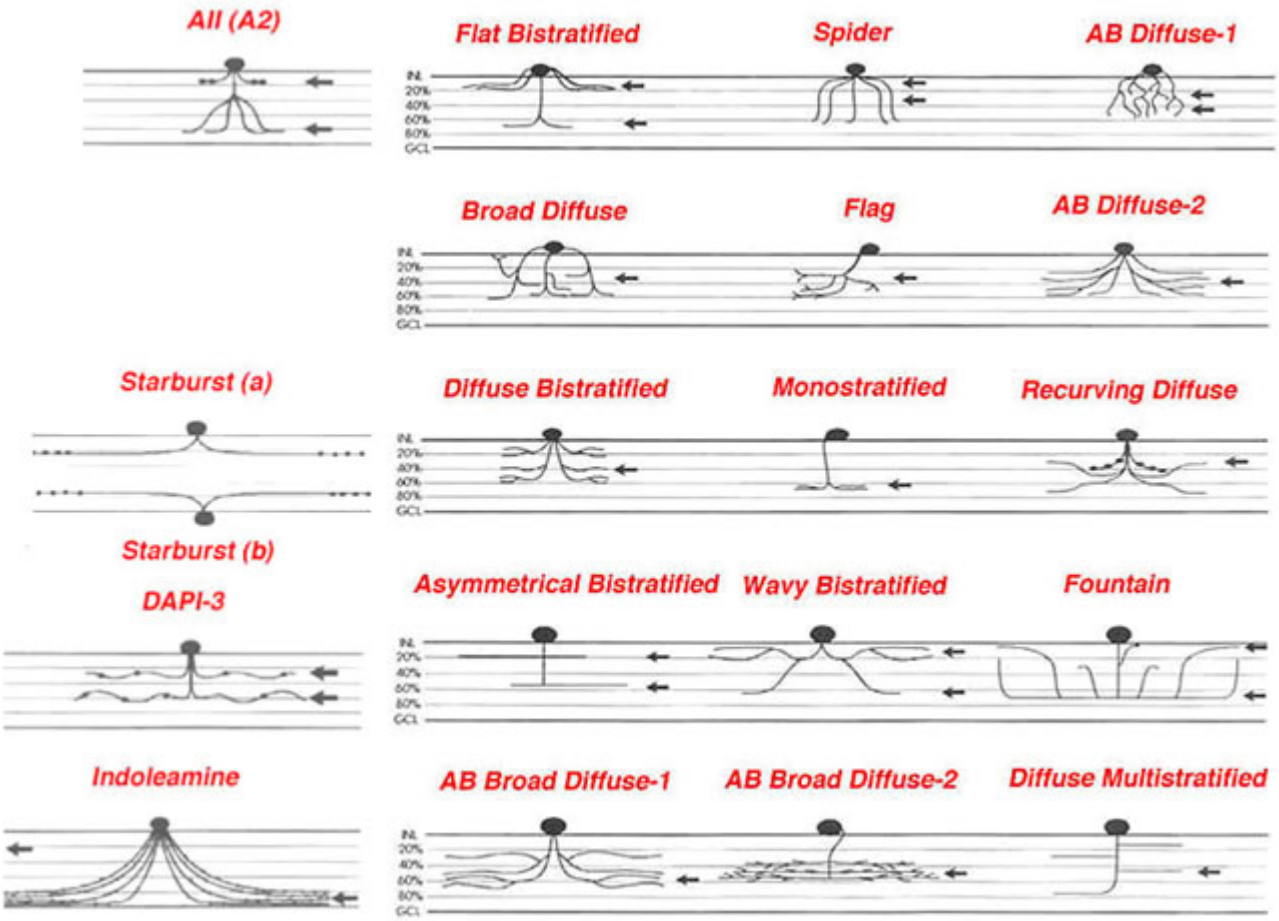

Figure 2. Schematic drawings of some of the amacrine cells of rabbit retina show each type has a characteristic morphology and stratification of the dendrites to specific strata (1-5) of the inner plexiform layer. All other mammals have similar cells. Adapted from MacNeil and Masland, 1998 (5).

opening, a surge of glutamate receptor-mediated spontaneous excitatory postsynaptic currents (sEPSCs) and GABA/glycine receptor-mediated spontaneous inhibitory postsynaptic currents emerges around P25 (Fig. 5B). Amplitudes of RGC light responses in cat and ferret retina are also found to increase after eye opening (25, 26).

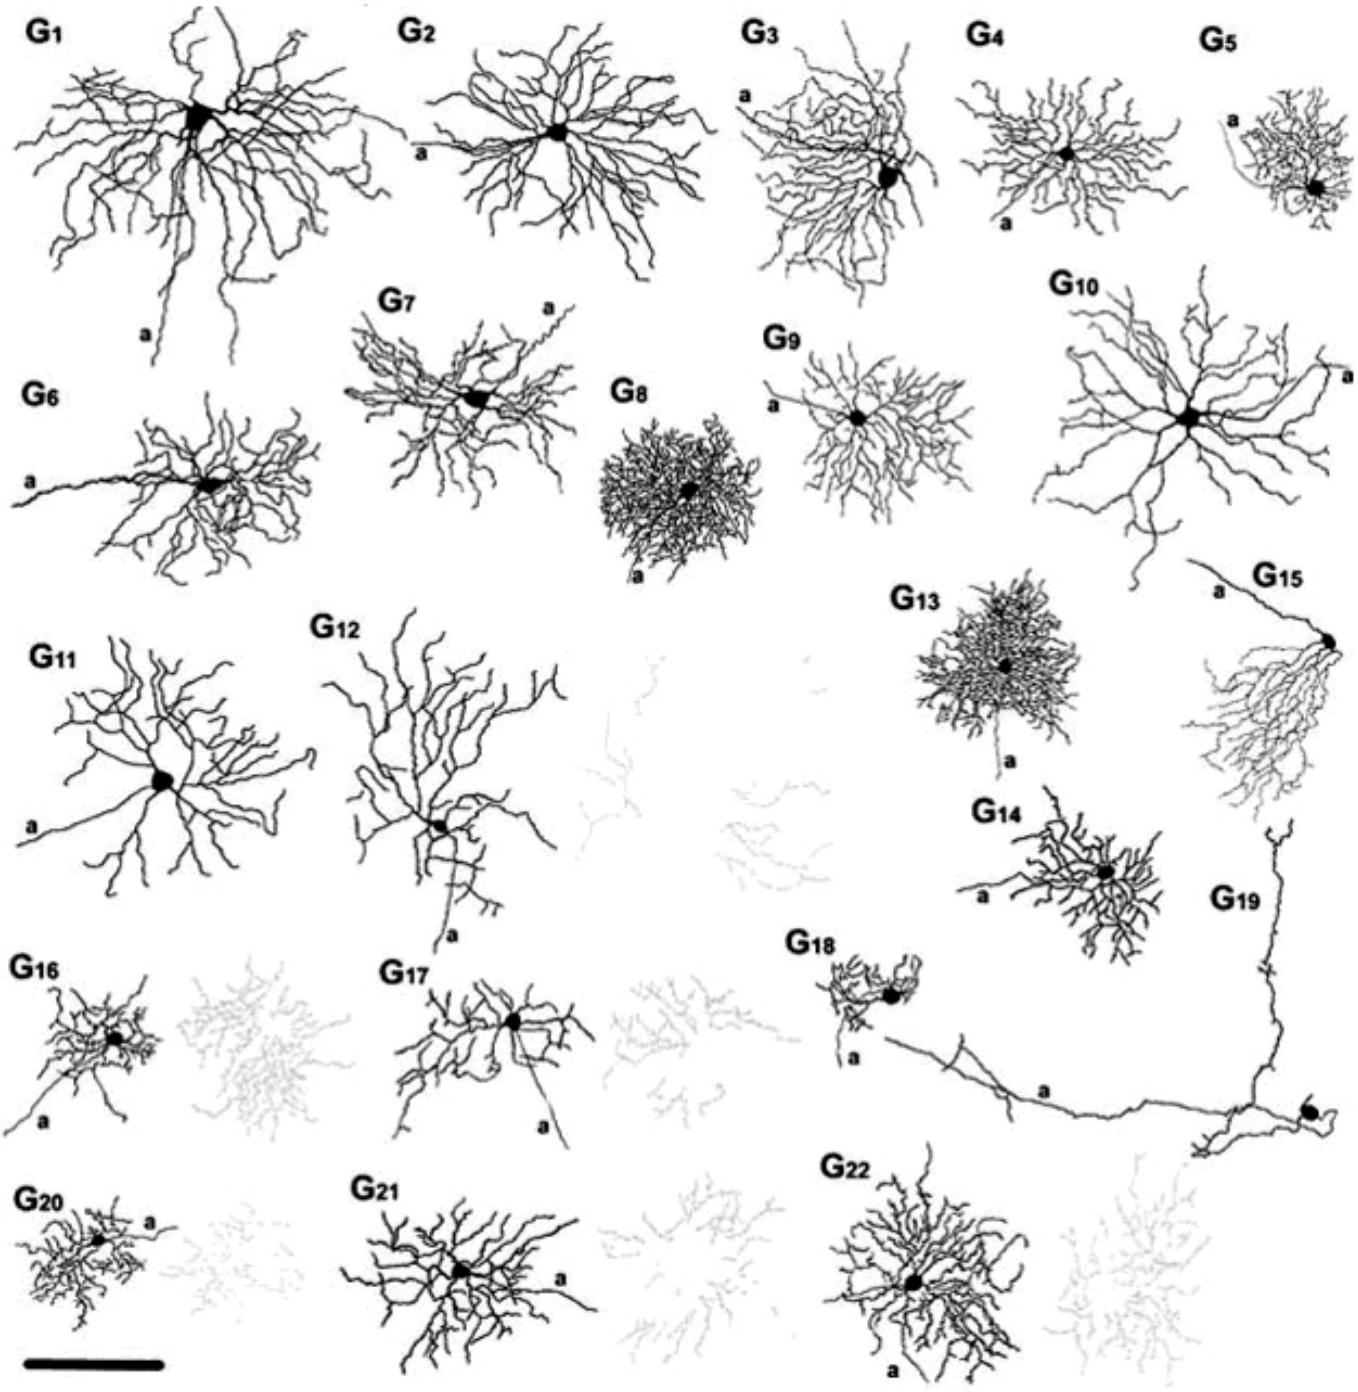

Figure 3. About 22 subtypes of retinal ganglion cells (RGCs) are present in the mammalian retina (See chapter on ganglion cells, Webvision). Camera lucida drawings show the RGCs of mouse retina. Adapted from Volgyi et al., 2009 (19).

In rabbit and rat, the amplitudes of retinal light responses measured by electroretinography continuously increases in the first month after birth and reaches the adult level by the ages of P30 to P40 (27, 28).

During synaptogenesis, the dendrites of mouse RGCs undergo very active remodeling. More than 30% of dendritic filopodial branches in the mouse are replaced every hour by continuous dendritic growth and elimination (pruning) between P10-13 (see Fig 6 and movie 1). This developmental remodeling of RGC dendrites is thought to play an important role in synaptogenesis and the formation of lamina-restricted dendritic distributions of RGCs.

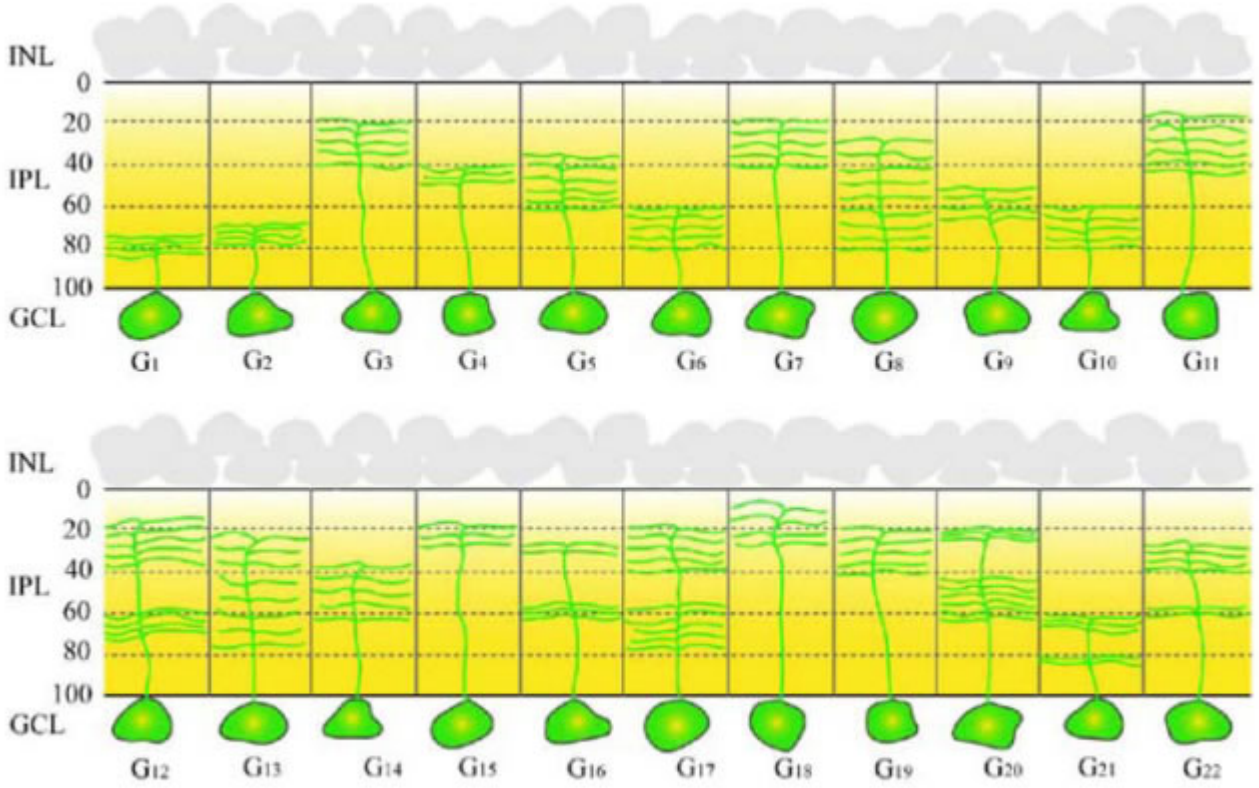

Figure 4. Dendritic ramification depth of the 22 mouse RGC subtypes (From Volgi et al., 2009 (19)). Solid horizontal lines represent the inner and outer borders of the IPL, whereas dashed lines separate the 5 IPL strata. Numbers on the left represent percent depth level in the IPL. Summary diagrams of RGCs are separated by vertical lines into the subtypes but do not represent the diameter of the dendritic trees.

3. Formation of lamina-restricted dendritic distributions of RGCs

Many studies have shown that the dendritic morphology and synaptic connections of RGCs undergo profound refinement during postnatal development. Early in postnatal development, the dendrites of many RGCs ramify diffusely throughout the IPL of the retina in cats, rats and mice (Fig. 7, A1, A2). With subsequent maturation, RGC dendrites become much more narrowly stratified in the IPL (Fig. 7, A2, B2 and B3) (26, 29-34) at least partially due to a developmental restriction of RGC dendrites (31). Recent studies suggest that different subtypes of RGCs acquire their lamina-restricted dendritic ramification patterns in different ways.

Some RGCs seem to achieve their restricted lamina patterns by direct targeting without significant pruning. In Figure 8 A1-A3, a bistratified RGC has a bistratified dendritic distribution pattern early at P5 (A1) and retains this bistratified pattern into adulthood (A2 and A3) without an initial diffuse distribution pattern. Similarly in Zebrafish some RGCs directly elaborate their dendrites to the middle of the IPL and later became strictly monostratified, occupying a single stratum in the middle of the IPL (Fig. 8 B1, B2 and B3) (35).

It is also clear that some RGCs form their lamina-restricted dendritic patterns through both direct targeting and selective dendritic pruning (Fig. 9). In Figure 9, A1-A3, the dendritic trees of a subtype of RGCs are diffusely ramified with many side branches originally and become bistratified to two strata above and below the

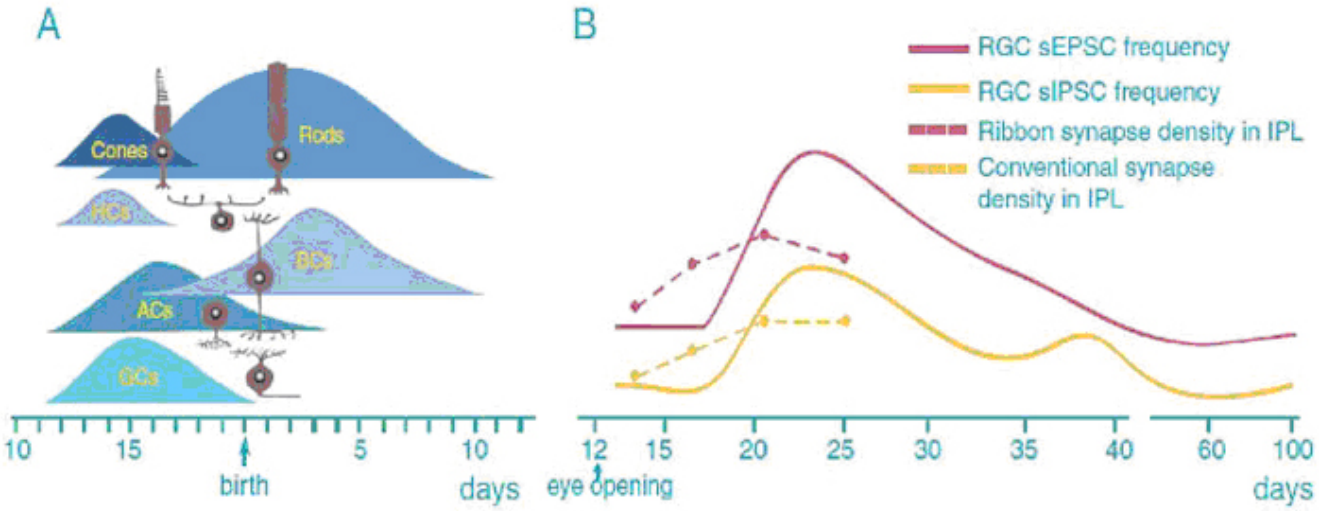

Figure 5. In mouse retina, neurogenesis begins before birth and is largely completed shortly after birth (A.). However neurogenesis of rods and bipolar cells starts before birth and continues for 1-2 weeks after birth (77). B: Synaptogenesis of mouse retina begins before eye opening and continues for several weeks after eye opening. The density of both ribbon and conventional synapses in the IPL reaches peak at P21 (78). The synaptic strength measured as the frequency of RGC spontaneous activity increases with age and peaks around 2 weeks after eye opening (55). The curves show the relative cell populations, synaptic densities and frequencies of spontaneous synaptic inputs as a function of time. Adapted from Xu and Tian, 2004 (79).

cholinergic starburst type a cell with significant pruning of their dendritic branches (33). Similarly in Figure 9 B1-B3, a zebrafish RGC starts its dendrites in the inner strata of the IPL and then selectively prunes the dendrites in the inner strata and grows the dendrites in the outer strata of the IPL over time (35).

4. Regulation of the formation of lamina-restricted dendritic patterns of RGCs

The regulatory mechanisms for the formation of the lamina-restricted dendritic patterns of RGCs are not completely understood. It has been reported that many molecular cues play crucial roles in the formation of laminar-restricted dendritic pattern of some subtypes of RGCs. The immunoglobulin superfamily adhesion molecules, DSCAMs and sidekicks, have been reported to direct laminar-specific axonal and dendritic ramification of bipolar cells and RGCs in chick retina (36) and RGC neurite arborization and mosaic formation in mouse retina (37). The transmembrane semaphorin Sema6A and its receptor PlexinA4 (PlexA4) have also been reported to control the stratification of the dendrites of dopaminergic amacrine cells, melanopsin containing RGCs and calbindin-positive cells into ON and OFF sublaminae of the IPL in mouse retina (38). Fig 10A shows that transmembrane semaphorin Sema5A and Sema5B normally constrain dendritic targeting of melanopsin-expressing RGCs to the IPL. In Sema5A-/- and Sema5B-/- mice the RGCs exhibit aberrant dendritic branching in INL, OPL and ONL (Fig. 10B, 10C and 10G).

Several reports have also shown that both spontaneous synaptic activity mediated by glutamate receptor (GluR) before eye opening and light evoked retinal activity after eye opening regulate the normal development of the lamina-restricted dendritic patterns of RGCs. In an early developing vertebrate retina like mouse, RGCs fire periodic bursts of action potentials that are highly correlated and propagate across the RGC layer in a wave-like fashion (39). These spontaneous retinal waves are mainly mediated by cholinergic and glutamatergic synaptic transmission (40-45) (see chapter by Ford and Feller, Webvision). The retinal wave mediated by AChR seems to

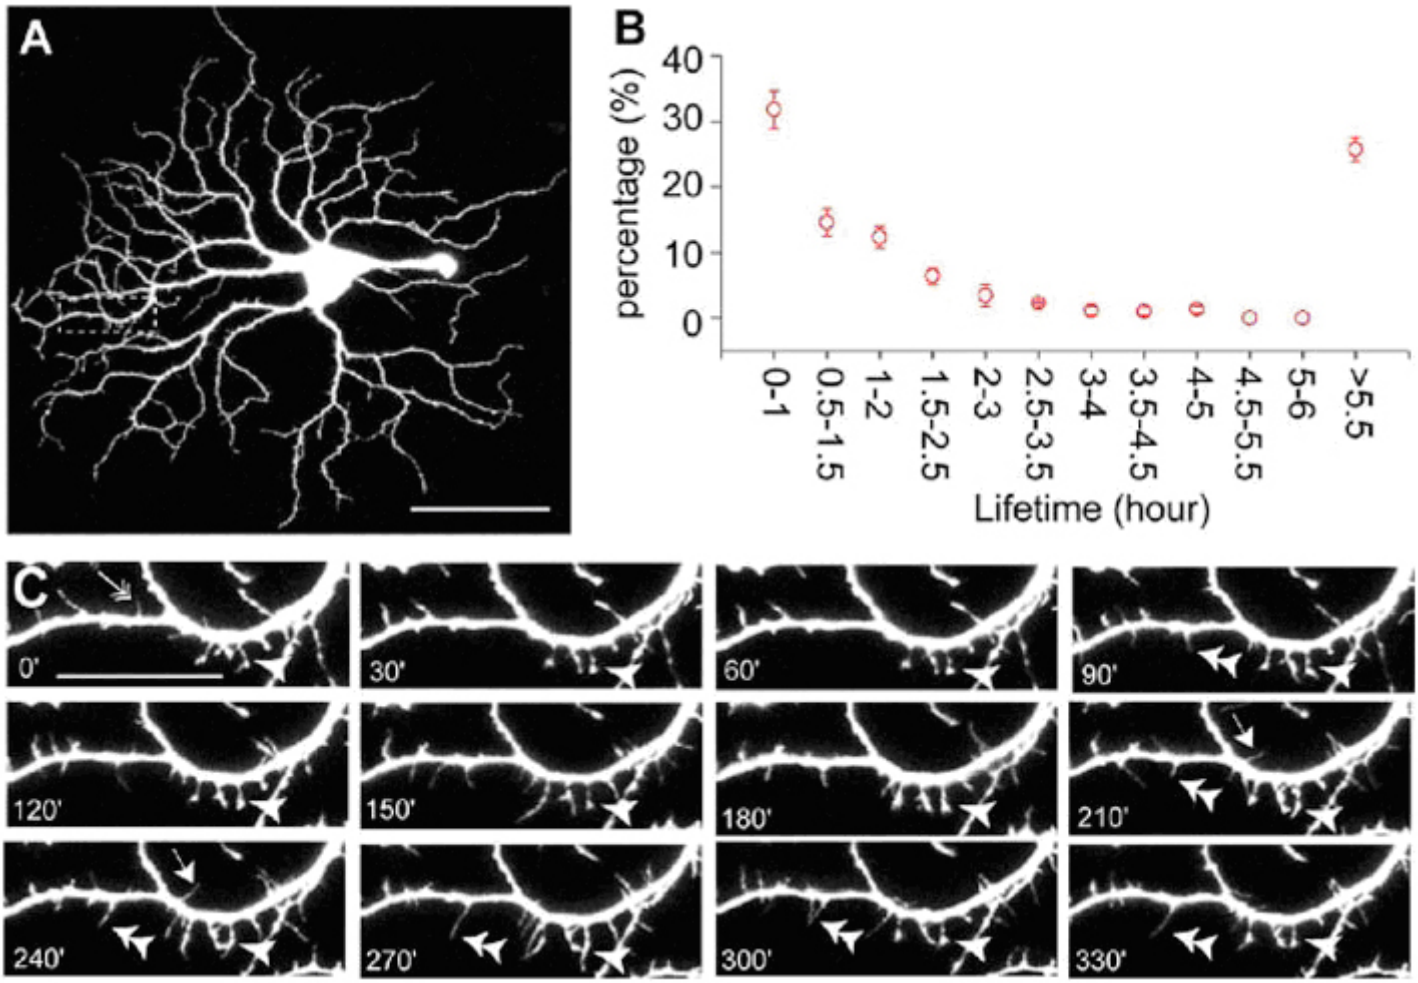

Figure 6: Dendrites of mouse RGCs undergo very active remodeling during synaptogenesis in postnatal development. RGC dendritic motility was examined using time-lapse confocal imaging on retinas of YFP+ mice at P13-14. A: Representative image of an A1 YFP+ RGC of a Thy1-YFP mouse. Scale bar, 60 µm. B: Average lifetime of RGC filopodia of P13-14 mice. Note that more than 30% of the filopodia are replaced every hour. Filopodia that existed at the beginning and disappeared before the end of the recording period and filopodia that emerged during the recording period and persisted until the end of the recording were discarded since the lifetime of these filopodia could not be determined. C: Representative time-lapse images of a segment of the dendrite from the RGC shown in (A) (indicated by the dash-line box) taken at 30 min intervals. Arrow, transient filopodia; arrowhead, static filopodia: double arrowhead, new filopodia; double-headed arrow, filopodia lost over the recording period. Scale bar, 20 µm. See also Movie . Adapted from Xu et al., 2010 (44).

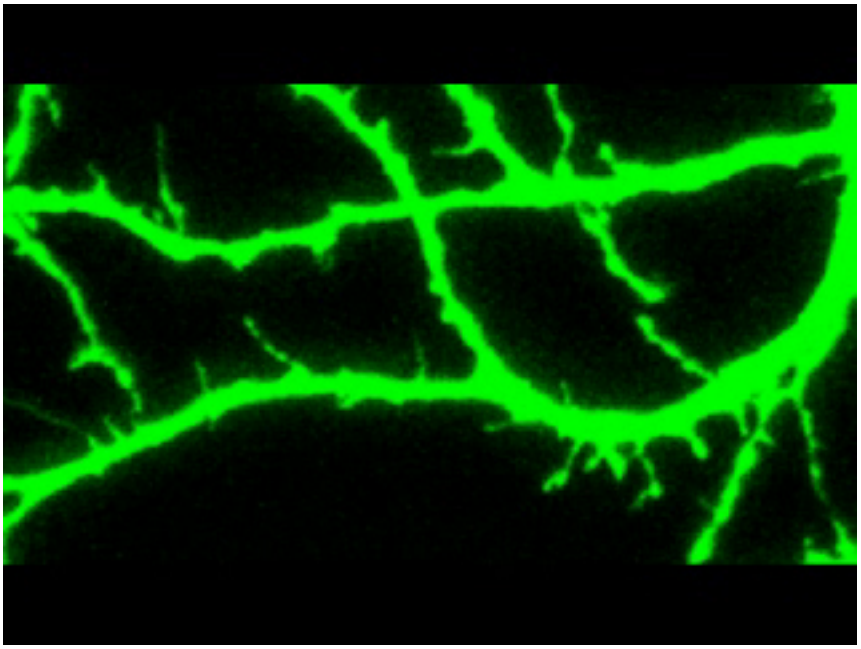
have little effect on the formation of laminar-restricted dendritic pattern of RGCs. In mice, genetic deletion of β2 subunits of nAChR or the sole synthetic enzyme for acetylcholine, choline acetyltransferase, eliminates the retinal waves mediated by nAChRs and causes an insignificant or non detectable change of the development of the lamina-restricted dendritic ramification of RGCs (40, 46).

On the other hand, intraocular injection of APB, an agonist for class III metabotropic GluRs (mGluR6), results in a blockade of glutamate release from ON and rod bipolar cells and causes an arrest of the developmental stratification and segregation of RGC dendrites into ON and OFF synaptic pathways in cats, ferrets and rats (29, 30, 47, 48) (Fig 11).

Also, intraocular injection of antagonists for NMDA and AMPA receptors, AP5 and NBQX, increases the density of filopodia by more than 100% after 5 days of treatment in mice (see Fig 12, compare A and B). Xu et al. (44) showed that pharmacological blockade of GluR-mediated activity slows the kinetics of RGC dendritic



Movie 1. Changes in filopodial growth and shape in the course of one hour.
Download video

growth and elimination by approximately 50% (Fig. 12D). The disrupted GluR-mediated activity in retina during early postnatal development is associated with profound and permanent defects of RGC dendritic morphology and synaptic function in adults (44). Similarly, Lau et al. (49) showed that blockade of NMDA receptors before eye opening increases the spine density of RGCs in hamsters.

However, genetic blockade of glutamate release from ON bipolar cells eliminates spontaneous and light evoked synaptic inputs to ON RGCs without effect on the spontaneous and light evoked synaptic activity of OFF RGCs and causes no detectable effect on the lamina-restricted dendritic ramification of either ON or OFF RGCs (50). In addition, genetic deletion of the mGluR6 receptor, which blocks ON bipolar cell light evoked synaptic activity, failed to impair dendritic stratification of mouse RGCs (51). Therefore, the effect of GluR-mediated synaptic activity on the development of the lamina-restricted dendritic ramification and synaptic connections of RGCs is somewhat controversial and needs to be further investigated. The effect of light evoked synaptic activity on the development of RGC dendritic restriction and synaptic connection seems to vary among subtypes of RGCs and selective to some synaptic features. Morphologically, dark rearing blocks an age-dependent remodeling of dendritic complexity of a class of "aberrant" RGCs in hamster retina (52). In mice, light deprivation increases the density of conventional synapses in the IPL (53). The developmental ramification of RGC dendrites into OFF lamina of the IPL is selectively impaired by light deprivation in RGCs of mouse retina (54). Functionally, light deprivation blocks the surge of spontaneous synaptic inputs to RGCs, the age-dependent increase of inner retinal light responses measured by ERG oscillatory potentials (55, 56), the segregation of RGC synaptic inputs from ON and OFF synaptic pathways (54), and the maturation of the size of inhibitory receptive field of RGCs (57).

However, light deprivation seems preferentially to affect the maturation of dendrites of OFF RGCs, but not ON RGCs. Xu and Tian (54) quantitatively analyzed the developmental refinement of the dendrites of a random group of RGCs in mouse retina and determined the ramification depth and width of RGC dendrites in the IPL at different postnatal ages (Fig. 13). They showed that a large proportion of RGCs have a single layer of narrowly stratified dendritic plexus ramifying near the centre of the IPL before eye opening (P12), where they could synapse with both ON and OFF bipolar cells. After eye opening, a significant portion of RGCs redistribute their

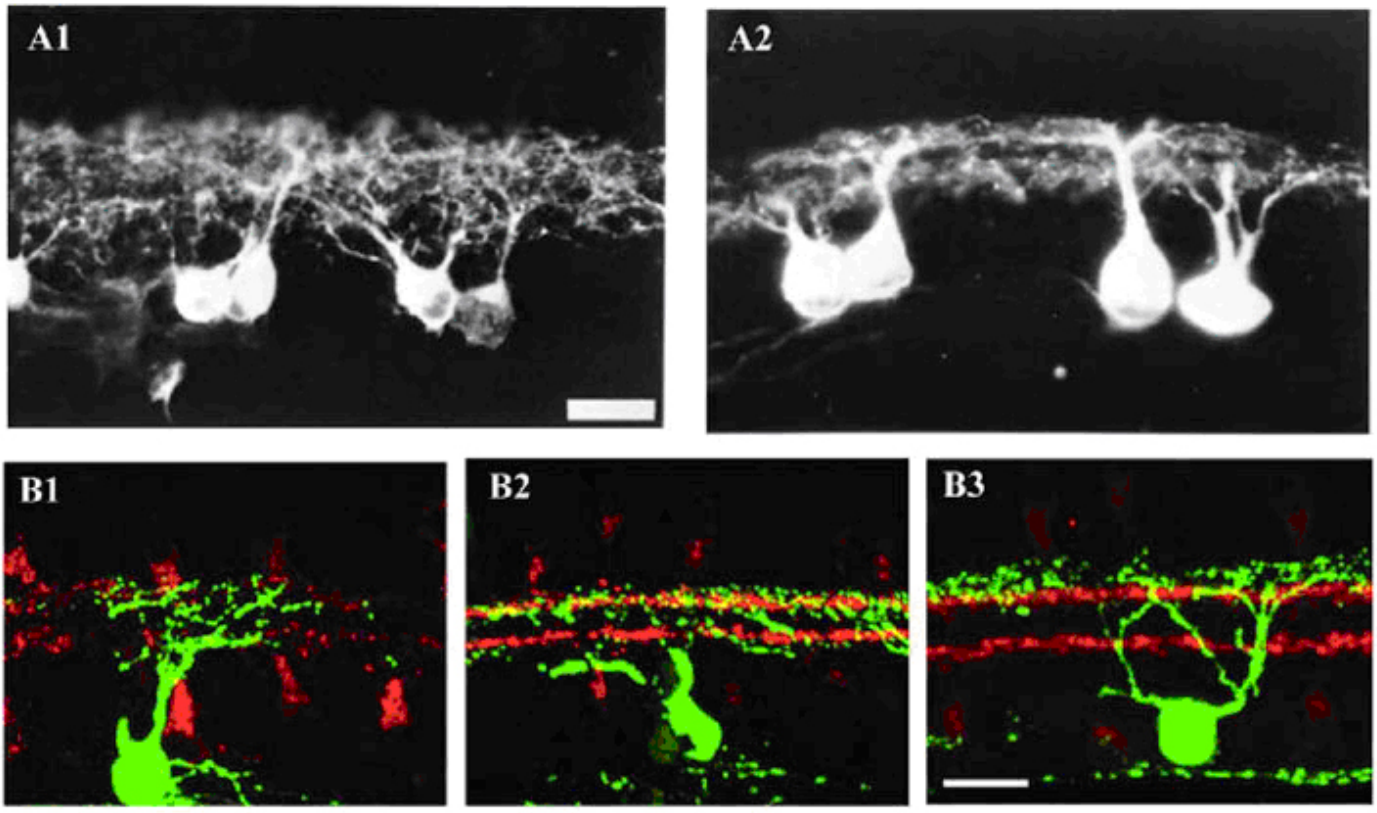


Figure 7: Dendrites of RGCs can reach mature stratified pattern through selective pruning. A1 and A2: Light micrographs of DiI (1,10-dioctadecyl-3,3,30,30-tetramethyl indocarbocyanine perchlorate) labeled RGCs from transverse sections of the central region of a P2 and a P10 cat, respectively. In A1, the RGC dendrites are distributed throughout the total IPL at P2 while, in A2, the dendrites have the distinct appearance of two tiers of dendrites within the IPL and the stratification pattern of ON and OFF layers. Scale bar in A1, 20 um. Reproduced from Bodnarenko and Chalupa, 1993 (29). B1, B2 and B3: Retinal sections from P5, P8, and P12-P13 JAM-B mice, respectively. RGCs were labeled with anti-GFP (green) and starburst amacrines with anti-ChAT (red). In B1, the dendrites of JAM-B RGC are distributed throughout the total IPL at P5. At P8 (B2), the JAM-B RGC selectively loses dendrites in the inner IPL. At P12-13 (B3), the dendrites of JAM-B RGC exhibit a lamina-restricted distribution in the outer IPL. Scale bar in B3, 20 um. Adapted from Kim et al., 2010 (33).

dendrites from the centre of the IPL toward the inner and outer borders of the IPL (Fig. 14A). This laminar-specific redistribution of RGC dendrites is associated with an age-dependent decrease of the number of RGCs receiving synaptic inputs from both ON and OFF bipolar cells (Fig. 14C). In dark reared mice, the RGC dendritic redistribution from the centre of the IPL to sublamina a of the IPL is blocked, which results in a significant increase of the number of RGCs ramifying at the center of the IPL, and a decrease of the number of RGCs ramifying only in sublamina a, in comparison with age-matched controls (Fig. 14A). Physiologically, the number of RGCs responding to both the onset and the offset of light stimulation of mice raised in constant darkness from birth to the ages of P27-30 was 4-fold higher than that of age-matched controls raised in cyclic light, but comparable to the percentage of ON-OFF responsive RGCs of P10-12 mice (58) (Fig. 14C). Similarly, long-term treatment of cat eyes with intraocular injection of APB significantly reduced the number of αRGCs ramifying in the sublamina a and increased the number of multistratified α cells (48).

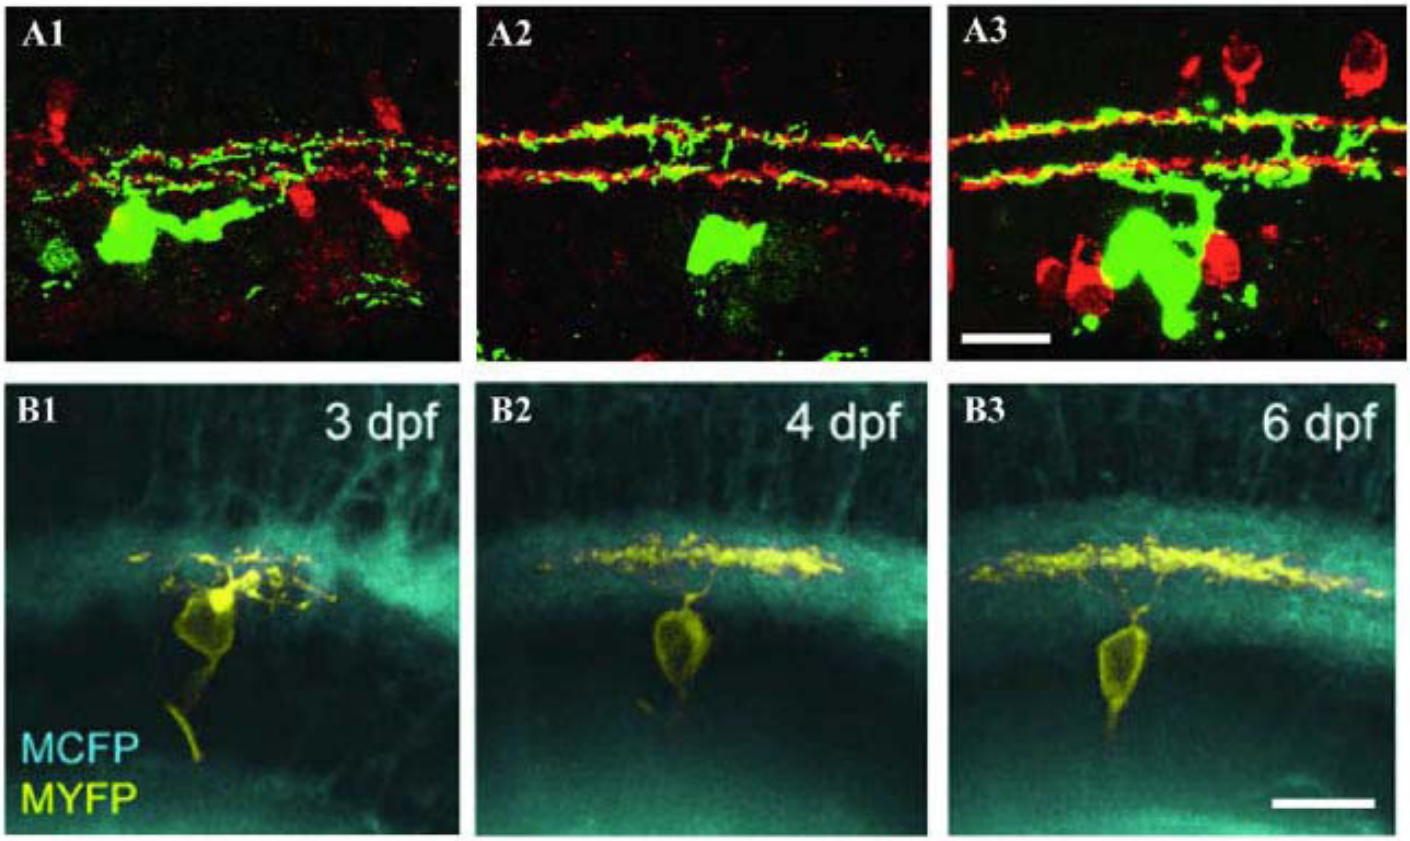

Figure 8. Dendrites of RGCs can reach mature stratified pattern by direct targeting. A1, A2 and A3: Retinal sections from P5, P8, and P12-P13 BD mice, respectively. RGCs were labeled with anti-GFP (green) and starburst amacrines with anti-ChAT (red). The BD RGC forms the distinct bistratified dendritic distribution pattern early during postnatal development at P5 (A1) without an initial diffuse distribution pattern. The bistratified distribution pattern remains throughout the postnatal development to adulthood (A2 and A3). Scale bar in A3, 20 um. Adapted from Kim et al., 2010 (33). B1, B2 and B3: In vivo time-lapse image of an isolated immature RGC (MYFP) in the Q01 background (MCFP) transgenic zebrafish retina. Time-lapse images taken at 3, 4 and 6 dpf, respectively, show orthogonally oriented image stacks of the entire arbor of the RGC. This RGC directly elaborates its dendrites targeting the inner half of the IPL that later became monostratified, occupying a single stratum in the middle of the IPL. Scale bar in B3, 10 um. Adapted from Mumm et al., 2006 (35).

5. The possible mechanisms of developmental regulation of RGC dendrites

During developmental refinement, the dendritic arborizations of RGCs undergo dynamic elaboration, maintenance or elimination to attain their lamina-restricted ramification pattern. Although neuronal activity influences this remodeling in many subtypes, the underlying molecular mechanisms have not yet been identified. Several studies suggest that calcium is important to link the neuronal activity with dendritic growth and patterning (59). Thus, it has been reported that synaptic stimulation induces calcium influx through voltage-dependent calcium channels and is sufficient to activate a transcriptional program that regulates dendritic growth (60).

BDNF/TrkB has also been shown to play an essential role in the activity-dependent development of RGC dendrites (61). Activation of BDNF promotes the anatomical segregation of the dendrites of ON- and OFF-center RGCs in different sublaminae of the IPL (61, 62), while deletion of TrkB strongly inhibits visual experience-dependent refinement of RGC dendrites (62). In addition, the expression of BDNF in the retina is up-regulated by visual stimulation (61, 63-65). This suggests that light deprivation retards RGC dendritic

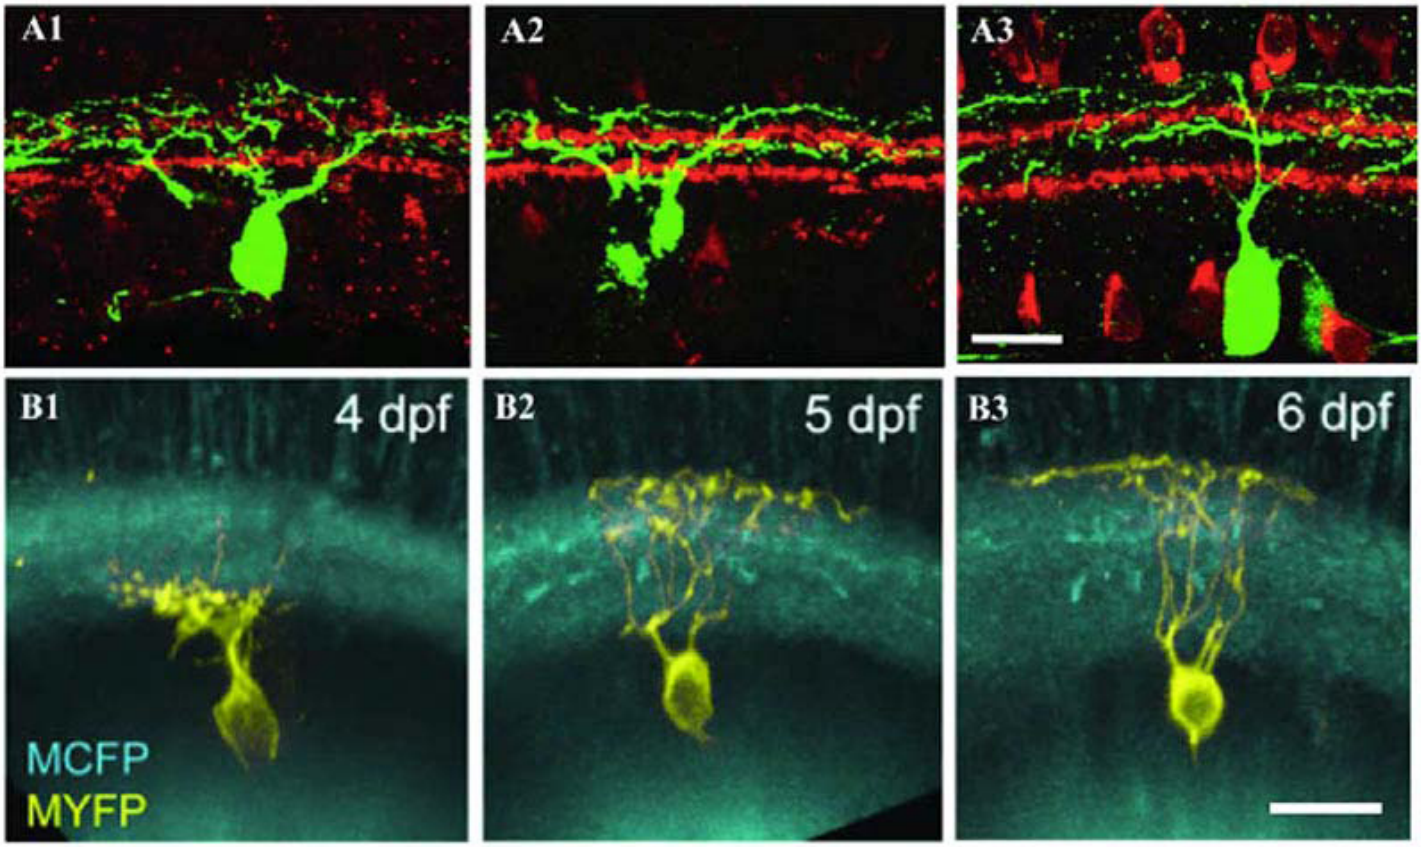

Figure 9. Dendrites of RGCs can reach mature stratified pattern by targeted growth and selective pruning. A1, A2 and A3: Retinal sections from P5, P8, and P12-P13 W7 mice, respectively. RGCs were labeled with anti-GFP (green) and starburst amacrines with anti-ChAT (red). The W7 RGCs selectively distributed their dendrites in the outer IPL at P5 (A1). With development, the dendritic complex is further pruned to form two narrowly restricted strata in the outer IPL at P12-13 (A3). Scale bar in A3, 20 μm. Adapted from Kim et al., 2010 (33). B1, B2 and B3: In vivo time-lapse image of an isolated immature RGC (MYFP) in the Q01 background (MCFP) transgenic zebrafish retina. Time-lapse images taken at 4, 5 and 6 dpf, respectively, show orthogonally oriented image stacks of the entire arbor of the RGC. This RGC initially ramifies its dendrites in the inner IPL at 4 dpf (B1). With development, the inner arbor of this RGC was pruned, the cell selectively grew dendrites toward the outer IPL and developed a narrowly restricted lamina of dendrites in the outer IPL at 6 dpf. Scale bar in B3, 10 μm. Adapted from Mumm et al., 2006 (35).

maturation by reduction of the expression of BDNF. Conversely, over-expression of BDNF precludes the retardation of laminar refinement in dark reared mice (62).

Recent studies demonstrated that genes typically associated with the immune system, such as those in the major histocompatibility complex (MHC), are expressed by neurons in various regions of the CNS, including retina, and play important roles in synapse formation and activity-dependent synaptic plasticity (66-72). Genetic deletion or mutation of a number of MHC class I genes result in the failure of eye-specific segregation of RGC axon projections to the dosal lateral geniculat nucleus (dLGN) (68, 72). Also, long-term potentiation, long-term depression, learning, memory, and neurogenesis in hippocampus are impaired (68, 73).

Xu et al. (44) reported that the key component of MHCI receptor, CD3ζ is specifically expressed by RGCs in mouse retina. Similar to the pharmacological blockade of GluR-mediated activity, genetic mutation of CD3ζ profoundly reduces the kinetics of RGC dendritic growth and pruning, and impairs the lamina-specific segregation of RGC dendrites in the IPL. In addition, CD3ζ-/- mice show a selective reduction of GluR-mediated synaptic transmission in RGCs suggesting that CD3ζ-mediated signaling participates in activity-dependent synaptic maturation of RGCs. However, some of the important questions, such as what are the exact molecule mechanisms with which activation of MHC/CD3ζ on neurons affects the maturation of RGC dendrites, and how

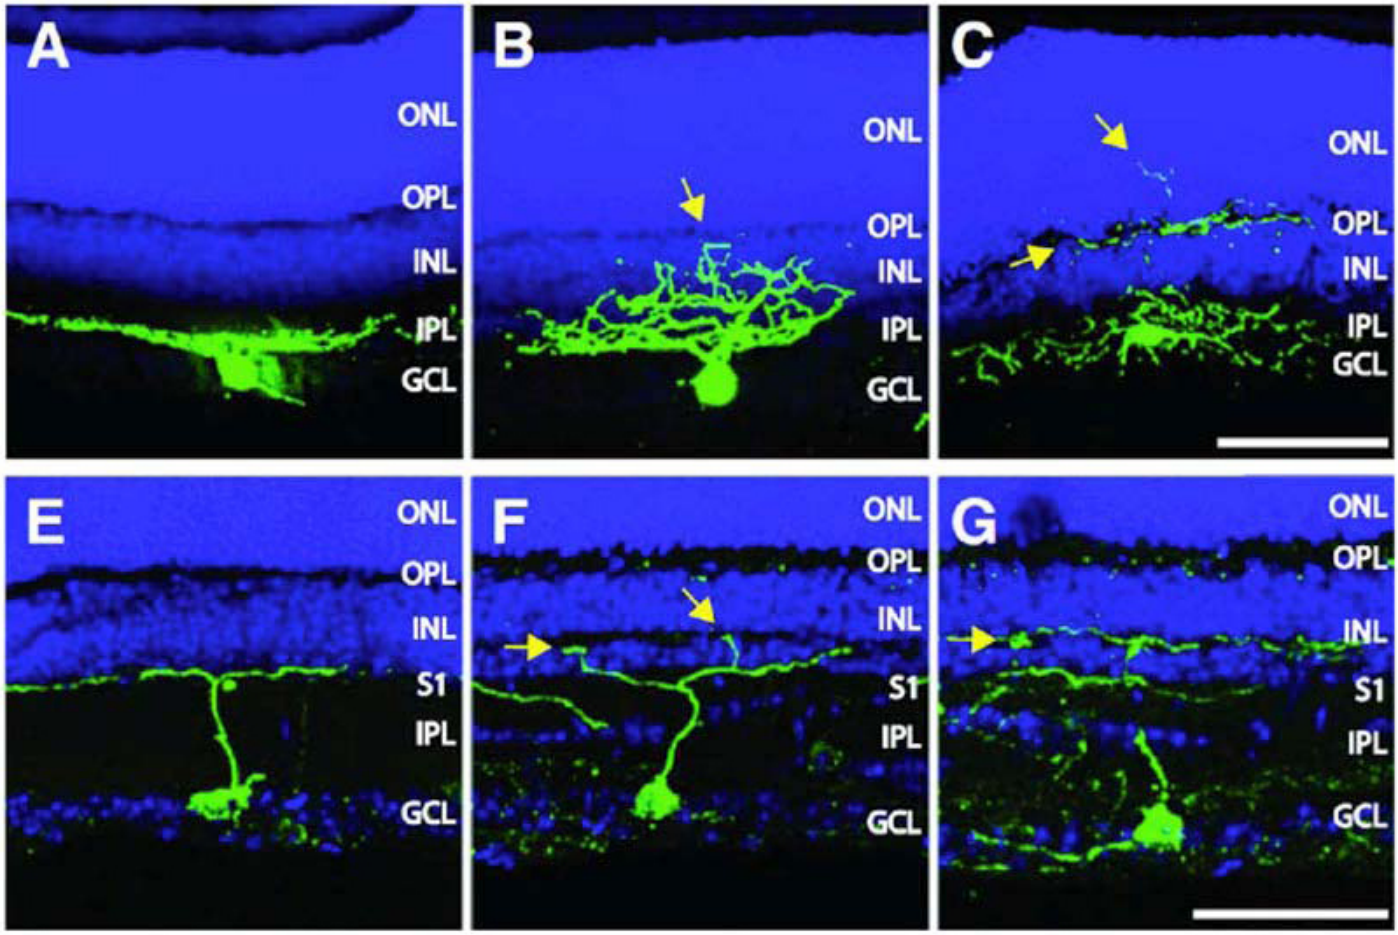

Figure 10. Sema5A and Sema5B constrain dendritic targeting of RGCs to the IPL. WT; Thy-1:GFP-M (A) and Sema5A-/-; Sema5B-/-; Thy-1:GFP-M (B and C) adult retina sections were immunostained with anti-GFP or WT (E) and Sema5A-/-; Sema5B-/- (F and G) adult retina sections were immunostained with an antibody against melanopsin. A: A representative RGC in WT; Thy-1:GFP-M retina exhibits narrowly stratified dendritic plexus. B: A GFP-expressing RGC in a Sema5A-/-; Sema5B-/-; Thy-1:GFP-M retina shows dendritic arbors that aberrantly extend into the INL. C: Another GFP-expressing RGC in a Sema5A-/-; Sema5B-/-; Thy-1:GFP-M retina shows dendritic arbors that aberrantly extend into the INL, OPL and ONL. E: A representative M1-type ipRGCs in a WT adult retina, which normally exhibits dendritic stratification within the S1 sublamina of the IPL. F: A M1-type ipRGCs in a Sema5A-/-; Sema5B-/- retina shows dendritic arbors that aberrantly extend into the INL. G: Another M1-type ipRGCs in a Sema5A-/-; Sema5B-/- retina shows dendritic arbors that aberrantly extend into the INL as well as other sublaminae of the IPL. Scale bars, 50 um. Adapted from Matsuoka et al., 2011b (80).

MHC/CD3ζ-mediated signaling interacts with neurotransmitter-mediated synaptic activity in dendritic maturation, need to be further addressed.

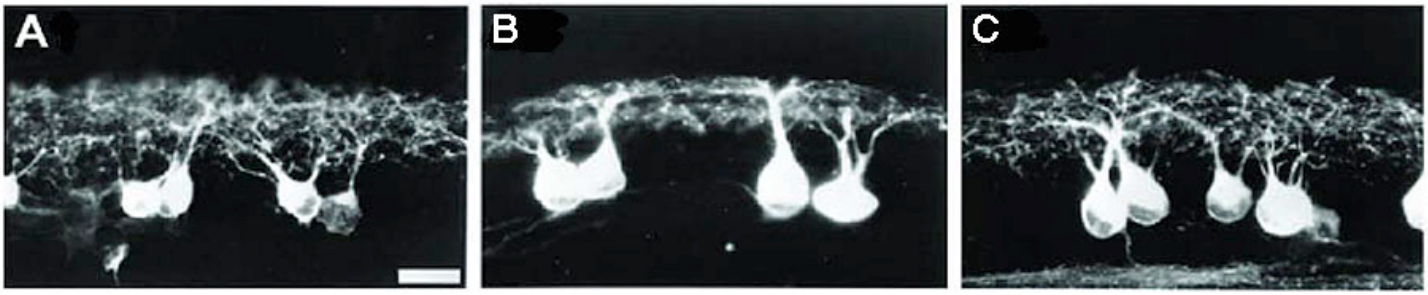

Figure 11. Glutamate released from bipolar cells regulates the dendritic development of RGCs. A, B and C: Light micrographs of DiI labeled RGCs from sections of a P2, a P10 and an APB-treated P10 cat retina, respectively. At P2 the RGC dendrites are distributed throughout the total IPL (A), at P10 the dendrites have the distinct appearance of two tiers of dendrites within the IPL (B). APB treatment prevented the formation of the lamina-restricted distribution of RGC dendrites (C). Scale bar in A, 20 um. Reproduced from Bodnarenko and Chalupa, 1993 (29).

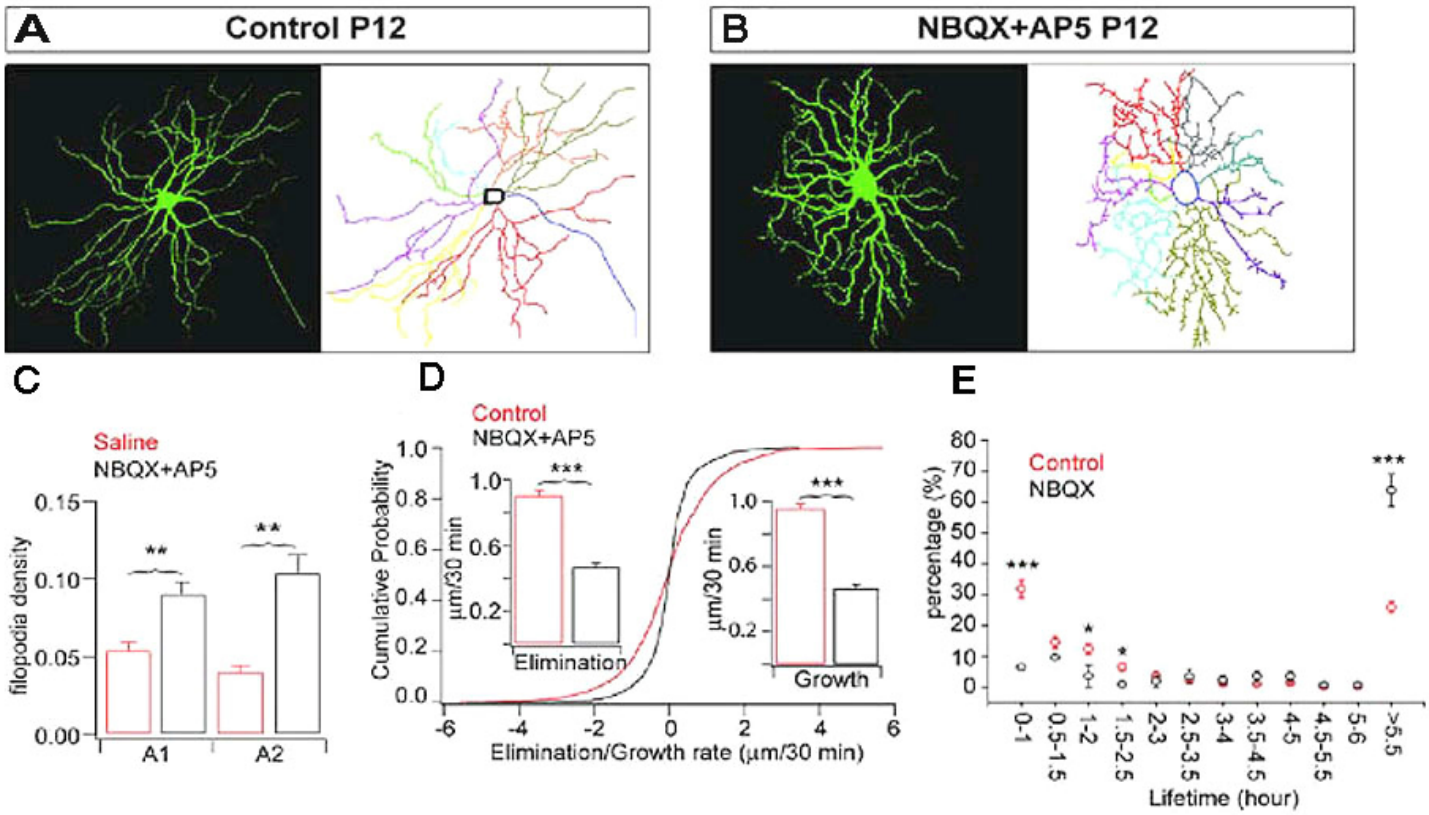

Figure 12. GluR-mediated activity regulates the dendritic development of RGCs. A and B: Representative images and dendritic reconstructions of YFP-expressing RGCs of P12 retinas in control and with intraocular treatment of NBQX+AP5. Note that NBQX +AP5 treatment significantly increase the number of filopodia. C: The average densities of filopodia of A1 and A2 RGCs of NBQX +AP5 treated retinas are 80-100% higher than that untreated retinas. D: The speeds of filopodia growth and elimination are reduced by NBQX+AP5 treatement. Filopodia growth and elimination were determined by the difference of the length of the filopodia recorded at two succeeding time points (recording time interval, 30 minutes). E: Average lifetime of RGC filopodia was significantly prolonged in NBQX+AP5 treated retinas. Adapted from Xu et al., 2010 (44).

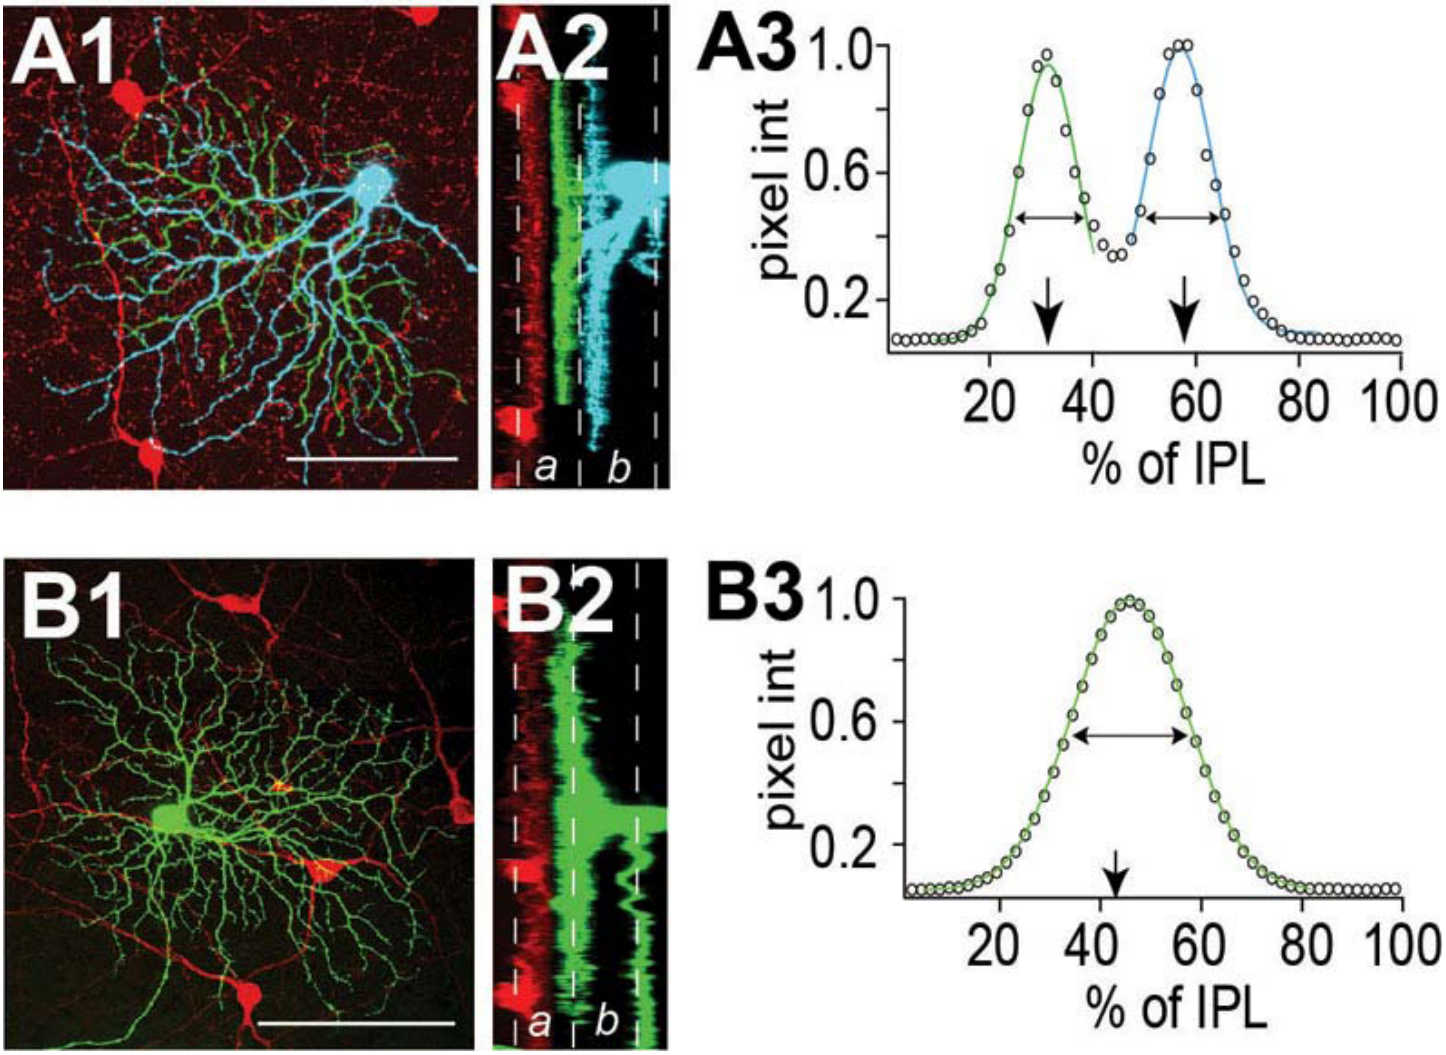

Figure 13. RGC dendritic distribution in the IPL can be quantified. The dendritic distribution of YFP-expressing RGCs in the IPL was quantified from confocal images Thy1-YFP mice. A: A stacked image (A1), the 90° rotation view (A2) and the quantitative dendritic distribution (A3) of a bistratified RGC. The dendrites ramified in the sublamina b are colored in blue and the dendrites ramified in the sublamina a are colored in green. Dopaminergic amacrine cells are colored in red. In A2, the three dashed lines indicate the inner and outer borders of the IPL, and the boundary of the sublaminae a and b, respectively. In A3, double-arrow lines indicate dendritic widths. Single arrows indicate the locations of the two peaks of dendritic density. B: A stacked image (B1), the 90° rotation view (B2) and the quantitative dendritic distribution (B3) of a mono-stratified RGC. Adapted from Xu and Tian, 2007 (54)..

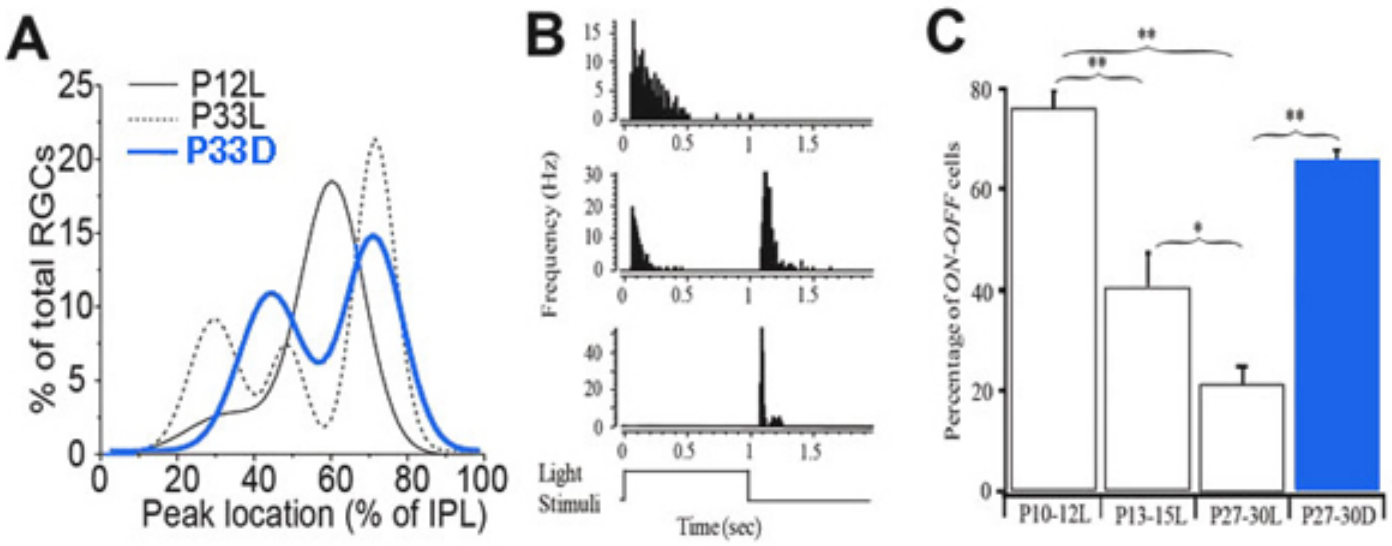

Figure 14. Light deprivation alters the dendritic ramification and synaptic inputs of mouse RGCs. A: Peak dendritic location of all mono-stratified RGCs of P12, P33 and P33 dark-reared mice. Note that the number of RGC with peak located near 30% of the IPL is significantly reduced in dark-reared mice (P33D). B: Representative frequency histograms of RGC light responses of an ON cell (top), an ON-OFF cell (middle), and an OFF cell (bottom), recorded using a multielectrode array system. C: Percentage of RGCs that are ON-OFF to light decrease with age. Note that light deprivation from birth (blue) prevents the age-dependent decrease of ON-OFF responding cells. Reproduced from Xu and Tian, 2007 (54); Tian and Copenhagen, 2003 (58).

About the Author

Dr. Ning Tian was initially trained as a physician in China (Yichang Medical School) and then received his Master Degree in clinical visual physiology from Zhong-sen Ophthalmic Center, Sun Yat-sen University of Medical Sciences, China. He practiced clinical ophthalmology for a while before doing a PhD in Biophysics and Physiology at the State University of New York at Buffalo with Dr. Malcolm Slaughter. Ning then did a postdoc with Dr. David Copenhagen at University of California, San Francisco. After being an Assistant Research Ophthalmologist at the University of California, San Francisco from 1998-2000, he headed a laboratory at Yale

University (2000-2009). Ning is presently an Associate Professor of Ophthalmology and Neurobiology in the Moran Eye Center, University of Utah. His research is focused on understanding the cellular and molecular mechanisms that regulate the maturation of retinal ganglion cell synaptic function and dendritic structure.

Evolution of the Vertebrate Eye

Evolution of Phototransduction, Vertebrate Photoreceptors and Retina

Trevor D Lamb, PhD[1]

Created: May 14, 2013; Updated: July 10, 2013.

1. Introduction

"Nothing in biology makes sense except in the light of evolution" (1).

Theodosius Dobzhansky's insight is especially apposite in trying to comprehend the nature of our rod and cone photoreceptors, and the organization of our retina. Unless we understand how these cells and structures arose, through hundreds of millions of years of evolution, we have little prospect of making sense of their morphological and molecular structure, or being able to answer the recurring conundrum 'Why does the retina do it this way?'. In addition to providing a rationale for the arrangement of our retina, a study of the evolution of our eye and its cones and rods is immensely satisfying, in offering potential answers to questions such as 'How and when did our eyes originate?' and 'Why should we and all other vertebrates possess eyes so different from those of (for example) insects?'.

The apparent lack of transitional forms that have been preserved during the course of vertebrate eye evolution has provided perennial fodder for 'creationists'. But, as Charles Darwin (2) explained,

"if numerous gradations from a perfect and complex eye to one very imperfect and simple, each grade being useful to its possessor, can be shown to exist ... and if any variation or modification in the organ be ever useful to an animal under changing conditions of life, then the difficulty of believing that a perfect and complex eye could be formed by natural selection, though insuperable by our imagination, can hardly be considered real".

One of the goals of this article is to document evidence for such gradations in the photoreceptors, in the phototransduction cascade, and in the retina, during the course of chordate and vertebrate evolution. A second major aim is to construct a set of 'scenarios' for the long sequence of events that contributed; in this regard the term 'scenario' is used in its dictionary sense of 'a postulated sequence or development of events'.

Historically, three main avenues for studying eye evolution have been utilized: examination of eyes in the fossil record, examination of the structure of eyes in extant species, and examination of embryological development. Recently, a number of powerful new avenues have been developed, utilizing molecular evidence; for example, comparative molecular genetics across extant species, as well as the combination of evolutionary and developmental analysis (evo-devo approaches). This article concentrates on the eyes of extant chordates, and examines clues to eye evolution that can be obtained from morphological, embryological and molecular features. In doing so, it builds on the scenarios put forward by Lamb et al (3, 4).

For other recent reviews of various aspects of the evolution of phototransduction and photoreception, see Arendt et al (5), Vopalensky & Kosmik (6), Larhammar et al (7), Shichida & Matsuyama (8), Kusakabe et al (9), Collin et al (10), Fain et al (11), Porter et al (12) and Nilsson (13). For descriptions of the types of eyes that have evolved across the entire animal kingdom (rather than primarily in chordates, as treated here), see the lavishly illustrated book by Schwab (14). For the evolution of vertebrate sensory systems and brains, see Butler (15) and Butler & Hodos (16).

Corresponding author.

One question that has often been asked is *'How many times have eyes and photoreceptors evolved independently?'* Answers to this question can vary greatly, depending on one's concept of 'independence'. As we shall see below, the common ancestor of cnidaria, protostomes and deuterostomes already possessed the great majority of the components needed for constructing an ocellus and/or a retina; e.g. it already possessed transcription factors, growth factors, opsins, photoreceptor cells (of the ciliary and microvillar forms), pigment cells, and neurons, etc. Using this common set of tools, different events occurred in different lineages, leading to very different eyes. In certain protostomes, a simple ocellus replicated many times to form a compound eye; in our own lineage, an extensive light-sensitive retina formed and a single optical element developed in front of it.

Although the eyes that have resulted are radically different from each other, it turns out that the photoreceptors upon which they are based are remarkably similar to each other, and indeed are derived from a common ancestral type, so that one can now conclusively reject the claim of Salvini-Plawen & Mayr (17) that "Photoreceptors have originated independently in at least 40, but possibly up to 65 or more different phyletic lines".

As was so aptly pointed out by Jacob (18), it is important to realize that evolution works by 'tinkering' with what is already available, and without any overall 'purpose' (such as to give rise to vision). In the case of the evolution of phototransduction, photoreceptors, and retina, numerous examples of such tinkering will become apparent in the Sections ahead; see also Goldsmith (19).

2. Origins

By way of background, the following sub-sections briefly summarize in turn: the origin of vertebrates, the origin of the vertebrate-style eye, the origin of opsins, and the origin of photoreceptor cells.

Origin of vertebrates

A summary view of the origin of vertebrates is presented in Figure 1, on a timescale extending from 700 to 400 Mya (millions of years ago); this diagram primarily illustrates extant taxa that are relevant to vertebrate evolution, though three extinct taxa of interest are also shown (using dashed lines). Although there is widespread agreement about the sequence of the branchings that occurred, there is less certainty about the timings of the various divergences. Molecular evidence suggests that many of the branchings occurred considerably earlier than is recorded in the fossil record, and the timings shown in Figure 1 are based on a recent reconciliation of molecular and fossil evidence, as reported by Erwin et al (20). In the following discussion, the branchings will be described from the perspective of our own direct ancestors, shown by the red curve, with various important branchings numbered as #1 to #5.

Around 700 Mya (#1), the early Eumetazoa that were our distant ancestors separated into Cnidaria (e.g. jellyfish, corals, etc.) and our own line of bilaterally symmetric animals (Bilateria). Then, around 665 Mya (#2), the ancestors of the great majority of extant invertebrate species (Protostomes) diverged from our Deuterostome line. A few million years later, the common ancestor of Hemichordates and Echinoderms (e.g. sea urchins) diverged from our ancestors. Shortly afterwards, around 655 Mya (#3), Cephalochordates (e.g. amphioxus) diverged Â– and from the time of that split (at the latest) our ancestors have been chordates. After perhaps another 50 million years, at ~600 Mya (#4), Tunicates (e.g. sea squirts) diverged, and then a further 100 million years elapsed before the occurrence of the next split from which descendants have survived, when ancestors of the extant jawless vertebrates (Agnathans) diverged from our own lineage of jawed vertebrates (Gnathostomes), around 500 Mya (#5). From the time of that divergence (and possibly from some time before it) our ancestors have been vertebrates.

The preceding interval of ~100 million years, between #4 and #5 (from ~600–500 Mya), was important not only for the evolution of the vertebrate eye, but also more generally as a period of exceptional innovation in the

evolution of body plans. Frustratingly, though, two factors complicate analysis of the transitions that occurred through that period. First, none of the numerous intermediate forms that diverged from our own lineage during that 100 million year time-span have survived to the present day. A few important examples of extinct species are indicated in Figure 1, but there is a huge gap between extant species. Secondly, soft tissues are poorly preserved in the fossil record, so that few clues to transitional forms of chordate eyes can be obtained from the extinct species that are known.

Despite these difficulties, there is a remarkable amount that we can surmise about vertebrate eye evolution, (*i*) from comparative analysis of the eyes of extant animals, (*ii*) from analysis of embryonic eye development, and (*iii*) from molecular genetic analysis of photoreceptors and retinas. But before we look in detail at the eyes of living vertebrates, it will help to set the scene if we briefly consider the origin of the vertebrate-style eye, the origin of opsin photopigments, and the origin of photoreceptor cells.

Origin of the vertebrate-style eye

To help answer the question *"When did the vertebrate-style eye arise?"* one can usefully examine the eyes of extant chordates - jawed vertebrates, cyclostomes, tunicates, and cephalochordates.

Jawed vertebrates. The eyes of all extant jawed vertebrates (e.g. fish, tetrapods, birds) are remarkably similar and appear to be built to a common plan. As a result, we can be certain that the last common ancestor of all extant jawed vertebrates, that lived ~420 Mya, possessed a 'vertebrate-style eye'. But can we delve even further back into the past?

Lampreys. The ancestors of lampreys diverged from our own ancestors around 500 Mya (Figure 1), yet the lamprey's camera-style eyes are extremely similar to the eyes of jawed fish and other jawed vertebrates. Thus, the lamprey's eye has a lens, an iris, and a set of six extraocular muscles that are broadly homologous to those of jawed vertebrates (Section 3). Furthermore, the lamprey retina has a structure closely comparable to that of vertebrates, with the five classes of homologous neurons (photoreceptors, horizontal, bipolar, amacrine and ganglion cells) distributed into three main nuclear layers and two plexiform layers. The southern hemisphere lamprey Geotria australis possesses five morphological classes of retinal photoreceptor cell together with five classes of opsin, each of which is closely related to the retinal opsins of jawed vertebrates (see Section 6 for details); northern hemisphere lamprey species, however, have lost several opsin classes.

In view of the overwhelming parallels between the eyes of lampreys and jawed vertebrates, it seems a near certainty that the last common ancestor of these taxa possessed a camera-type eye, broadly comparable to that of extant lampreys and gnathostomes, and hence that the vertebrate-style eye already existed ~500 Mya. However, one cannot totally reject the possibility that, even though the last common ancestor of lampreys and jawed vertebrates possessed the requisite genes, its eyes might have exhibited a form more rudimentary than a fully-developed camera-style eye, and that both lampreys and gnathostomes perfected the physical manifestation of the eye by some degree of convergent evolution.

Hagfish. The 'eyes' of hagfish represent a special case that will be considered in detail in Section 3. Although hagfish are descended from a lamprey-like ancestor, their 'eyes' exhibit a much more rudimentary form than the eyes of lampreys, and it will be argued that there are strong grounds for thinking that those features are retained from an earlier stage of eye evolution.

Tunicates and cephalochordates. Of the chordate taxa that diverged prior to the agnathans (lampreys and hagfish), none of those that survive to the present day possess an organ that can properly be described as an eye. The cephalochordate amphioxus possesses several groupings of photoreceptors, and larval tunicates possess a simple ocellus. In both cases ciliary photoreceptors with C-opsins are present, and appear homologous to our own cones and rods. Although their photoreceptors and opsins hold important clues to the evolution of

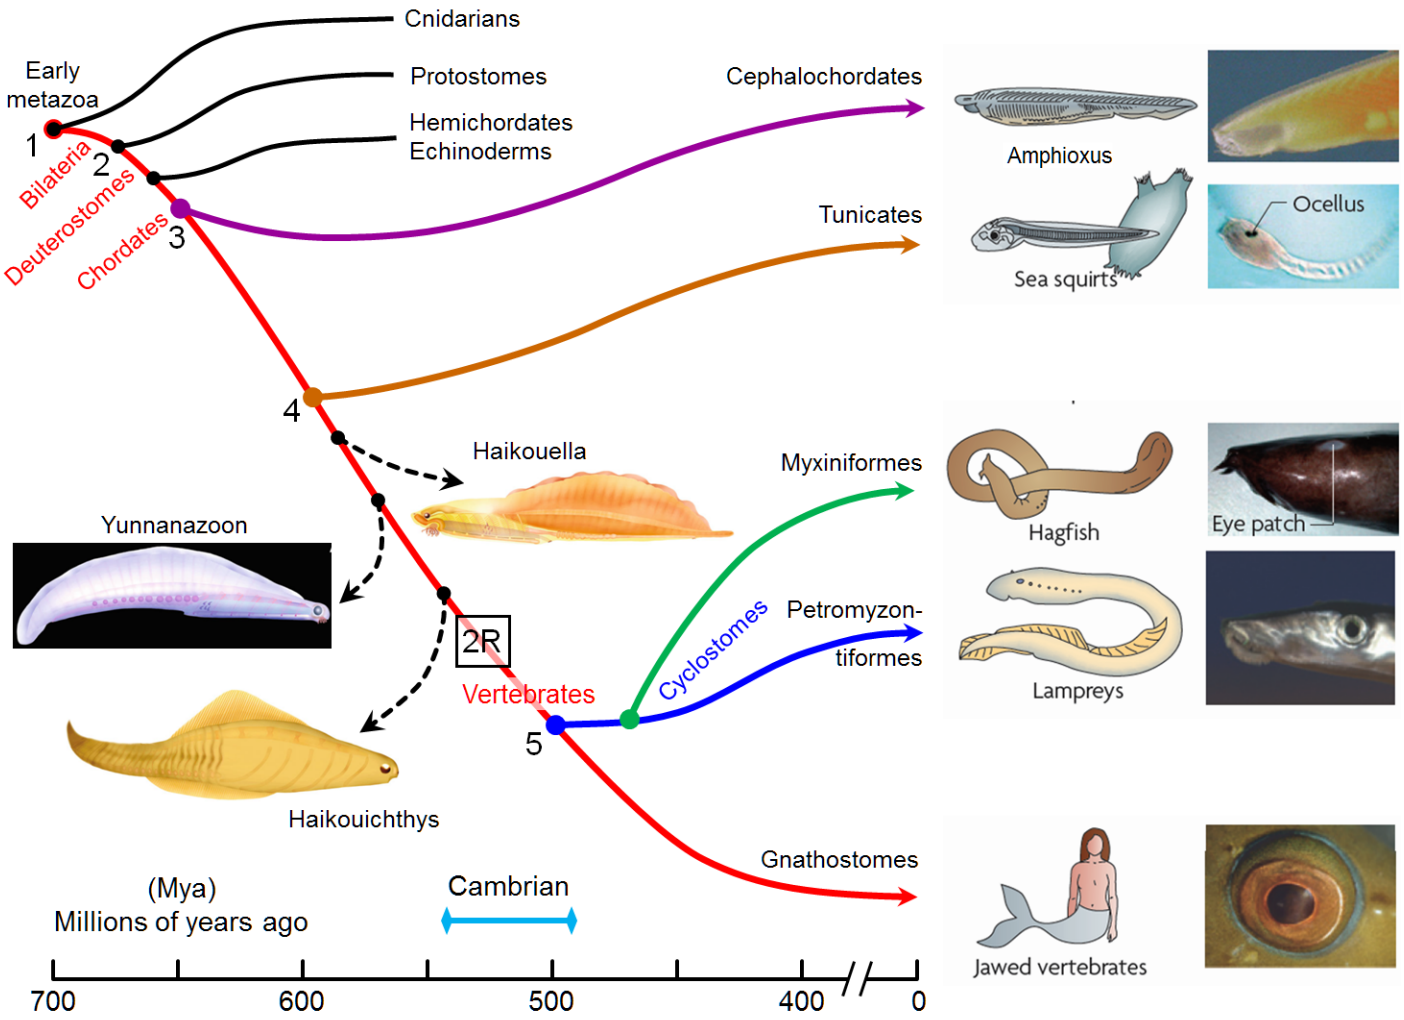

Figure 1. The origin of vertebrates, over a time-scale from roughly 700 to 400 million years ago (Mya), with timings of the branchings taken from a reconciliation of fossil and molecular data by Erwin et al (2011). The red curve indicates our direct ancestors, beginning with early metazoans, and the numbers along the curve denote major branchings that are significant to the evolution of the vertebrate eye. #1, Cnidarians branched off around 700 Mya, and since then our ancestors have been bilaterally symmetric (bilaterians). #2, Protostomes branched off around 665 Mya, and since then our ancestors have been termed deuterostomes. #3, #4, By the time that cephalochordates and then tunicates diverged (around 650 and 600 Mya), our ancestors possessed a notochord, and are referred to as chordates. #5, By the time that the ancestors of lampreys diverged around 500 Mya, they and our own ancestors were vertebrates. It has recently been confirmed that the '2R' two rounds of whole-genome duplication occurred prior to that divergence of ancestral lampreys. Subsequently (by around 420 Mya) our own ancestors evolved jaws and hence became jawed vertebrates (gnathostomes). Black curves indicate taxa that are not considered in any detail in this article; dashed black curves indicate extinct taxa of potential interest. See text for details. Source of illustrations: *Haikouella*, *Yunnanazoon* and *Haikouichthys* from Chen (21); remainder from Lamb et al (3), where original sources are given.

vertebrate photoreceptors, these primitive organisms clearly diverged prior to the evolution of the vertebrate-style camera eye.

Some extinct chordates of interest. Three extinct species of early chordates are indicated schematically in Figure 1 (diagrams from Chen (21)). These are the earliest known chordates to have possessed structures that in extant vertebrates arise from migratory neural crest tissue, and accordingly they have been named 'crest animals', or Cristozoa, by Chen and colleagues. These pre-craniate crest fossils have been found only in the Lower Cambrian strata of Yunnan in south-western China; they are around 3 cm in length. Of the three species, *Haikouella lanceolata* has the most basal form, and *Yunnanazoon lividum* appears somewhat more developed, while

Haikouichthys ercaicunensis is the most developed and appears to be a transitional form to craniates. Each of these fossil species is reported to exhibit paired eyes, with diameters of around 0.3, 0.6 and 0.4 mm respectively, but unfortunately so little detail of these soft tissues is preserved that it is not possible to describe the internal features of the eyes - even, for example, whether they possessed a lens.

Comparison of chordate eye features. Item A compares a number of features of the eyes (or eyespots) of the extant chordate species referred to above. There seems little doubt that the last common ancestor we shared with lampreys (~500 Mya, Figure 1, #5) possessed a fully-fledged 'vertebrate-style camera eye' while, further back, it seems inconceivable that our last common ancestor with sea squirts (~600 Mya, Figure 1, #4) could have had anything more complicated than a simple eyespot.

A crucial period for eye evolution in chordates and other phyla. Clearly then, the interval #4 to #5, from 600-500 Mya, was crucial to the evolution of the vertebrate-style eye. Furthermore, it seems plausible that the most profound changes in physical appearance occurred towards the end of that period, during the time of the Cambrian 'explosion' in body forms. At roughly the same time, eyes were evolving in a number of other phyla as well, often with radically different physical form (14, 22).

Recent discoveries of exceptionally well preserved fossil eyes from the Early Cambrian (~515 Mya) have shown that some of the earliest arthropods already possessed compound eyes containing many thousands of ommatidia. Paterson et al (23) have reported that *Anomalocaris* had eyes at least 12 mm in diameter, containing well over 16,000 ommatidia. These animals, which had bodies up to 90 cm long, are acknowledged as free-swimming apex predators, and have now been confirmed to have possessed compound eyes with the potential for high spatial resolution (~1°). Our own ancestors were tardy in developing eyes, and they may have been preyed upon by visually-guided protostomes for tens of millions of years.

Driving force for the evolution of eyes? In analyzing the emergence of sensory systems in the Cambrian, Plotnick et al (24) have proposed that two factors that rendered the acquisition of spatial vision highly valuable were, firstly, the enormous increase in spatial complexity in the landscape that occurred during the Cambrian and, secondly, the need of free-swimming organisms to navigate. Optic-flow information from spatial vision provided at least a partial solution to the latter requirement. On top of these pressures there was of course the need to detect prey and to avoid predators.

Origin of opsins

Opsins, and their major divisions (25) arose very early in metazoan evolution. In this article the term 'opsin' will refer only to 'Type 2 animal opsins', and not to the 'Type 1 microbial opsins' of bacteria or the 'channelrhodopsins' of algae, both of which are unrelated and appear to have arisen by convergent evolution. The phylogeny of ciliary opsins will be considered in Sections 5 and 6 for chordates generally, and for the vertebrate retina, but for now the questions are: *How did the ancestral opsin originate?* and *What were the initial stages in its diversification?*. In addressing these questions, important clues have been obtained through analysis of a number of cnidarian opsin sequences that have become available since 2007 (12, 26-31).

Animal opsins evolved from within the eponymous 'Rhodopsin family' of the 'GRAFS' superfamily of G-protein coupled receptors (GPCRs), and it is known that this superfamily originated in an ancient eukaryote that existed prior to the divergence of fungi (32)). Recently, Feuda et al (30)) analyzed the phylogeny of opsins and proposed a scheme for the early origin of opsins. They showed that the closest relatives of the opsins are found in the lineage that includes the vertebrate receptors for melatonin. However, for the corresponding GPCRs in invertebrates the ligand has not yet been identified, and so it is not clear what the ancestral ligand might have been at the time that the opsin lineage diverged.

One potential problem with the analysis of Feuda et al (30) is its reliance on the (unproven) existence of R-opsins in cnidaria, but that issue appears to have been resolved by an independent and nearly simultaneous study of

Table 1. Comparisons between eyes and eyespots of extant chordate groups

Item A: Comparisons between eyes and eyespots of extant chordate groups

opsins from a coral (31), that clearly identified the existence of an R-opsin. The following scenario for the early origin of animal opsins, illustrated in Figure 2B builds on the report of Feuda et al (30), and is presented here as the first in a series of scenarios/hypotheses for the events that gave rise to photoreceptors:

A-1) The forerunner of the first opsin arose through duplication of a GPCR in an ancient metazoan, at a time prior to the divergence of the amoeba-like placozoans.

A-2) That forerunner protein did not possess the retinal-binding lysine ('K296') in the seventh transmembrane helix (30); this suggests that retinaldehyde ligand occupied the internal cavity by means of non-covalent binding, as for ligands in conventional GPCRs, and in Figure 2B this pre-opsin is termed a 'retinaldehyde receptor'. The placozoan Trichoplax has a homolog of opsin (dubbed placopsin by Feuda et al, 2012), that likewise is devoid of the retinal-binding lysine residue.

A-3) Acquisition of an appropriately situated lysine residue within the seventh transmembrane segment of that receptor allowed the retinaldehyde ligand to bind covalently. Initially, the Schiff base bond is likely to have been unprotonated, so that the molecule would have absorbed in the UV. Acquisition of an appropriately located negatively charged residue (e.g. E181) permitted the bond to be protonated, thereby creating the ancestral opsin, and enabling the absorption peak to be shifted into the 'visible' spectrum.

A-4) As for most opsins (though not for vertebrate visual opsins), the activated metarhodopsin state of this opsin was thermally stable and could undergo photoreversal to the rhodopsin state. Hence this protein probably did not require a source of 11-*cis* retinal and could instead utilize all-*trans* retinal perfectly well.

A-5) Subsequently, two duplications of that earliest opsin occurred, during the relatively short interval between the divergence of placozoa and the divergence of cnidarians from bilaterians. Thus, all of the duplications

indicated in Figure 2B took place shortly prior to the first of the numbered branchings shown in Figure 1 (i.e. prior to #1).

Hypothesized association between opsin type and membrane type . A contributory factor in the co-evolution of opsin classes and photoreceptor classes may have been a preferential association of the different opsins with different regions of membrane, as indicated in Figure 2B. Accordingly, the hypothetical scenario for the early evolution of opsins is extended as follows:

A-6) The two variants of opsin that emerged after the first duplication event may have trafficked preferentially to the membrane of sub-cellular organelles and to surface membrane. Those variants would have given rise to the RGR- division and the C-/R- division, respectively, of modern opsins.

A-7) Following the duplication event that created the distinction between C- and R-opsins, these two variants trafficked to ciliary and microvillar membrane, respectively. In Figure 2B this duplication is shown as having occurred subsequent to the duplication mentioned in the previous point, but at present one cannot reliably distinguish the order in which this pair of duplication events occurred.

A-8) Subsequently, cells expressing the C- and R-opsin classes became distinct from each other, through a process termed 'division of labor' (5, 33), leading to (a) ciliary photoreceptors that possessed C-opsins and (b) microvillar photoreceptors that possessed R-opsins; see next Section. The third variant of opsin, RGR-opsin, tended to be expressed in the membranes of intracellular organelles, possibly as an additional opsin in the first two classes of photoreceptors.

A-9) Later in evolution, further division of labor occurred, so that (for example) RGR-opsin could be expressed in separate cells. This would explain how it is possible, on the one hand, for squid photoreceptors to contain an R-opsin in their microvillar membranes as well as retinochrome (an RGR-opsin) in their intracellular organelles, and, on the other hand, for vertebrate cones and rods to contain only a C-opsin in their outer segments whereas RPE cells contain only RGR-opsin in their endoplasmic reticulum.

Classification and diversity of photoreceptor cell types

A view that pervades quite widely is that photoreceptor cells fall into two varieties: rhabdomeric photoreceptors in the eyes of invertebrates (protostomes) and ciliary photoreceptors in the eyes of chordates. However, neither the rigid association of photoreceptor type with phylum, nor the rigid classification of photoreceptors into two categories, can be supported.

Ciliary and rhabdomeric classification. Based on the manner in which the opsin-containing region is elaborated into an extensive surface area, Eakin and his collaborators discerned two classes of photoreceptor: the **ciliary** form, exemplified by vertebrate rod and cone photoreceptors, where the membrane expansion forms a modified cilium, radiating from a classic 9+0 non-motile axonemal structure, and the **rhabdomeric** form, exemplified by insect photoreceptors, where the membrane expansion occurs as microvilli arranged in a highly-ordered manner (33); see for example Figure 3 and Figure 4 below.

Based to a substantial extent on Eakin's classification, three theories were proposed to account for the evolution of photoreceptor types. Eakin himself proposed what became known as a diphyletic model of photoreceptor evolution, wherein the rhabdomeric line of photoreceptors arose in protostomes, as a variant of the ancestral line of ciliary photoreceptors (34). Eakin acknowledged a number of exceptions to his model (such as deuterostomes with microvillar photoreceptors), but he proposed that those exceptions arose via independent evolution.

In a variant of Eakin's model, Vanfleteren & Coomans (35) interpreted rhabdomeric photoreceptors to represent a modified form of the ancestral ciliary photoreceptors, in which the elaboration of the microvillar membranes is induced to occur by a ciliary structure that often degenerates subsequently; other authors termed this a monophyletic model of photoreceptor evolution. In contra-distinction to both these models, Salvini-Plawen &

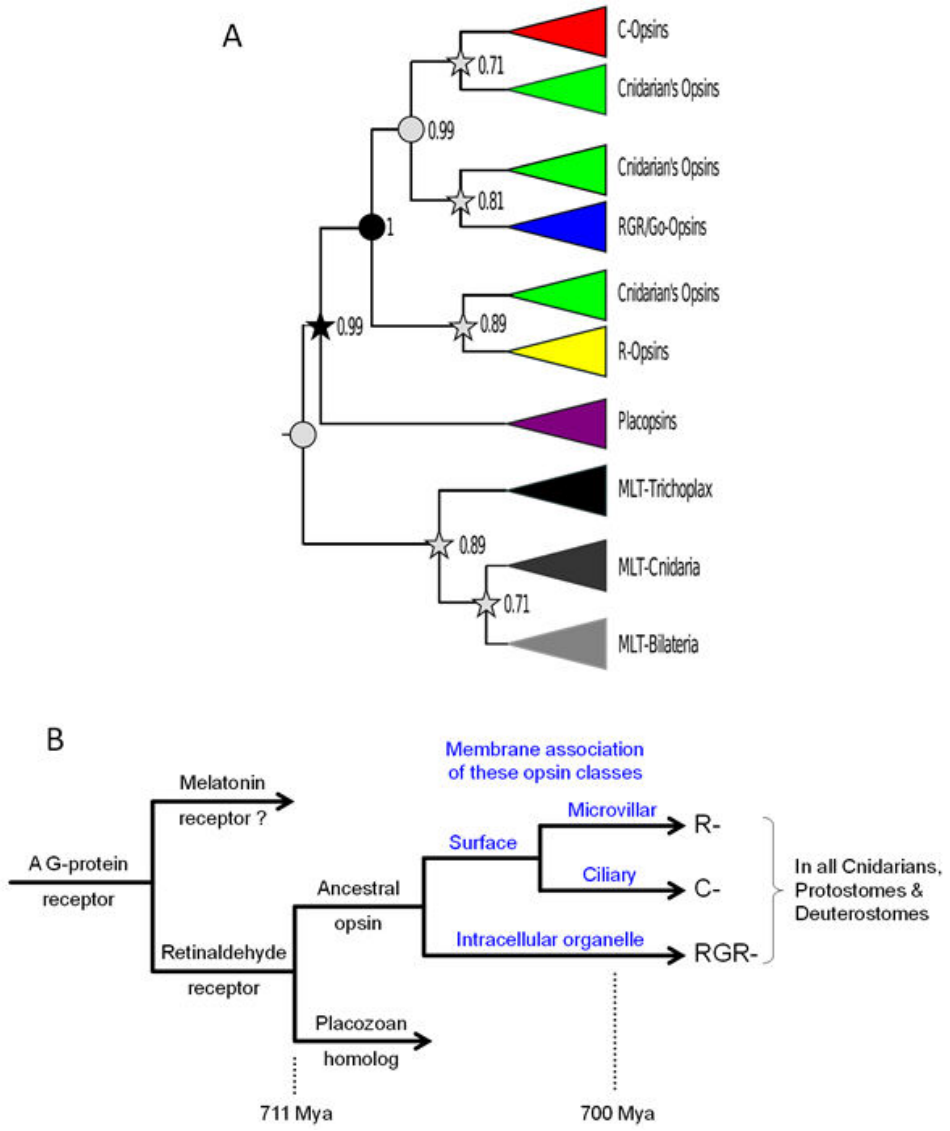

Figure 2. Origin of opsins, and their possible association with membrane type. A, Opsin phylogeny. Cnidarians have orthologs of each bilaterian opsin subfamily; i.e. the C-, R-, and RGR/Go-opsin subfamilies. Numbers indicate support values (Bayesian PPs) for key nodes. From Feuda et al (30). B, Hypothesized duplications of ancestral opsin and its precursors, and suggested association with membrane type. An ancient GPCR (related to extant vertebrate melatonin receptors) duplicated, and its ligand became retinaldehyde, which bound non-covalently; this is denoted as 'Retinaldehyde receptor'. After the divergence of the amoeba-like placozoans (~711 Mya), this GPCR evolved a lysine residue in its seventh transmembrane segment and a negatively charged residue (counterion) so that retinaldehyde bound covalently via a protonated Schiff base linkage; this form is denoted 'Ancestral opsin'. Within a relatively short interval (prior to the divergence of cnidarians, ~700 Mya), this opsin duplicated twice, giving rise to three major families of opsins: C-opsins, R-opsins, and RGR/Go-opsins. It is proposed that these three opsins preferentially associated with ciliary membrane, microvillar membrane, and the membranes of intracellular organelles, respectively. Note that all these events occurred just prior to the starting point of Figure 1.

Mayr (17) proposed that photoreceptors had evolved independently on at least 40 occasions, in what they termed a polyphyletic origin of photoreceptors. With the benefit of hindsight, one can see that there are aspects of both Eakin's and Vanfleteren & Coomans' models that had merit.

Diversity of photoreceptor types. The diversity of photoreceptor types across the animal kingdom is truly remarkable, to the extent that in perhaps the majority of organisms photoreceptor morphology fails to fall neatly into the two categories of ciliary and rhabdomeric. For an overview of the range of light-sensitive structures that occur in different organisms, the interested reader is referred to the comprehensive summary of photoreceptor

morphology provided by Vanfleteren (36). Numerous kinds of membrane elaboration occur, quite apart from the conventional 'ciliary' and 'rhabdomeric' structures.

Furthermore both ciliary and microvillar forms of membrane frequently co-occur within a single type of photoreceptor, as sketched in Figure 3 (36). For example, microvillar photoreceptors often exhibit ciliary structures such as centrioles during development (Figure 3A), though in most cases in protostomes these cilia are transient.

Importantly, such co-occurrence is also seen in deuterostome (and even vertebrate) photoreceptors. In the microvillar photoreceptors of amphioxus, the cilia persist; thus, Hesse cells bear a single 9+0 cilium, while Joseph cells bear two (37). And vertebrate ciliary photoreceptors typically possess microvilli that emanate from the distal region of the inner segment and that appear closely associated with the ciliary outer segment (Figure 3B3); however, these microvilli do not exhibit the organization typical of rhabdomeric photoreceptors, at right angles to the incident light, and instead they are arranged longitudinally. A third example amongst deuterostomes is found in hemichordates, where the cerebral eyes in the larvae of an acorn worm contain photoreceptor cells that possess both a well-developed cilium and numerous microvilli closely packed and at right-angles to the axis (38).

A final illuminating example comes from a marine gastropod, *Aporrhais pespelecani*. In the larval eye, the photoreceptors are ciliary, but at metamorphosis the ciliary photoreceptors additionally develop microvilli, thereby undergoing conversion into mixed ciliary-plus-microvillar photoreceptors in the adult (39); unfortunately, the nature of the opsin and transduction cascade in these photoreceptors is not known.

Even the extreme cases are homologous. In light of the sheer diversity in photoreceptor morphologies, one can view the classical cases of the fly photoreceptor and the vertebrate rod cell as representing extrema in a vast gradation of photoreceptor structural types. But even though the morphological disparity between these two cell types is large, the homology between them (Figure 4) is quite remarkable, as noted by Ready & Tepass (40). Both cells develop from a simple columnar epithelium. Both retain a zonula adherens (ZA) region that delineates basal from apical membrane, and that links neighboring cells; in the vertebrate retina, these intercellular contacts form the outer limiting membrane. In developing photoreceptors of both types, two sub-domains develop in the membrane apical to the ZA. The first is a Crumbs-rich supporting domain that in *Drosophila* forms the fly stalk, and that in vertebrate photoreceptors forms the inner segment. The second more apical sub-domain expands massively to form the light-sensitive membrane, in *Drosophila* as microvilli, and in vertebrate photoreceptors as the ciliary sacs or discs.

Scenario for the origin of photoreceptor cells

By drawing together threads from the concepts above, the following scenario is proposed for the origin of the main two morphological variants of photoreceptor, namely **ciliary** and **microvillar**:

B-1) The ciliary variant represents the ancestral class of photoreceptor. That ancestral photoreceptor expressed the ancestral opsin in its ciliary membrane and it also exhibited microvilli extending from its soma in the vicinity of the cilium.

B-2) In deuterostomes and cnidarians, mechanisms evolved for the massive elaboration of the ciliary region of cell membrane.

B-3) After R-opsins diverged from C-opsins (see above), they tended to traffic to microvillar membranes.

B-4) In bilaterians, mechanisms evolved for the elaboration of those microvillar membranes, leading to the principal distinction between 'ciliary' and 'microvillar' photoreceptors.

B-5) In certain arthropods and mollusks the elaboration of microvilli culminated in the formation of highly-organized rhabdomeres, and hence the evolution of a number of cases of truly 'rhabdomeric' photoreceptors.

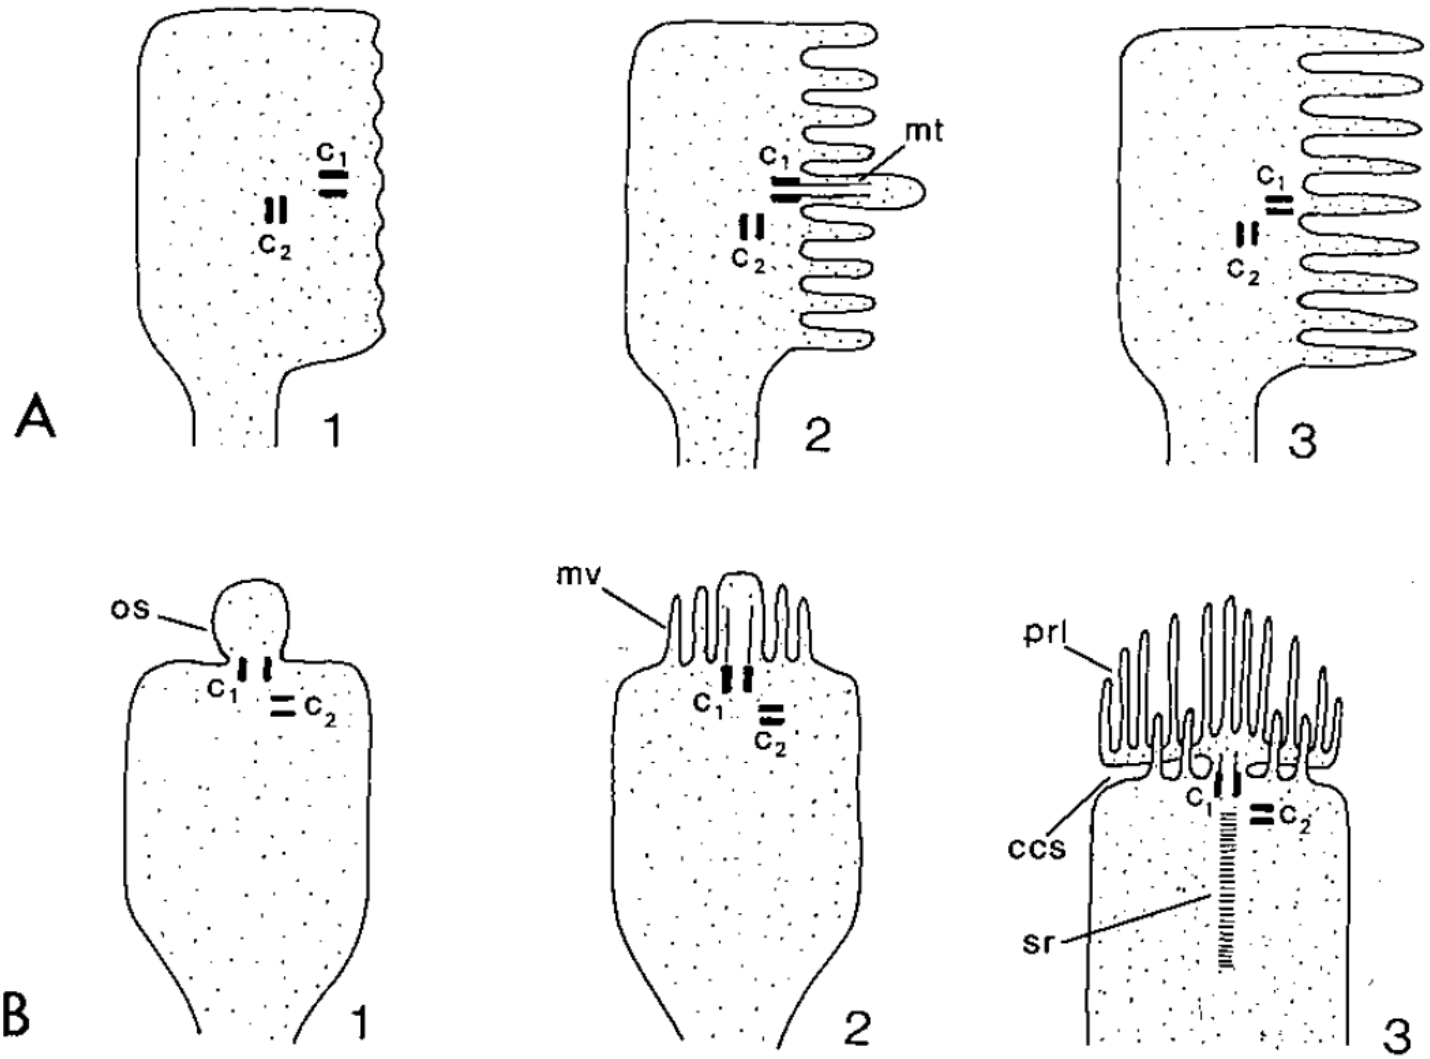

Figure 3. Co-occurrence of ciliary and microvillar structures within photoreceptors. Sketches of three steps in the development of a rhabdomeric photoreceptor (A) and a ciliary photoreceptor (B). A, Arthropod rhabdomeric photoreceptor. B, Tunicate ciliary photoreceptor. In both cases paired centrioles (c_1, c_2 are seen. In rhabdomeric photoreceptors, the ciliary apparatus may disappear during subsequent development. In the chordate photoreceptor, an outer segment bud appears first, then microvilli develop, and subsequently the ciliary membrane (of the outer segment) expands. Note that this diagram was designed to illustrate Vanfleteren & Coomans model of ciliary induction of photoreceptor membrane (35), but is here presented simply to sketch the concept of co-occurrence of structures. c_1, c_2, distal and proximal centrioles; ccs, circumciliary space; mt, microtubules; mv, microvilli; os, outer segment; prl, photoreceptive lamellae; sr, striated rootlet. From Vanfleteren (36).

B-6) Many different mechanisms for elaboration of the opsin-containing membrane have arisen, that have led to the evolution of many different varieties of membrane specialization, and hence to the formation of a vast number of photoreceptor morphologies in different organisms.

Association between opsin class and transduction cascade. There is a strong association between the class of opsin and the nature of the G-protein transduction cascade in the photoreceptor. In vertebrates, C-opsins typically activate a member of the Gi family (which includes Gt and Ggust), leading to modulation of cyclic nucleotide levels and to altered opening of CNGCs (cyclic nucleotide gated channels) and thereby to generation of the electrical response. R-opsins instead activate a Gq, which uses a PLC (phospholipase C) as the effector protein, with TRP/C channels usually generating the electrical activity. Plachetzki et al (27) provide evidence that the ancestral opsin is likely to have employed CNGCs to mediate its electrical response, and that the linkage of R-

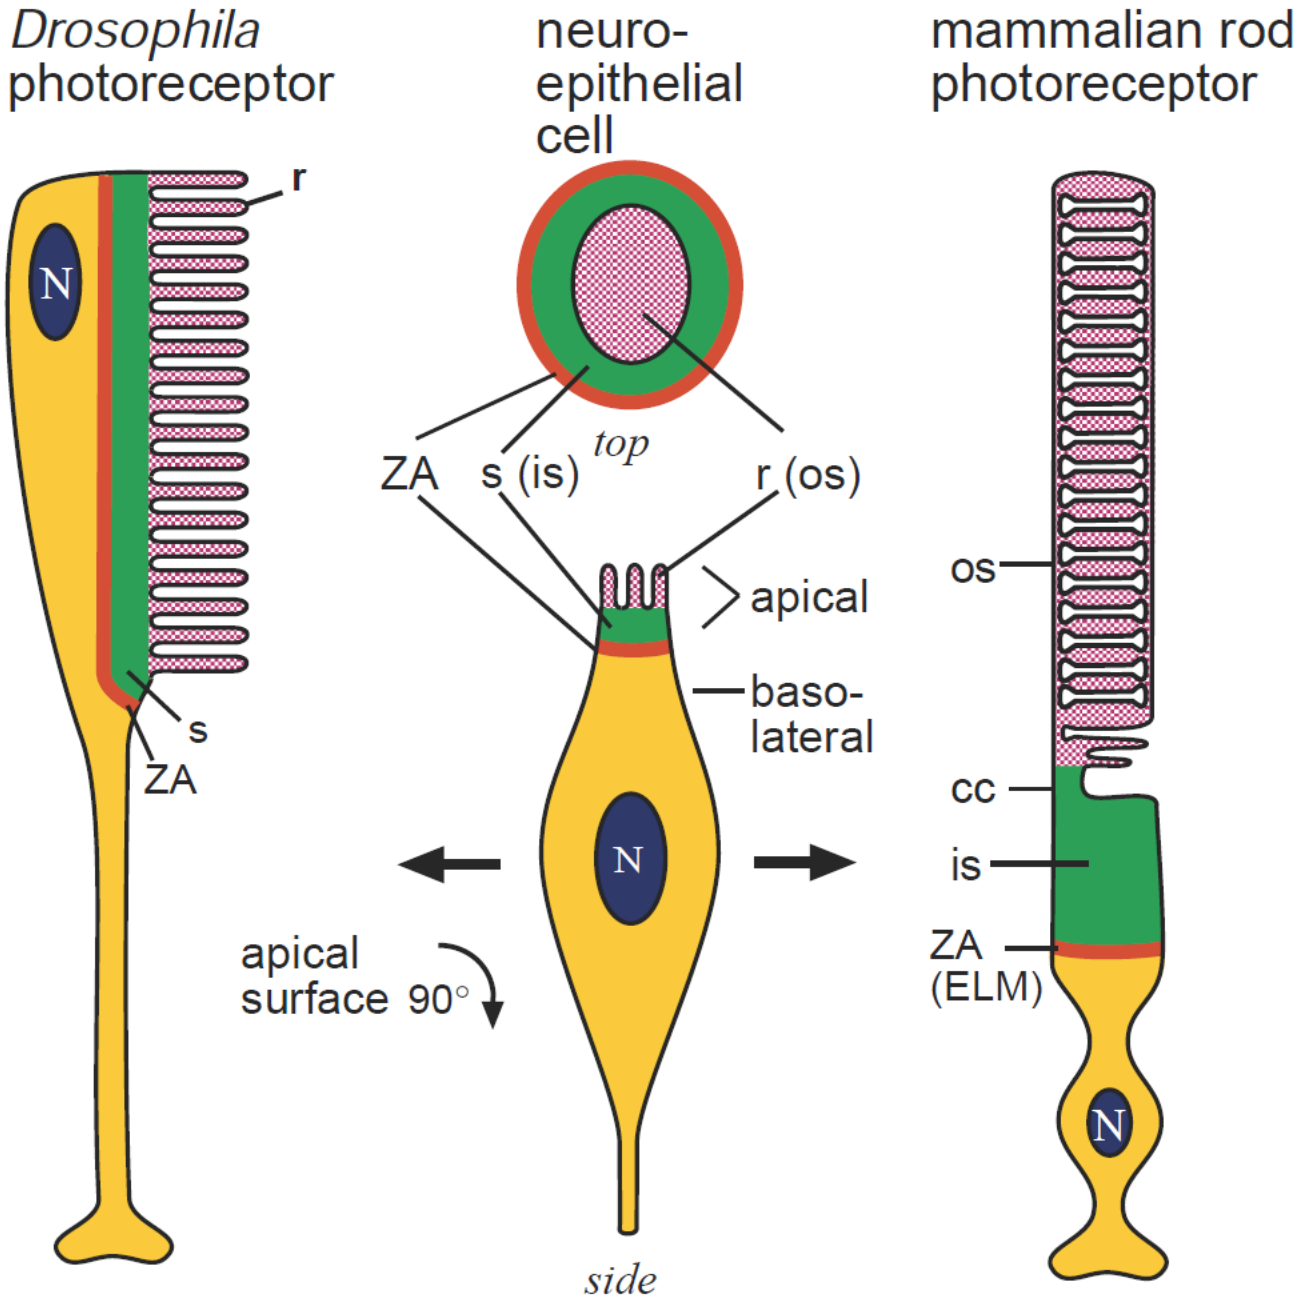

Figure 4. Rhabdomeric and ciliary photoreceptors and their homologies. Conservation of cell polarity and topology between *Drosophila* rhabdomeric photoreceptor (left) and vertebrate rod photoreceptor (right). The center image pair, in top and side view, depicts an ancestral (or an immature) photoreceptor, which can evolve (or develop) into either of the two illustrated final forms simply by different modes of expansion of the apical membrane (pink); that apical membrane is separated from the baso-lateral membrane (yellow) by a zonula adherens (ZA, brown). r, rhabdomere; s, fly stalk; os, outer segment; cc, connecting cilium; is, inner segment; ELM, external limiting membrane; N, nucleus. From Ready & Tepass (40).

opsins to TRP/C channels is likely to have arisen subsequently. The molecular genetic evidence for the co-evolution of opsins and their transduction cascades will be expanded upon in Section 8.

3. Ciliary photoreceptors in the eyes of extant chordates

In order to understand vertebrate eye evolution, one of the primary challenges is to explain the sequence of events by which a handful of photoreceptors and a pigment cell in an ancient chordate ancestor could have evolved into an exquisite retina, by the time that vertebrates appeared. (Closely related issues, that will not be treated here, concern the co-evolution of the requisite optical and motor apparatus, and of appropriate brain areas.) In considering the evolution of the vertebrate retina, we will now survey the light-sensitive organs of living chordate species, beginning with the simplest ocelli and progressing to the vertebrate retina. For each example of chordate light-sensitive organ, we will briefly examine the general features of the organ, and then concentrate on its ciliary photoreceptors.

In Section 7 we will consider why it was ciliary photoreceptors rather than microvillar photoreceptors that triumphed in chordate and vertebrate eyes. Then in later sections we will examine the embryological development of the mammalian retina, as well as molecular clues to eye evolution.

Cephalochordate light-sensitive organs (amphioxus)

Lacalli (41, 42) has described four distinct light-sensing regions in the cephalochordate, amphioxus (Figure 5). Each of these regions lies along the neural tube, in a fairly dorsal position, on the midline (i.e. unpaired), and none has any kind of lens or other imaging apparatus. Two of these organs contain ciliary cells (usually presumed to be photoreceptors) whereas the other two contain microvillar photoreceptors. Although these latter cells have in the past often been referred to as 'rhabdomeric' cells, they do not actually display the highly-organized structure of genuine rhabdomeres and it is preferable to refer to them as 'microvillar', as used by Gomez et al (43) and co-workers.

Ciliary photoreceptors. The 'frontal eye' is a tiny rostral region containing a few ciliary cells that has been proposed to be the homolog of the vertebrate lateral eyes. The 'lamellar body', not far behind the frontal eye, also contains ciliary cells, which in this case exhibit very extensive lamellar membranes; this organ has been proposed as the homolog of the vertebrate pineal. Although the lamellar body is present as a distinct organ in larvae, the cells appear to disperse in the adult. To date, neither of these types of ciliary cell (frontal eye or lamellar body) has actually been shown to be light-responsive.

Microvillar photoreceptors. A little more caudally, a set of 'Joseph cells' is found, each being a microvillar photoreceptor, and further caudally a chain of 'dorsal ocelli' or 'organs of Hesse' are found, that each contain a microvillar photoreceptor partly enveloped by a pigment cell. Recently, it has been established that phototransduction in these cells is closely homologous to that in rhabdomeric photoreceptors of protostomes, utilizing the R-opsin melanopsin (44) to trigger a classical 'rhabdomeric' transduction cascade that involves Gq and PLC (45, 46), and that presumably is closely similar to the cascade in the intrinsically photosensitive retinal ganglion cells (ipRGCs) of the vertebrate retina.

Molecular markers. Very recently, Vopalensky et al (47) identified a number of molecular markers expressed in cells of the frontal eye of amphioxus (Figure 5C), and they concluded that this organ indeed appears homologous to the lateral eyes of vertebrates. In particular, the simple ciliary cells in the first row of the frontal eye appear homologous to cone and rod photoreceptors, in co-expressing C-opsins along with the transcription factors Pax4/6, Otx and Six3/6; furthermore, the presence of the inhibitory Gi-type G-protein alpha subunit is suggestive of the vertebrate-style OFF response to light. Cells in the second row might conceivably be homologous to retinal ganglion cells; they project axons to the neuropil, and they contain serotonin, though so far there is insufficient information to decide on their possible homology to ganglion cells. Finally, the pigmented cells appear homologous to vertebrate RPE cells, in terms of melanin content, location adjacent to the photoreceptors, and regulatory signature (of Mitf, Otx, and Pax2/5/8).

The previously proposed homology of the lamellar body to the vertebrate pineal organ is not supported, because of the demonstrated absence of both Otx and Rx - as well as by the inability to detect an opsin. Thus, although the cells of the lamellar body clearly exhibit a ciliary lamellate ultrastructure, there is as yet no evidence that they are photoreceptors, and the organ appears not to be homologous to the vertebrate eyes or pineal.

Electrophysiology. The Joseph cells and dorsal ocellar cells of amphioxus have recently been studied using electrophysiological techniques, and unequivocally identified as microvillar photoreceptors (43), but the ciliary cells of the frontal eye and lamellar body have not yet been studied in this way.

Tunicate ocellus (larval *Ciona* and *Aplidium*)

Ocellus. The closest extant sister group to vertebrates comprises the tunicates, including sea squirts such as *Ciona intestinalis* and *Aplidium constellatum*. The sessile adult form of the sea squirt has not been reported to possess any kind of discrete eyespot, though scattered opsin-expressing cells apparently occur. However, the tadpole-like larval stage (Figure 6A) has a simple photosensory organ, termed an ocellus (Figure 6D), that contains a handful of ciliary photoreceptors surrounded by a single large pigment-containing cell. It has been suggested that this ocellus is the remnant of paired ocelli in an ancestor (48). The larva does little, beyond swimming to the bottom, embedding its head on a rock, dissolving its nervous system, and transforming itself into a squirt.

Photoreceptor cells. The ciliary photoreceptors of two species of sea squirt are illustrated in Figures 6B-E (from (49, 50)). A total of a dozen or so photoreceptor cells (about seven are sectioned in Figure 6B) protrude through the single pigment cell, with their outer segments lying beneath the lens formed by the three lens vesicle (LV) cells. A schematized *Ciona* photoreceptor is shown in Figure 6C. A large somatic region gives rise at its base to an axonal process (AX), while from its upper end a process penetrates the pigmented cell and gives rise to the axoneme (A), from which expands the outer segment (OS) with its lamellae (L). The electron micrographs from the closely-related ascidian, *Aplidium*, were obtained transversely (Figure 6D) and longitudinally (Figure 6E) with respect to the axis of the outer segment, and show the rather 'petal-like' concentric arrangement of lamellae. Both the studies above reported microvilli interdigitating with the lamellae, though Eakin & Kuda (50) suggested that these originated from the pigment cell (Figure 6C) whereas Barnes (49) reported that they originated from the inner segment of the photoreceptor (see Figure 6E).

Electrophysiology. Electrical responses have been recorded from ascidian ciliary photoreceptors in only one study, on *Aplidium constellatum* (51), where it was reported that it "proved exceedingly difficult to record electrical activity from these preparations, possibly because the retinal cells, which lie close to the surface of the small animal, are often damaged by the removal of the thick tunic". The rare penetrations gave resting potentials of -5 to -20 mV, with hyperpolarizing light responses of small amplitude (2 to 7 mV) that were accompanied by a decrease in membrane conductance. These responses are qualitatively similar to those of vertebrate retinal photoreceptors (with the small amplitude probably explained by damage), though there is insufficient data to allow a proper comparison to be made.

Hagfish eye (*Eptatretus* species)

There is now strong evidence that hagfish are descendants of a lamprey-like ancestor and that many of their morphological features have 'degenerated' from a more complex form. That interpretation is certainly accepted here but, notwithstanding this, the viewpoint that will be advanced below is that the hagfish eye provides a window into an early transitional form in the evolution of the vertebrate-style eye, as suggested previously by Lamb et al (3).

Although controversy has long surrounded the phylogenic position of hagfish, there is now powerful evidence that hagfish form a clade with lampreys (52), as indicated in Figure 1. Hagfish have the simplest body plan of all vertebrates (Figure 7A, B). They inhabit the oceans around most continents, often at great depths (in many cases 200 m or more) where they scavenge fallen carcasses; recently they have been found also to be predatory (53).

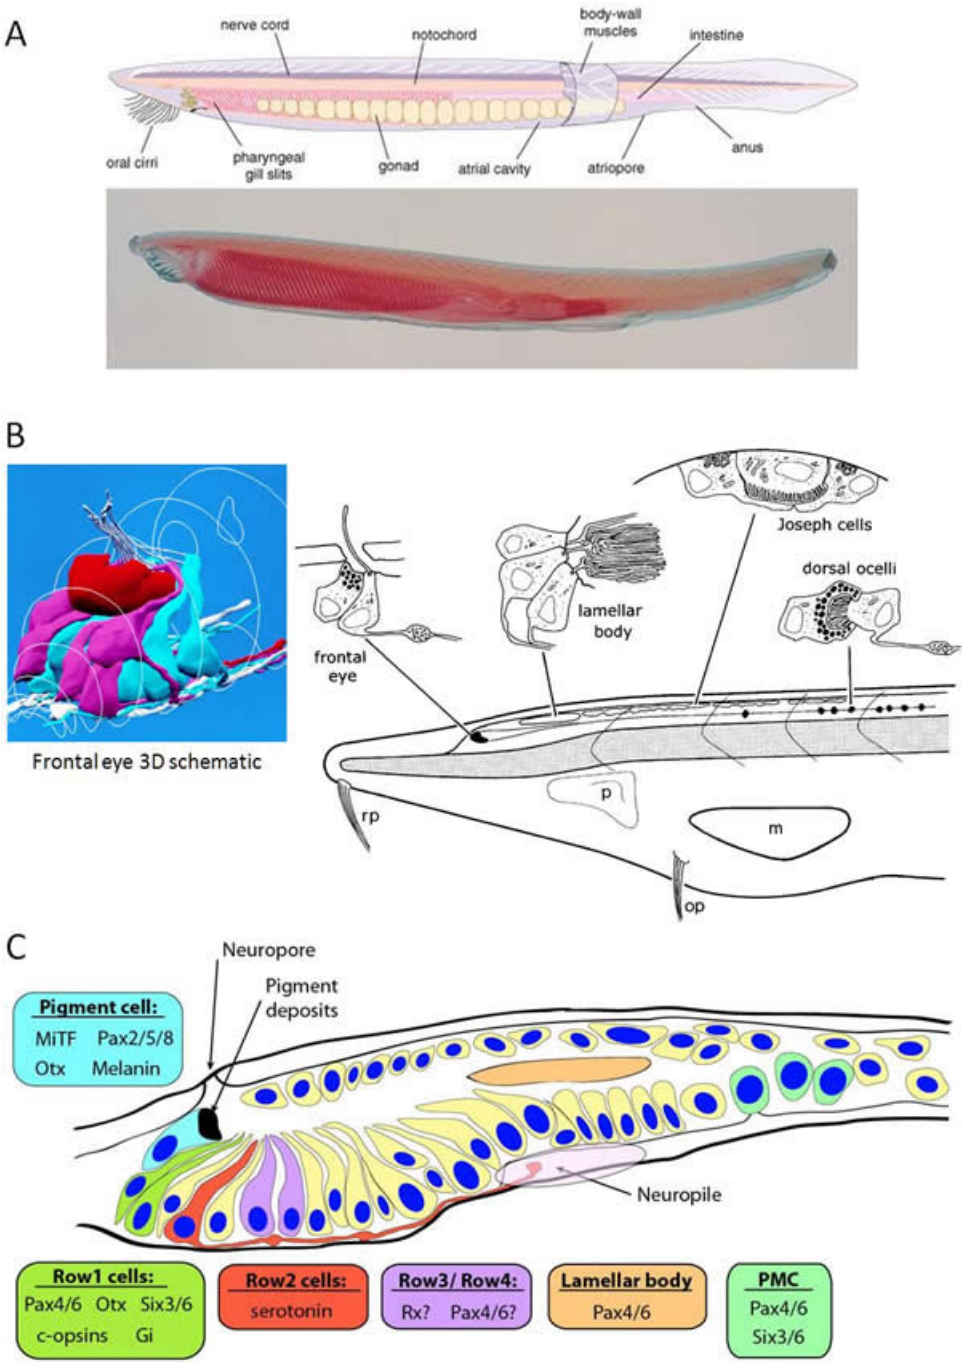

Figure 5. Amphioxus photoreceptors. A, Amphioxus adult, schematic and image. Typical length 2-3 cm. B, Light-sensitive organs in the head region of the larval amphioxus. The frontal eye and lamellar body contain ciliary cells; the Joseph cells and pigmented dorsal ocelli are rhabdomeric. The notochord is shaded; m, mouth. From Lacalli (42). C, Molecular fingerprint of the frontal eye of larval amphioxus. The expression profile of vertebrate eye-specific regulatory genes (Rx, Otx, Pax4/6, Mitf) and eye-associated proteins (C-opsins, Gi, melanin) supports the homology of Row 1 cells with vertebrate photoreceptors, and of pigment cells with vertebrate RPE cells. From Vopalensky et al (47).

Behaviorally, hagfish appear blind. However, in captivity, exposure to the onset of bright light leads, after a long delay (of the order of 10 s or more), to the onset of swimming and sometimes attempted burrowing. Upon removal of the animal's eyes, Newth & Ross (54) reported that the delay was unchanged, though Kobayashi (55) instead reported that it nearly doubled from around 10 s to 20 s. In either case, the eyes of the hagfish appear to mediate little in the way of rapid photosensitive behavior.

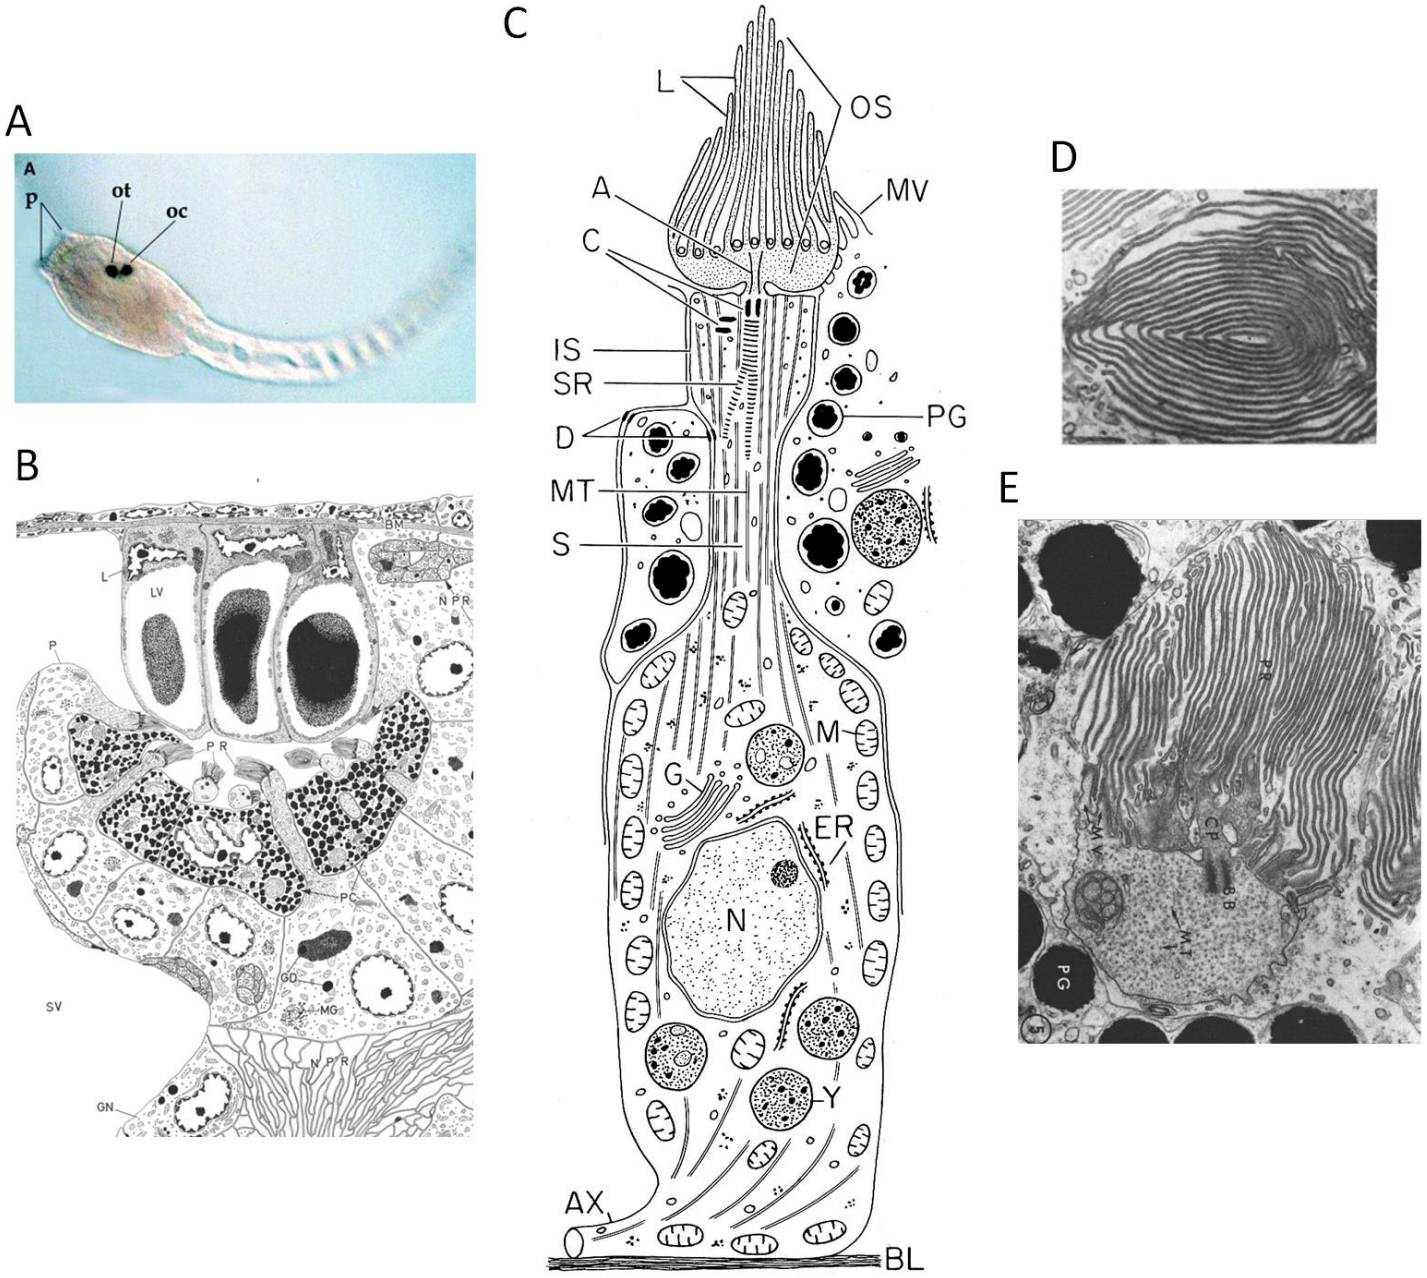

Figure 6. Photoreceptors of ascidian larvae, *Ciona* and *Aplidium*. A, *Ciona intestinalis* larva. Diameter of head is ~80-100 µm. ot, otolith; oc, ocellus. From D'Aniello et al (266). B, Schematic of eyespot of *Aplidium constellatum* larva at low magnification. LV, lens vesicle (3 cells); PR, photoreceptor cells (~7 are shown); NPR, neuronal processes extending from basal region of the photoreceptor cells; PC, pigment cell (a single cell). From Barnes (49). C, Schematic of a photoreceptor protruding through part of the pigment cell, in *Ciona intestinalis* larva. Abbreviations for photoreceptor: OS, outer segment; L, lamellae; A, axoneme (9+0 double filaments); MT, microtubules; N, nucleus; AX, axon. For pigment cell: MV, microvilli; PG, pigment granules. From Eakin & Kuda (50). D, E, Outer segment of a photoreceptor of *Aplidium constellatum* larva. D, Transverse section, showing concentric arrangement of lamellae. E, Longitudinal section. BB, basal body; CP, connecting piece; MV, microvilli. From Barnes (49).

Hagfish are able to secrete a potent slime from a series of lateral pores (Figure 7B), and this slime functions as a highly-effective defense mechanism. The spectacular movies (Supplementary Video S1, Supplementary Video S2) obtained by Zintzen et al (53) show the rapid release of slime into the mouth of a predator at the moment that it bites a hagfish, accompanied by an almost instantaneous gagging reaction and retreat by the predator. Of 14 attacks that were filmed, none was successful, and in each case the hagfish continued swimming as if nothing

had happened. The evolution of such a successful defense mechanism may have enabled hagfish to have survived in their niche virtually unaltered for hundreds of millions of years.

Hagfish eyes. Locket & Jorgensen (56) provided a comprehensive review of hagfish eyes, which had first been studied in the late nineteenth century, and then using electron microscopy in the late twentieth century. The following description for *Eptatretus* species is based largely on the reports of Holmberg (57, 58), Fernholm & Holmberg (59) and Locket & Jorgensen (56).

General features of the hagfish eye. At the location on the head where one would expect to find an eye, the hagfish simply has a patch of translucent (almost transparent) skin (Figure 7D). Beneath this translucent patch of skin is what in the hagfish passes for an eye (Figure 8A, Figure 8B). This organ has no extraocular muscles, no lens, and no iris, and is embedded in fat, through which a very slender optic nerve passes. The size of the eye varies considerably between individuals, but is typically around 1 - 1.5 mm in diameter, though rarely spherical in shape. The sclera/cornea is not divided into separate opaque and transparent regions, and is instead fairly uniformly translucent. No pigmentation is found in the eye, either in the sclera, choroid, or retinal epithelium, even though the skin of the animal may be darkly pigmented. Lining the sclera is a tenuous layer of capillaries, presumably comparable to the choroidal vasculature of jawed vertebrates. In the absence of a lens, much of the chamber is filled with the vitreous body. The optic nerve is thin, containing only a couple of thousand unmyelinated axons. Neither hagfish nor lampreys exhibit myelin (60, 61), and these axons project predominantly to the hypothalamus (62, 63), just as their likely homologs, the melanopsin-expressing ipRGCs, do in mammals (64).

The hagfish retina is roughly cup-shaped and lines half to two-thirds of the globe, though the choroid fissure often remains open (65). As for jawed vertebrates, the retina comprises two apposed layers, the neural retina and the retinal epithelium, though in hagfish the epithelial layer is unpigmented. Several authors have remarked that the neural retina and retinal epithelium often seem to be separated by a gap, but it is possible that this is a fixation artifact (perhaps arising from dilution of the high tonicity extracellular medium, which resembles sea-water). At the peripheral margin of the retina, the inner layer reduces to a single layer of cells and is continuous with the outer layer, though there is no extension to a ciliary body or iris.

Neural retina. The neural retina (Figure 8B) of hagfish is simpler than that of lampreys or jawed vertebrates, with only two layers of somata, comprising photoreceptor cells and projection neurons. No author has reported identifiable horizontal cells or bipolar cells, though Locket & Jorgensen (56) reported some instances of a ciliated structure resembling a Landolt club. The neural arrangement of the hagfish retina is strongly reminiscent of the pineal organ in non-mammalian vertebrates (see Section 3) and, interestingly, the hagfish lacks a pineal. It is presumed that hagfish photoreceptors make direct synaptic contact onto the projection neurons (ganglion cells), though as yet the identity of the cells that are post-synaptic at the photoreceptor synapse has not been determined. There are distinct outer and inner limiting membranes bounding the retina.

Photoreceptor morphology. The morphology of photoreceptors from the hagfish *Eptatretus stoutii* is illustrated in Figure 9 (57). The schematic in Figure 9A shows the general arrangement, of roughly cylindrical receptor cells (R) surrounded by glial cells (G). The region corresponding to the inner segment lies vitreal to the outer limiting membrane, in contrast to the situation in jawed vertebrates and lampreys. It contains a region corresponding to the ellipsoid, packed with mitochondria (Figure 9C), from which the cilium arises, but there is no sign of a paraboloid or myoid. The outer segment protrudes through the outer limiting membrane into the ventricular/extracellular space (ES), where it comes into contact with a non-pigmented epithelial cell (E) and the fine processes that descend from that cell. Compared with other vertebrate retinas, the outer segments are packed very sparsely in the ventricular space (Figure 8B and Figure 9A).

The electron micrographs in Figure 9B and Figure 9C show the lamellar arrangement of the outer segment membranes. According to Holmberg (57) and Locket & Jorgensen (56) the lamellae are enclosed by the plasma

membrane, though this is not clear-cut from the micrographs. Some authors report the lamellae to be quite regular (Figure 9B (57)), while others do not; e.g. "These discs in *Eptatretus*, however, are not stacked closely, but in a loose and often disordered way" (56). The cilium has the classical 9+0 double filament structure, but unusually is located centrally, on the axis of the inner and outer segments, so that the outer segment lamellae extend roughly symmetrically on either side of the cilium (Figure 9C); this contrasts with the situation in vertebrate cones and rods where the cilium is located at the edge of the outer segment.

At its base, the receptor cell is invaginated by a synaptic contact (Figure 9A), and the synaptic zone (Figure 9D) is characterized by synaptic vesicles surrounding a 'synaptic body' (SB), rather than a conventional synaptic ribbon. The contact is of the dyad type, rather than the triad found in the photoreceptors of lampreys and most jawed vertebrates, though (as mentioned above) the identity of the post-synaptic elements has not been reported. Nevertheless, it is presumed that there must be direct synaptic contact from photoreceptors onto projection neurons, as no other cell types have been reported.

Electrophysiology. Single cell recordings have not been made from hagfish photoreceptors, though ERG recordings were reported by Kobayashi (55), for a species named as *Myxine garmani* but subsequently reported by Fernholm & Holmberg (59) to have been *Eptatretus burgeri*. The excised eye was used, and recordings were made between a wick electrode on the surface of the eye and a moistened cloth on which the eye sat. Dim flashes elicited a slow response of characteristic positive-then-negative shape, and the amplitude of this complex response saturated at a relatively low intensity of ~10 lux. For bright flashes a small slow negative-going wave preceded this complex response. The spectral sensitivity of the response was maximal at around 500 nm, suggestive of rhodopsin.

Although Kobayashi interpreted the complex positive-then-negative wave as analogous to the b-wave of the ERG from the vertebrate eye, there were some remarkable properties that suggest a different interpretation. First, this response exhibited a relatively long latency of ~350 ms prior to a fairly rapid climb to its positive peak in a further ~200 ms. Secondly, the form of this complex response was completely unchanged, either when the flash intensity was further increased or when the flash duration was varied from 3 ms up to 1 s. Thirdly, the response exhibited a lengthy refractory period, so that an interval of ~4 s was required after a flash of 10 lux, before any response could be elicited from a second identical flash. Fourthly, dim adapting light could completely eliminate this response, and then during subsequent dark adaptation the response reappeared fairly abruptly.

From the combination of these features I suggest the alternative interpretation that the positive-then-negative response actually reflected the synchronous firing of very slow regenerative potentials ('action potentials') in the projection neurons (ganglion cells). For the future, it should be possible to test this assertion by making more comprehensive electrophysiological recordings from hagfish retinal cells, including intracellular recordings from ganglion cells, suction pipette recordings from photoreceptors, and further ERG recordings.

Hagfish photoreceptors exhibit some rod-like properties. In summary, the photoreceptors of *Eptatretus* species exhibit a number of rod-like properties: e.g. the outer segment lamellae are reported to be disc-like, the inner segment lacks a paraboloid or myoid, and the electrical response shows peak sensitivity at around 500 nm. However, there is still no evidence as to whether these cells can respond reliably to individual photons.

Lamprey pineal (*Petromyzon marinus* ammocoete)

Like the retina of the lateral eyes, the pineal is an evagination of the diencephalon, though it emerges upwards on the dorsal midline (see Section 13). In non-mammalian vertebrates, the pineal contains light-sensitive ciliary photoreceptors, and all ultrastructural work has shown the existence of only three main cell types: photoreceptors, projection neurons (ganglion cells), and glial cells. The photoreceptors make ribbon synapses onto ganglion cells, which send axons to the hypothalamus.

Photograph David Greenhalgh, copyright Australian Museum.

The photoreceptors in the pineal of the larval sea lamprey, *Petromyzon marinus*, have been investigated by Pu & Dowling (66), using light and electron microscopy as well as intracellular electrophysiological recording, and the following is based on their report. Figure 10 illustrates pineal photoreceptors and their organization within the pineal. The diagram in Figure 10A sketches the overall arrangement of the organ, while the schematic in Figure 10B illustrates the detailed features of the photoreceptor cell and its synaptic contacts.

Photoreceptor morphology. As sketched in Figure 10B (67), the photoreceptor cell is approximately cylindrical for most of its length, with a diameter approaching 10 µm, but the outer segments are often broader, with widths of 10 - 25 µm. The outer segment contains numerous lamellae, that can number more than 100 (Figure10C), which contrasts with the view of Nilsson (13) that there is "very limited membrane stacking" of pineal membranes. The lamellae are rarely flat, but usually somewhat curved, and they are reported to be somewhat less regularly stacked than for cone and rod outer segments in gnathostome retinas. The outer segment membrane is like that of cones, in being continuous with the plasma membrane (Figure 10C).

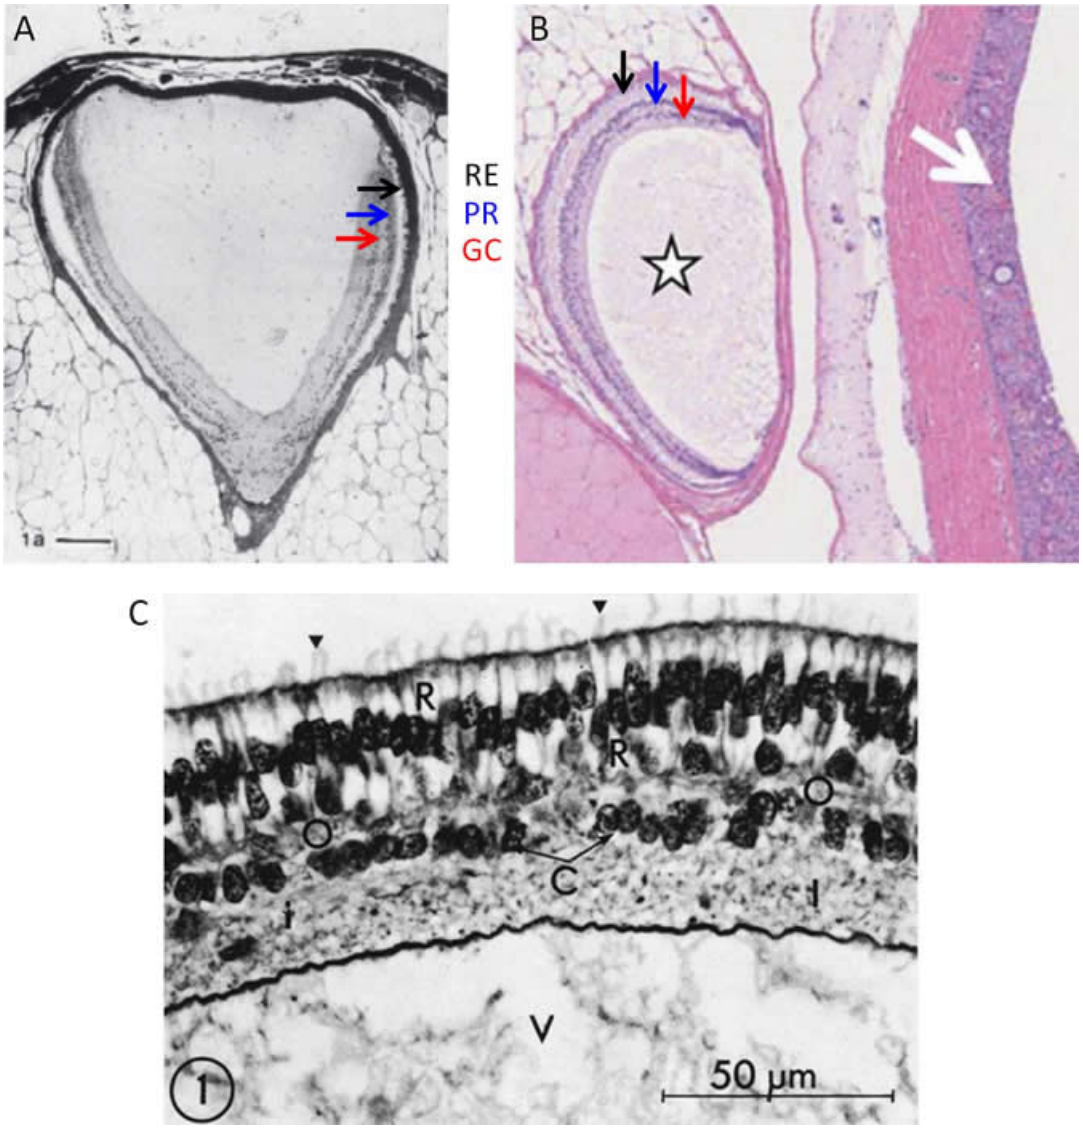

Figure 8. A,B, Light micrographs of sections through hagfish eyes. A, *Eptatretus burgeri*. Scale bar 0.15 mm. From Locket & Jorgensen (56). B, *Eptatretus stoutii*. Eye (starred) and eye-patch (arrowed). Stain: Hematoxylin and Eosin. From Zeiss et al (267). Arrows indicate nuclear layers as follows: red (GC) ganglion cells; blue (PR) photoreceptors; and black (RE) retinal epithelial cells. C, Electron micrograph of retinal section, *Eptatretus stoutii*. The two triangles mark two outer segments. R, receptor cells; O, outer synaptic layer; C, cell bodies of projection neurons; I, inner fiber layer; V, vitreous body. Distinct outer and inner limiting membranes are visible. Stain: Heidenhain's Azan. From Holmberg (57).

As well as the outer segment, a prominent inner segment protrudes into the lumen. At the base of the cell, synaptic contact is made with ganglion cells, predominantly at flat ribbon synapses (Figure 10B, Figure 10D), arranged either as dyads (Figure 10D) or 'monads'; triads were never seen, and nor were feedback synapses (66).

Electrical response to light. Pu & Dowling (66) made intracellular voltage recordings from these pineal photoreceptors, and response to flashes and steps of light are shown in Figure 11. The response was always a slow graded hyperpolarization, broadly similar to that recorded from vertebrate cones or rods, though without the characteristic rapid relaxation from an initial peak back to a plateau for bright stimuli. The flash responses were more than a log unit less sensitive than for cones (of the mudpuppy) and the spectral sensitivity peaked at around 545 nm. The time-to-peak for dim flashes was around 1 s (Figure 11A), much slower than for cones at room temperature, though similar to rods. The response-versus-intensity relation for flashes followed a hyperbolic saturation, $I / (I+\sigma)$. In response to prolonged illumination, the response slowly sagged, except at the

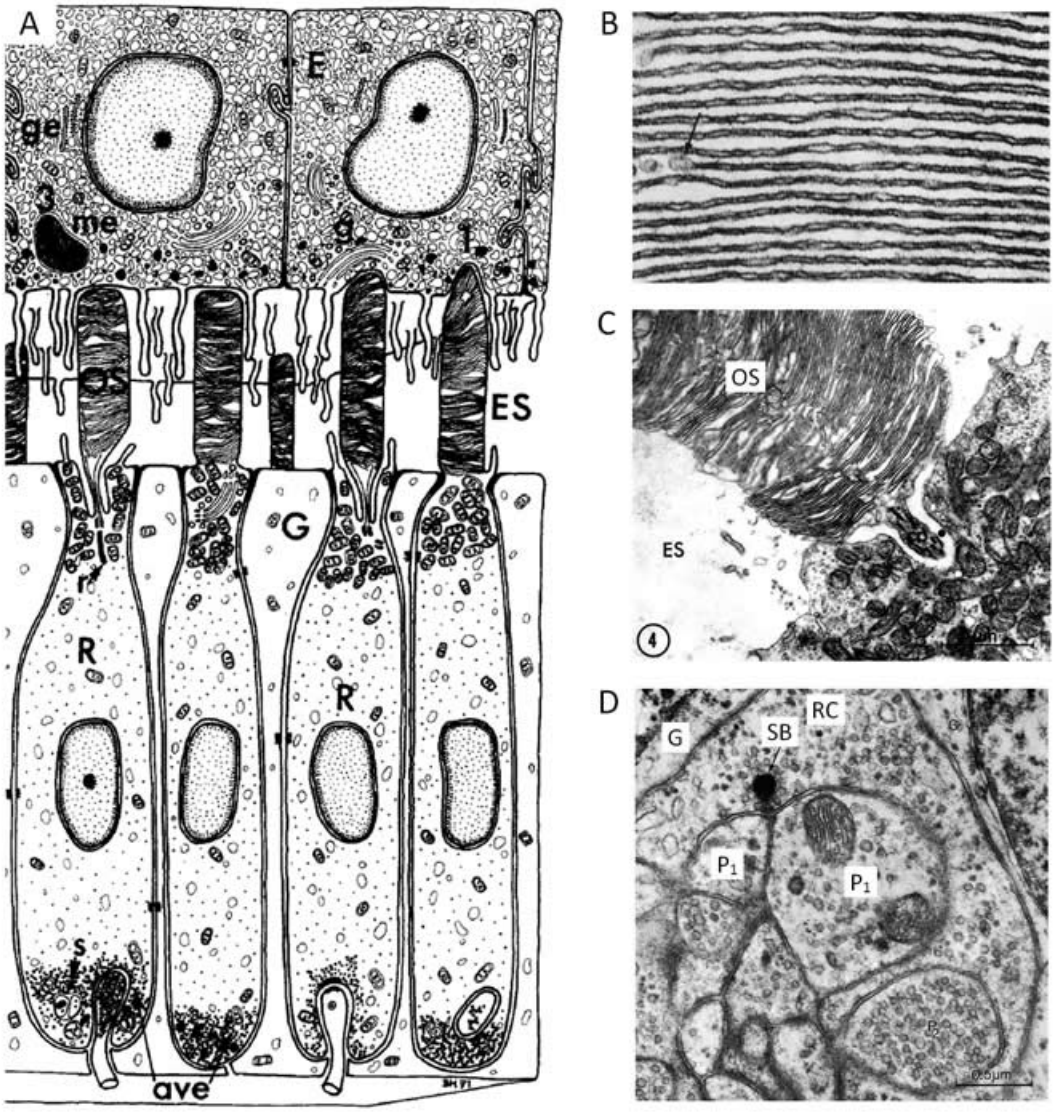

Figure 9. Photoreceptors of Pacific hagfish, *Eptatretus stoutii*. A, Schematic, showing four receptor cells (R) with outer segments (OS) protruding into the extracellular space (ES), and making contact with epithelial cells (E). Invaginating synapses are seen at the base: s, synaptic body; ave, agranular vesicles. G, glial cell. B, Outer segment lamellae are often stacked in an orderly manner. Interruptions of the kind marked by the arrow were presumed to be fixation artifacts, as they were seen only with osmium tetroxide and not with formaldehyde-glutaraldehyde. C, Lower power image, showing outer segment (OS) and connecting cilium. It is not clear whether the outer segment lamellae are enclosed by a plasma membrane or not. ES, extracellular space. The inner segment region contains an accumulation of mitochondria, analogous to the ellipsoid. D, Synaptic terminal. Within the terminal of the receptor cell (RC), a synaptic body (SB) is surrounded by vesicles, and makes contact with two post-synaptic processes (P_1, P_1). From Holmberg (57, 58).

highest intensities, for which it remained saturated (Figure 11B). Responses to incremental flashes were desensitized, roughly according to Weber's law, though much of the desensitization was the result of response compression, and only about 1.5 log units was due to a scaling of σ. At the cessation of steady light, the response began recovering immediately, as occurs in cones. Following intense 'bleaching' exposures, the sensitivity was fully recovered within 4 min, again similar to cones rather than rods.

Kusmic et al (68) obtained broadly comparable results in trout pineal photoreceptors, and additionally showed that the molecular mechanism appeared similar to that in retinal photoreceptors. Voltage clamp experiments showed that the light response was accompanied by a reduction in membrane conductance (as in retinal photoreceptors); however, bright flashes reduced the total conductance only by ~10%, which may explain a contrary report of a light-induced conductance increase by Morita et al (69). In addition, application of the

phosphodiesterase inhibitor IBMX led to an increase in the size of the light responses, as in retinal photoreceptors, and consistent with a light-induced decrease in cGMP concentration. Furthermore, the response-versus-intensity relation measured at a fixed time (prior to the peak) exhibited an exponential saturation, as expected for the classic vertebrate phototransduction cascade (70).

The light adaptation behavior reported by Kusmic et al (68) differed somewhat from that reported by Pu & Dowling (66), in that the responses to steady illumination did not sag at all. Further, for superimposed test flashes the time-to-peak did not shorten in the presence of background illumination. For dim test flashes, the time-to-peak was around 1.5 s in dark-adapted conditions and it remained the same in the presence of backgrounds; likewise, responses to brighter test flashes (which had shorter times-to-peak in darkness) did not accelerate.

From the spectral sensitivity reported by Pu & Dowling (66), and from the in situ hybridization results of Koyanagi et al (71), it seems likely that the opsin in the pineal photoreceptors recorded above was rhodopsin (though with a vitamin A_2-based chromophore in the larval lamprey), and the cells were probably from the ventral region of the organ. Photoreceptors in the dorsal region express parapinopsin (71) and exhibit UV-sensitive hyperpolarizations (71, 72).

Despite the fact that the pineal photoreceptors described above probably use rhodopsin as the visual pigment, their electrical responses can generally be described as resembling 'slow and insensitive cone-like responses', except for two properties. Firstly, light adaptation occurs without response acceleration. Secondly (and probably related), the response saturates in bright steady lights. In contrast, no matter how bright the steady light, the cones of jawed vertebrates always manage to return their circulating current and intracellular voltage to an operating point that permits them to continue responding to incremental stimuli (73).

Pineal ganglion cell responses. A typical response for a standard 'luminosity OFF' ganglion cell to moderately bright illumination is shown in Figure 12 (69), and compared schematically with a photoreceptor response. For sub-saturating intensities the form of the graded response in the ganglion cell closely resembles that in the photoreceptor. In other experiments it has been shown that maintained exposures reduce the firing rate in proportion to the logarithm of the intensity, over a range as great as 8 log units (74).

Lamprey lateral eye

Eye. The lateral eye of adult lampreys (Figure 13B, Figure 13C) bears a striking similarity to that of jawed fish. It is a camera-style eye, with a lens, an iris, and a set of six extraocular muscles. These extraocular muscles are in part homologous to those of jawed vertebrates (75) and interestingly an intermediate arrangement of muscles has been documented (76, 77) in a fossil placoderm, an agnathan armored fish that diverged from our lineage after the ancestors of lampreys had diverged.

Retina. As shown schematically in Figure 14, the retina of the silver lamprey (a northern hemisphere species) appears very similar to that of gnathostomes, and contains the conventional five classes of neuron (photoreceptors, horizontal, bipolar, amacrine and ganglion cells) as well as Müller glial cells. The nuclei are distributed into three main nuclear layers, and there are two plexiform layers, though one difference between lamprey and gnathostome retinas is an apparent 'flipping' of the ganglion cell layer and inner plexiform layer - thus, the bulk of the retinal ganglion cells and their fibers are positioned scleral to the inner plexiform layer in the lamprey (compare Figure 14A and Figure 14B) (75). Fritzsch has proposed that this arrangement in the lamprey retina (and likewise in some brain areas) is basal, and that the flipping of retinal layers in gnathostomes is derived (78, 79).

Also shown for comparison in Figure 14C, Figure 14D is a schematic of the retina of the southern hemisphere lamprey, *Geotria australis*, in its 'downstream' and 'upstream' migratory phases; the downstream phase is just post-metamorphic, when the juveniles migrate down to the sea, while in the upstream phase the fully-grown

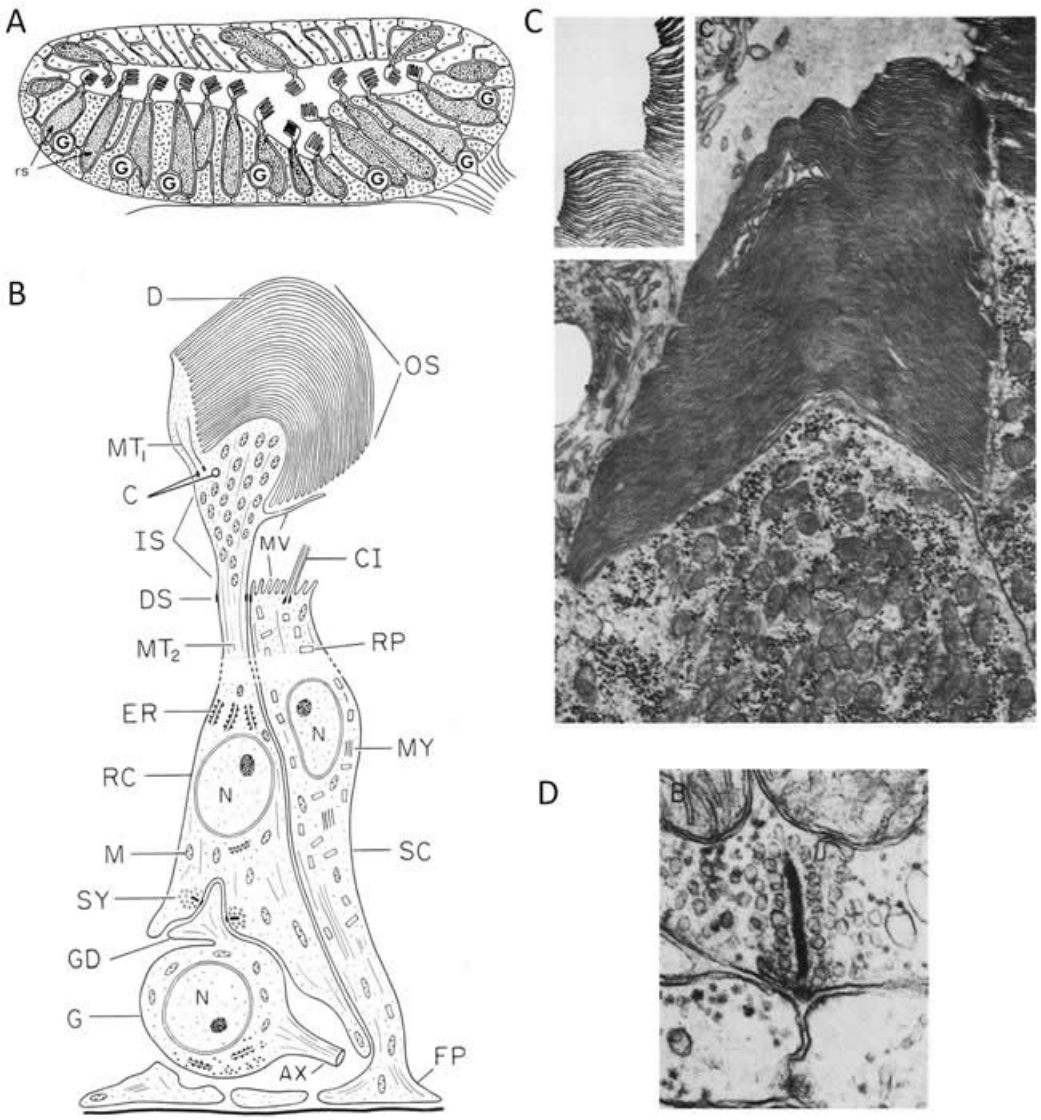

Figure 10. Lamprey pineal photoreceptors. A, Schematic of the pineal. Photoreceptors are darkly stippled, and are shown with their outer segments protruding into the lumen; glial cells are lightly stippled. Ganglion cells (G) lie near the basal end of the photoreceptors. B, Schematic of cellular organization in the pineal of the larval lamprey. A photoreceptor cell (RC) is shown making synaptic contacts with a ganglion cell (G). The outer segment (OS) is short but broad, and there is a distinct inner segment (IS) distal to the tips of the glial (supportive) cell (SC). No other identifiable classes of neuron are present. Sections deleted from cells are indicated by dashed lines. Selected abbreviations: C, centrioles; CI, cilium of supporting cell; D, discs (though these are actually cone-like sacs); MV, microvilli. From Eakin (67). C, Outer segment showing sacs, with membranes that are continuous with the plasma membrane (inset). The stacking of membranes may be less orderly than in vertebrate retinal photoreceptors. D, Synaptic terminal, showing a distinct ribbon contact onto a dyad; triads are not observed. A, C, D, From Pu & Dowling (66).

adults migrate back upstream to spawn near where they hatched. The retina of *G. australis* is broadly similar to those of other lampreys. Figure 14C, Figure 14D indicates the substantial increase in the size of the photoreceptors that occurs during the intervening marine phase.

The distribution of immunoreactivity for amino acid neurotransmitters and calcium-binding proteins in the retina of *G. australis* has recently been examined by Nivison-Smith et al (80), and shown to be generally similar to that found in jawed vertebrates. Experiments with the small organic cation agmatine were consistent with cation entry into photoreceptors and horizontal cells, again broadly similar to that seen in the jawed vertebrate retina.

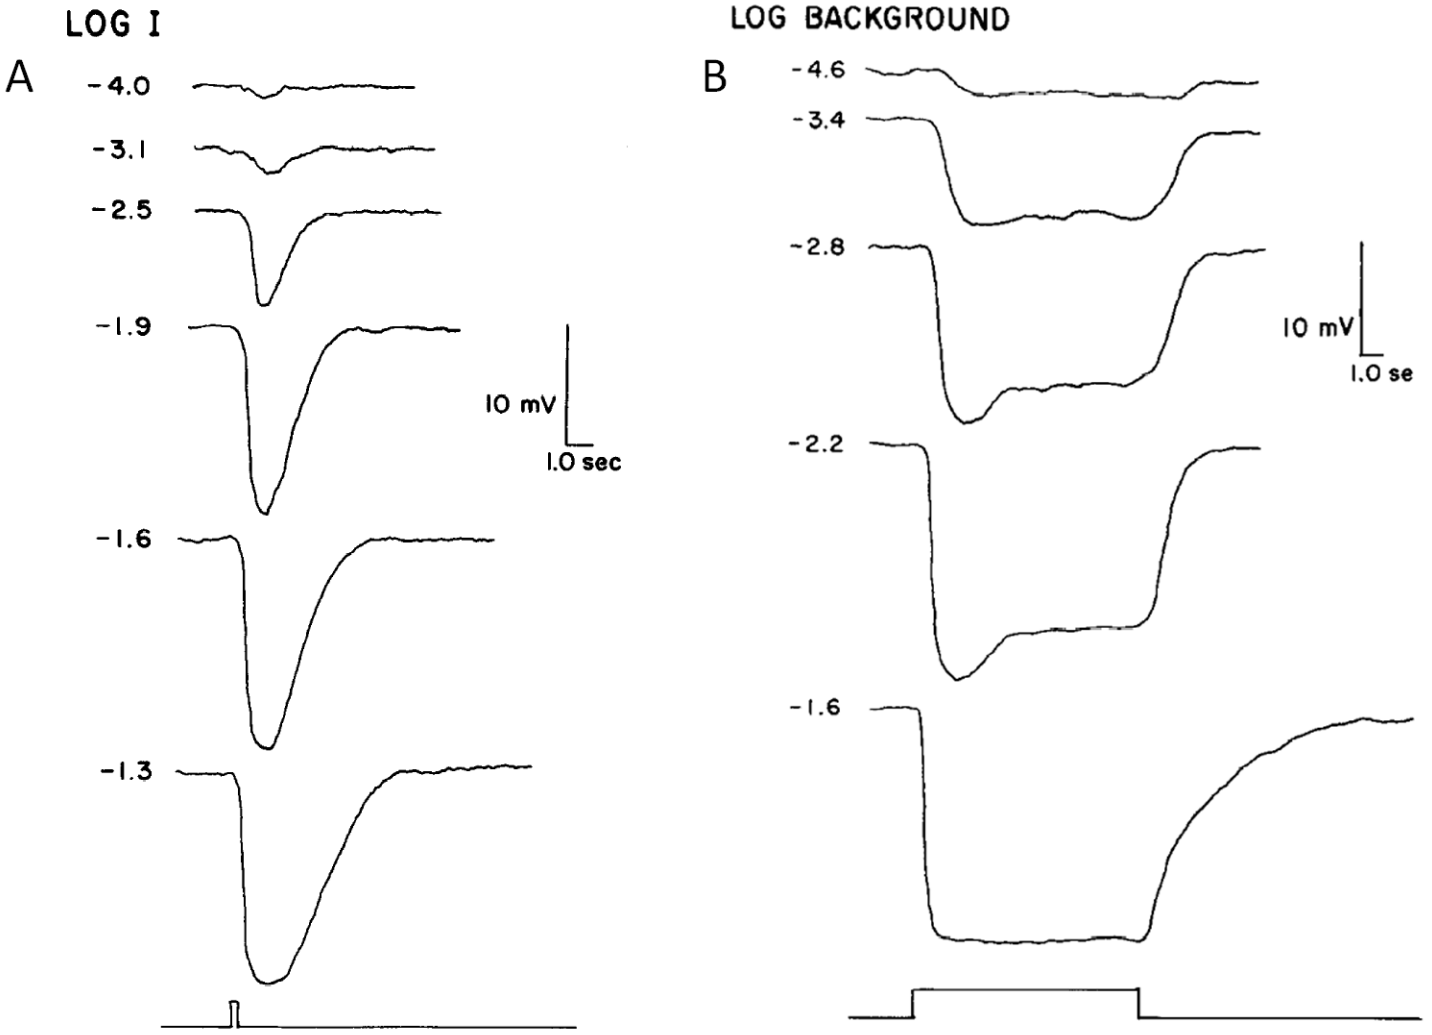

Figure 11. Intracellular light responses of pineal photoreceptors. Intracellular voltage responses of a dark-adapted pineal photoreceptor from a *Petromyzon marinus* ammocoete. Exposures of progressively higher intensity were presented as 200 ms flashes (A) or as steps of 9 s duration (B); white light. Numbers to the left of the traces give the log10 intensity, relative to the unattenuated intensity, which corresponded to ~10^{13} photons cm^{-2} s^{-1} measured at 540 nm. From Pu & Dowling (66).

Classes of opsin and photoreceptor. Lamprey opsins fall into five classes, that appear to be homologous (or nearly so) to those of jawed vertebrates; thus, the southern hemisphere lamprey *Geotria australis* clearly possesses LWS, SWS1 and SWS2 opsins, and its remaining two opsins, RhA and RhB, may well be members of the Rh1 and Rh2 families, respectively (81, 82). Furthermore, this species possesses five distinct classes of photoreceptor (83). Although the distribution of expression of opsin classes amongst photoreceptor classes has not yet been determined definitively, circumstantial evidence suggests the distribution indicated in Figure 15B (Shaun P Collin, personal communication). In contrast to the case in *G. australis,* other species of lamprey have lost varying numbers of classes of opsin and photoreceptor; thus, another southern hemisphere species *Mordacia mordax* has only a single class of opsin and a single class of photoreceptor, while northern hemisphere species generally have two classes of opsin (Rh1 and LWS) and two classes of photoreceptor.

Photoreceptor morphology. In northern hemisphere lampreys, these two types of photoreceptor have been termed 'long' and 'short', based on the length of their inner segments; somewhat confusingly, their outer segments are the reverse of this. Thus the 'long' cells have short (~7 μm long) conical outer segments arranged in a distal layer in close contact with the retinal pigment epithelium, whereas the 'short' cells (which outnumber the long cells

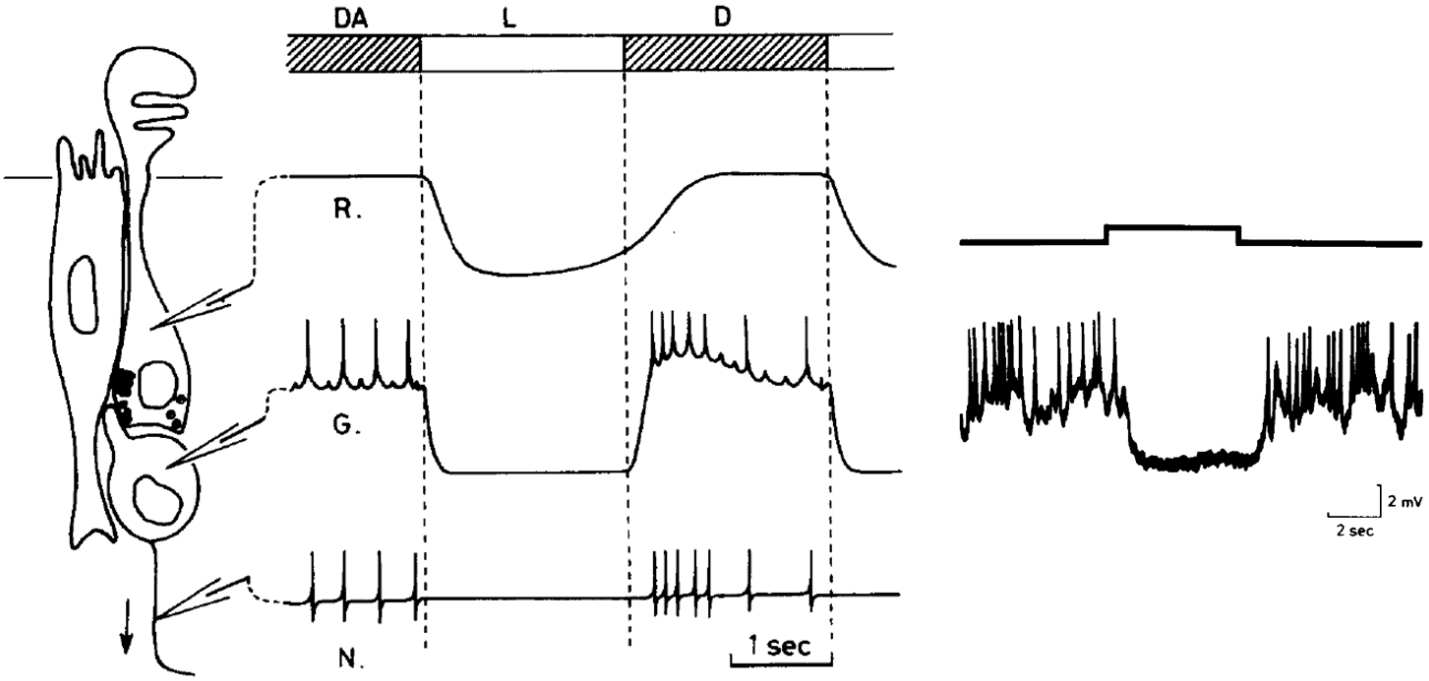

Figure 12. Light response of a pineal luminosity ganglion cell. Left, Schematic of pineal cells and recording electrodes. Middle, schematic of light responses in: R, photoreceptor (intracellular); G, ganglion cell (intracellular); N, nerve fiber (extracellular). Light monitor indicates: DA, dark-adapted; L, light; D, dark. Right, Intracellular recordings from a luminosity ganglion cell. Typical intracellular responses from photoreceptors were shown in Figure 11. From Morita et al (69).

3:1) have longer (~25 μm) cylindrical outer segments arranged in a proximal layer, and only their tips reach the RPE.

The ultrastructure of retinal photoreceptors in the lamprey *Petromyzon marinus* was examined by Dickson & Graves (84), who reported that both classes of cell (short and long) exhibited cone-like rather than rod-like morphology. Thus, in both cell types the outer segment membrane appeared to be continuous with the plasma membrane. Although small groups of sacs/discs were found to be surrounded by plasma membrane, there were frequent openings to the exterior, as illustrated in Figure 15C, Figure 15D. Autoradiography with labeled amino acids showed that newly-synthesized protein was distributed uniformly throughout the outer segment, as found in cones. In addition, the outer segments never exhibited incisures (the deep longitudinal infoldings of the surface membrane that divide the discs of the rods of jawed vertebrates into lobules). Finally, the synaptic terminals (Figure 15E) were reported to resemble cone pedicles rather than rod spherules. Thus, on all the conventional criteria that are used to distinguish cones from rods in jawed vertebrates, the short and long receptors of *P. marinus* would both be classified as cones.

Broadly comparable results were obtained in the southern hemisphere lamprey, *G. australis*, where ultrastructural examination led to the proposal that all five classes of photoreceptor are cone-like (83, 85). In each of the five classes of photoreceptor, the outer segment membrane is continuous with the extracellular matrix (Figure 15A), and the synaptic terminals contain between one and five synaptic ribbons. Furthermore, at least three of the cell classes contain a filtering pigment in the inner segment (Figure 15B).

Proteins of phototransduction. As will be described in Section 8, the distribution of isoforms of opsin, of transducin alpha, and of PDE catalytic and regulatory subunits, has been determined for *P. marinus* by Muradov et al (86, 87). The long receptors express an LWS opsin, a transducin alpha subunit GαL that may be ancestral, a common PDE6 that appears ancestral, and a PDE gamma subunit that clades with the gnathostome cone isoform. The short receptors express an Rh1 rhodopsin, a rod-like transducin alpha subunit GαS that

nevertheless retains cone-like features, the common PDE6 that appears ancestral, and a PDE gamma subunit that clades with the gnathostome rod isoform.

Lamprey genome. The first whole genome sequence and assembly for a lamprey has very recently been reported by Smith et al (88), for *P. marinus*. Analysis indicates that the '2R' two rounds of whole genome duplication that occurred near the base of the vertebrate lineage had already taken place prior to the divergence of the ancestral lamprey and gnathostome lineages (i.e. prior to 5 in Figure 1).

Electrophysiology. Govardovskii & Lychakov (89) examined the ERG response properties of the long and short photoreceptors of *Lampetra fluviatilis.* At scotopic intensities, they observed a b-wave driven by the 517 nm pigment (known to be present in the short cells), though this ERG response was not as sensitive as seen in the frog retina. At photopic intensities the a-wave was a combination of signals from the two spectral classes, and both sets of spectral response exhibited light-adaptation and could not be saturated. Thus, while both long and short cells had cone-like morphology, the short cells behaved electrophysiologically somewhat like rods, but both classes exhibited cone-like adaptation.

Did 'rods' exist in the ancestral vertebrate? As discussed above, lamprey 'rhodopsin' RhA/Rh1 is closely homologous to jawed vertebrate rhodopsin Rh1 (82, 83, 90). Pisani et al (82) have interpreted the sequence analyses to indicate that the common ancestor of lampreys and jawed vertebrates possessed an Rh1 gene. They went on to say: "The function of Rh1 in agnathans is not yet known, but assuming its function in the vertebrate cenancestor was not dramatically different from its scotopic function in most vertebrates, this implies that both photopic and scotopic vision evolved in the stem vertebrate lineage and must have been in place in the Cambrian by about 522-518 Ma". However, there is not yet sufficient evidence to go this far, because it is by no means certain that this Rh1 opsin was expressed in a 'true rod' or that the Rh1 actually mediated 'scotopic vision'. On current evidence, it is entirely possible that the ancestral Rh1-containing photoreceptor functioned simply as a 'slow sensitive cone', rather than as a true rod capable of reliably detecting individual photons, as is required in order for the visual system to attain the ultimate in scotopic performance, of the kind that is attained in jawed vertebrates. All that can be said for certain from this evidence is that the common ancestor of jawed and jawless vertebrates is highly likely to have had a rod-like opsin; but this is not at all sufficient to deduce that it had scotopic vision.

Summary of lamprey photoreceptor features. In northern hemisphere lamprey species that have long and short photoreceptors, the long cells have all the features of cones in jawed vertebrates. The short cells have most of the features of cones, though they express rhodopsin as well as a somewhat rod-like transducin alpha subunit and a rod-like PDE regulatory subunit; other components of phototransduction are yet to be classified. The short cells have high sensitivity, though as yet there is no evidence that they can reliably signal individual photon hits. In southern hemisphere lampreys, there are five classes of photoreceptor that all appear to have most of the features of cones. One of these expresses rhodopsin, but as yet there is insufficient evidence to say whether it has rod-like functional properties.

Jawed vertebrate lateral eye

The eyes of all jawed vertebrates are remarkably similar, in terms of overall layout and features. The retina has the same set of cell classes, and is organized in fundamentally the same way. Furthermore, the cone photoreceptors of all gnathostomes (and likewise the rods) are closely similar in structure, apart from size differences, and their electrical responses to light are also closely comparable. In view of the period of over 400 million years that has elapsed since the emergence of the first jawed vertebrates, it is impressive how little change has occurred in the basic plan of the eye and in the structure and response properties of the photoreceptors.

The structure and responses of cone and rod photoreceptors, as well as the process of phototransduction, in jawed vertebrates are dealt with comprehensively elsewhere (see other sections of Webvision; Ebrey and Koutalos

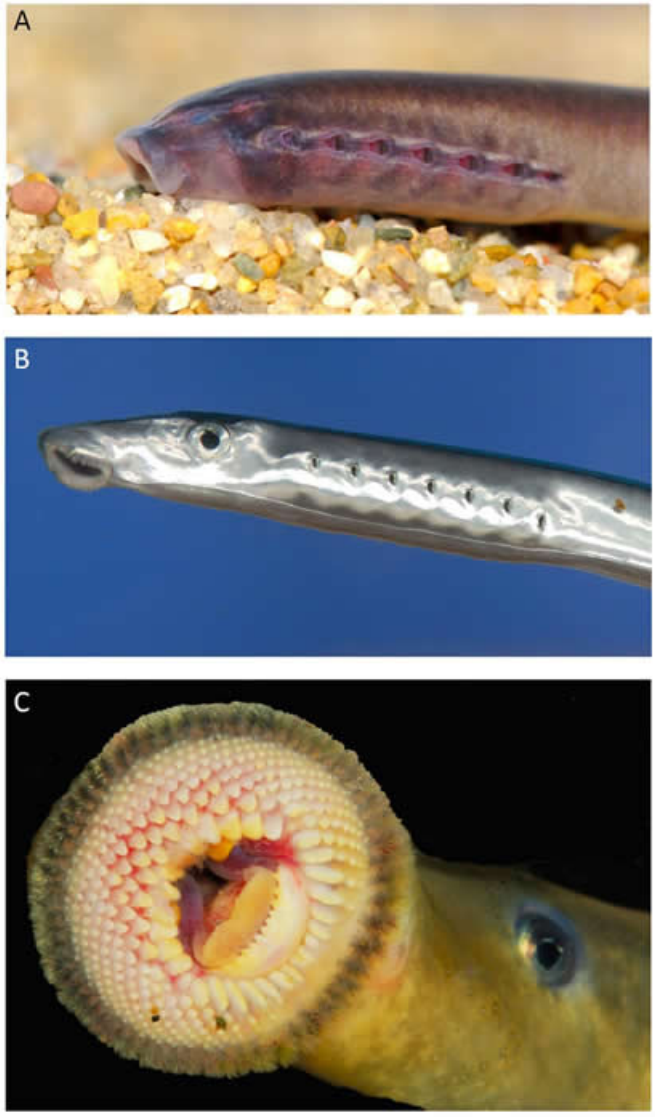

Figure 13. Lamprey (*Geotria australis*) and its lateral eyes. A, Ammocoete. The ammocoete's rudimentary 'eyes' cannot be seen as they are embedded beneath the skin. B, Downstream migrant. C, Upstream migrant. All images courtesy of Shaun P Collin.

(91); etc.), and will not be repeated here. For completeness, though, Figure 16 illustrates the main ultrastructural features of mammalian photoreceptors, for comparison with those of other chordates. The functional properties of cones and rods will be contrasted in Section 7 and the molecular components of the transduction cascade will be reviewed in Section 8.

4. Gradations in chordate eyes: retina and photoreceptors

From the descriptions in Section 3, one can discern gradations in types of retina and types of ciliary photoreceptor, that will now be described. Likewise, one finds gradations in the properties of the opsins (C-opsins), and these will be covered in Section 6.

Categories of chordate retina

The light-sensitive neural tissue in extant chordates can be classified into three groups:

a. *No 'retina'*. The 'primitive' chordates (cephalochordates and tunicates) do not have a retina, in the sense that the term is generally used, but rather a handful of ciliary photoreceptors associated with a pigment

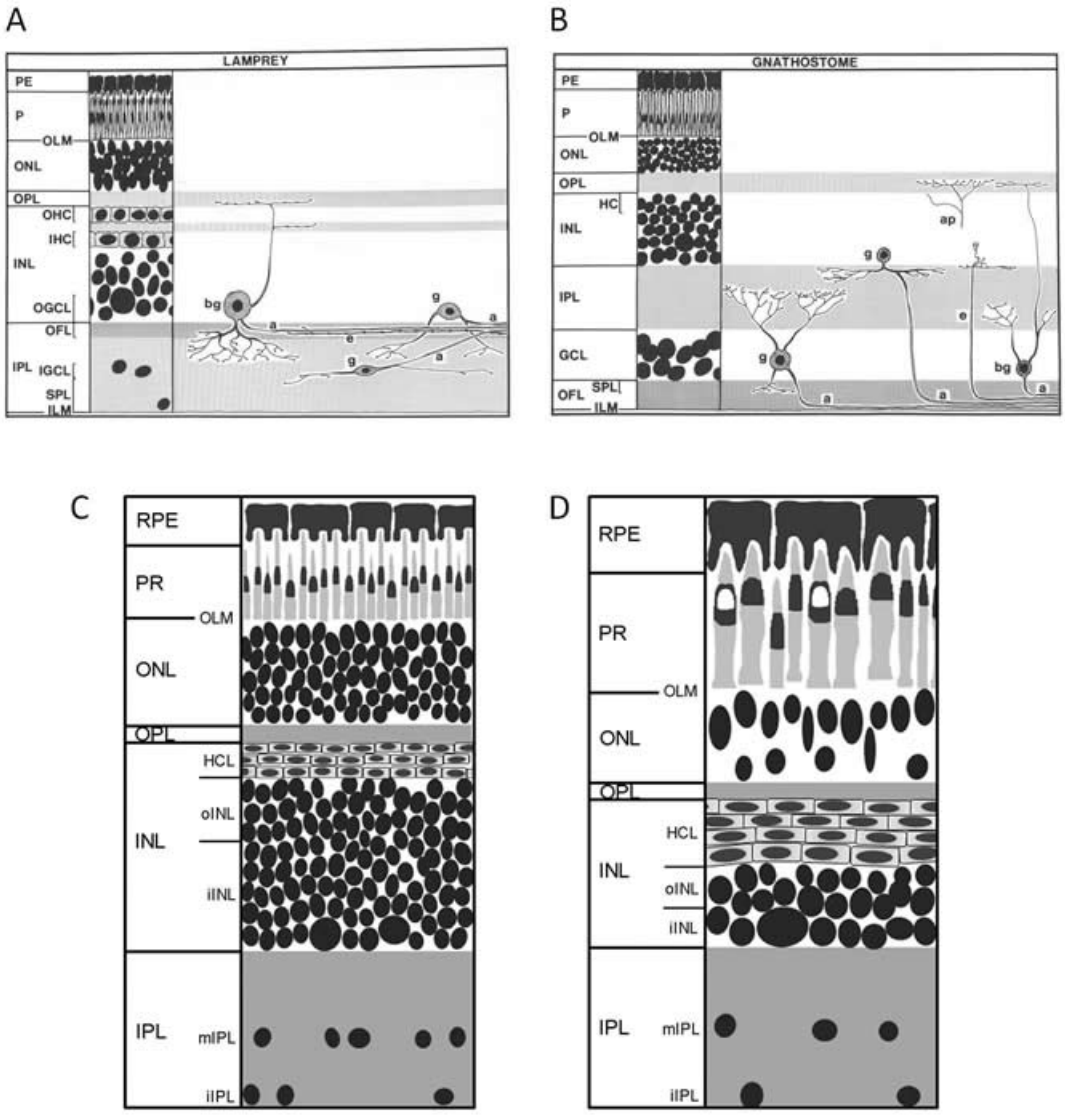

Figure 14. Comparison of lamprey and gnathostome retinas. Schematics of the organization of the retina of the lamprey lateral eye. A, Silver lamprey *(Ichthyomyzon unicuspis*, post-metamorphic juveniles). B, Gnathostome. The main difference is that in the lamprey the inner plexiform layer is vitreal to the majority of ganglion cells, so that most of the ganglion cells are located in the inner nuclear layer. C, D, Southern hemisphere lamprey, *Geotria australis*: in two of the animal's adult forms: (C) downstream migrant phase (post-metamorphic juvenile), and (D) upstream migrant phase (ready to spawn). The retina of the downstream migrant is densely packed with cells, lying ~10 layers deep in the INL (including at least two layers of horizontal cells); the retina of the upstream migrant is much larger, and is dominated by large photoreceptors and reduced layering of cells in the INL. Abbreviations in upper case are standard, with the addition of: IGCL, OGCL, inner and outer ganglion cell layers; IHC, OHC, inner and outer horizontal cells; OFL, optic fiber layer; SPL, superficial plexiform layer. a, axon; ap, ascending process of unknown origin; bg, biplexiform ganglion cell; e, efferent fiber; g, ganglion cell. A, B, from Fritzsch & Collin (75). C, D from Nivison-Smith et al (80).

cell, in the frontal eye and in the ocellus, respectively. In the tunicate ocellus, the ciliary photoreceptors each give rise to an axon, but its synaptic contacts have not been determined. In the cephalochordate frontal eye, it appears that the output axons arise from a second row of cells rather than from the ciliary photoreceptors themselves.

b. *Two-layered retina.* The hagfish lateral 'eye' and the dorsal light-sensitive organs of non-mammalian jawed vertebrates (pineal / parapineal / parietal) exhibit a two-layered retina, with ciliary photoreceptors making ribbon synapse contacts onto projection neurons (ganglion cells). The photoreceptors and projection neurons are embedded amongst glial cells, but no other classes of neuron have been identified (though their existence cannot be ruled out).

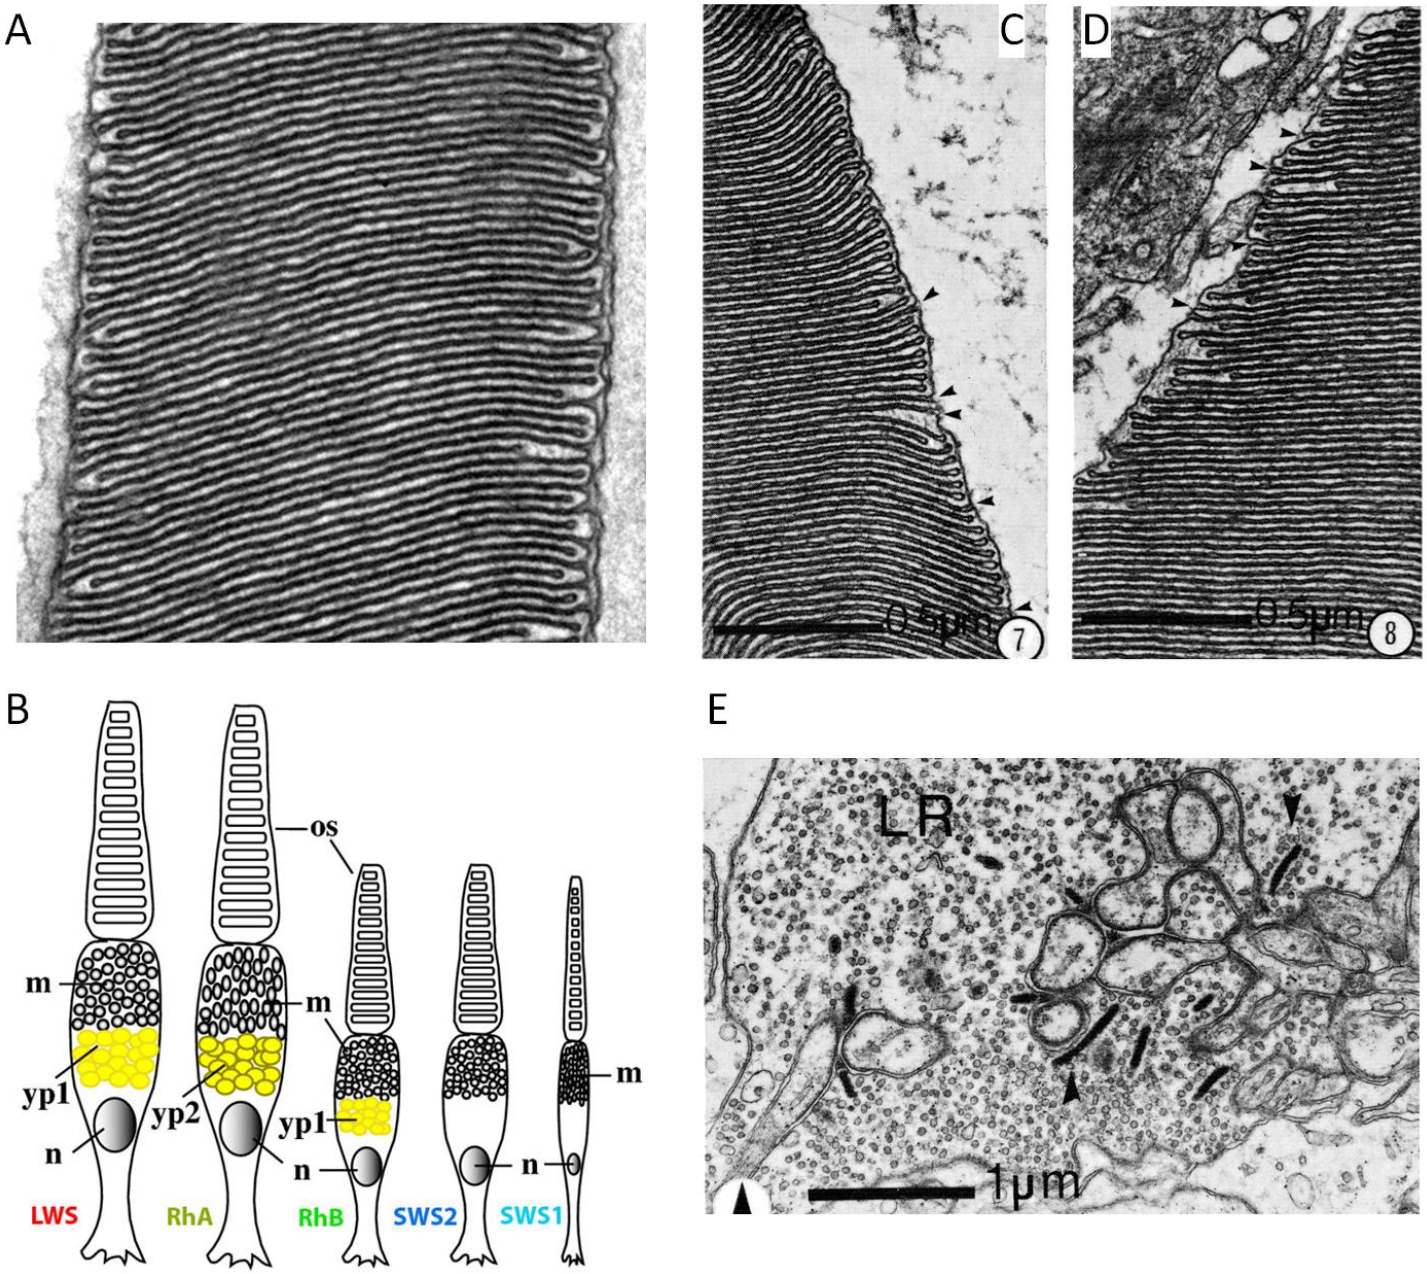

Figure 15. Lamprey retinal photoreceptors. Photoreceptors of *Geotria australis*, a southern hemisphere species (A, B), and of *Petromyzon marinus*, a northern hemisphere species (C, D, E). A, Outer segment, showing ordered stacking of sac-like membranes. From Collin & Trezise (85). B, Schematic of *G. australis* photoreceptors, showing the five distinct morphologies, and making a tentative assignment of the five classes of opsins (based on personal communication from Shaun P Collin). Abbreviations: m, mitochondria; n, nucleus; os, outer segment; yp1, yp2, yellow pigments 1 and 2. Modified from Collin (10). C, D: Outer segment ultrastructure, for long (C) and short (D) photoreceptors of *P. marinus*. E, Synaptic ribbons in the synaptic terminal of long photoreceptor (LR). C, D and E from Dickson & Collard (84).

c. *Three-layered retina.* The lateral eyes of lampreys and jawed vertebrates exhibit a three-layered retina, with bipolar cells interposed between ciliary photoreceptors and retinal ganglion cells, and with two additional classes of neuron in the form of horizontal cells and amacrine cells.

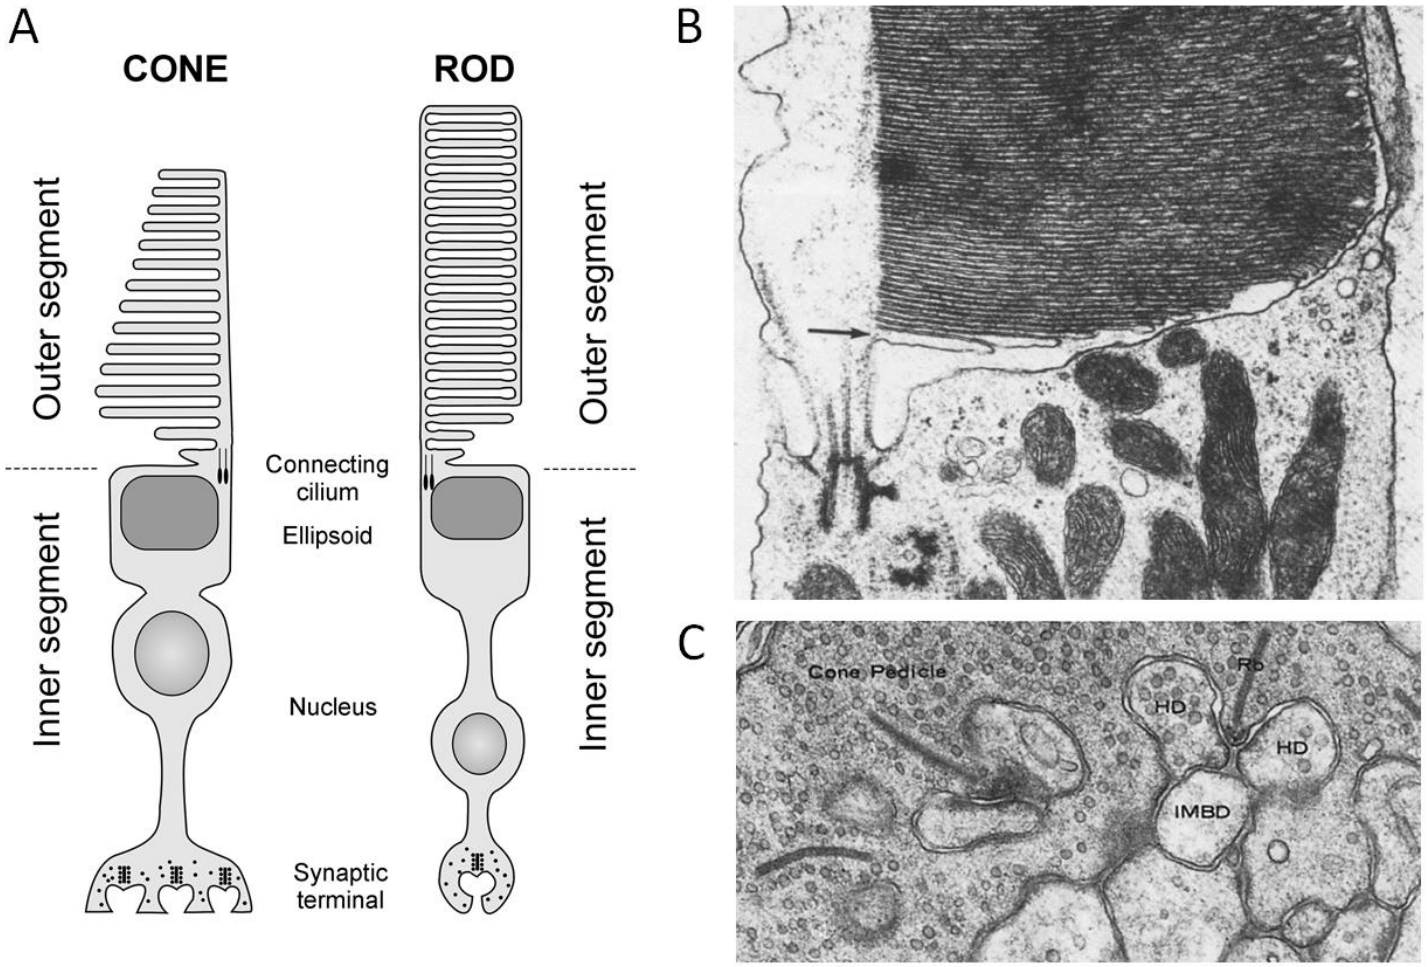

Figure 16. Jawed vertebrate retinal photoreceptors. A, Schematic of jawed vertebrate cone and rod photoreceptors. From Burns & Lamb (268). B, Outer segment, connecting cilium, and distal inner segment of a rhesus monkey cone. From Steinberg et al (129). C, Synaptic ribbons in the synaptic pedicle of a macaque cone. From Raviola & Gilula (269).

Gradations in morphological types of chordate ciliary photoreceptor

On morphological grounds, the ciliary photoreceptor cells of the chordate retinas described in Section 3 can be described as indicated schematically in Figure 17. In all cases, the light-sensitive outer segment is formed by a massive expansion of membrane surface, in the form of lamellae arising from a cilium that is characterized by 9+0 double filaments. This outer segment membrane is packed with a high concentration of visual pigment, together with lower levels of other proteins of phototransduction. The cell body is in most cases roughly cylindrical in shape, both above and below the nucleus. Synaptic output occurs at the end of the cell opposite the outer segment (i.e. at the 'base'), which is sometimes separated from the soma by an intervening 'axonal' segment. These features permit classification into at least five groups, as follows:

i. *Ascidian-style.* The outer segment lamellae are arranged rather like petals, lying roughly longitudinally around the centrally positioned connecting cilium. An axon leaves the base of the cell, but its synaptic contacts are not known.
ii. *Hagfish-style.* The outer segment lamellae are splayed out to either side of the connecting cilium, which lies centrally. Synaptic output occurs at a basal invagination, where synaptic vesicles are arranged around a 'spherical body' rather than a ribbon.

iii. *Pineal-style.* The outer segment lamellae are very broad, and often lie in a curve. It is generally reported that the lamellae constitute cone-like sacs rather than rod-like discs. The basal invaginating synapse exhibits synaptic ribbons, and makes a dyad (or sometimes monad) contact with ganglion cells.
iv. *Cones.* The outer segment lamellae (sacs) are arranged highly regularly, and their membranes form a continuum with the plasma membrane of the inner segment. In mammals the outer segment is roughly cylindrical in shape, though in non-mammalian vertebrates it tends to be conical. The inner segment can contain a variety of specializations, including the ellipsoid (with mitochondria, and sometimes spectrally-filtering oil droplet or vesicles), the contractile myoid, and the paraboloid.
v. *Rods.* Morphologically, rods are very similar to cones, though a significant exception relates to the topology of the outer segment membrane. During outer segment synthesis, cone-like sacs are generated, but these proceed to form a seal around the rim with neighboring sacs, to form discs separated from the plasma membrane, with the result that the narrow intradiscal space is isolated from the extracellular space.

Gradations provide evidence for gradual transitions during eye evolution. The gradations in type of retina and type of photoreceptor listed above provide powerful evidence that the vertebrate eye did not 'suddenly appear', and instead support the view that the evolution of our eye proceeded via myriad tiny changes. This conclusion, based (up until here) primarily on the morphology of ciliary photoreceptors, is greatly strengthened by evidence from analysis of gradations in opsins (Section 5 and Section 6), from analysis of the molecular genetics of the transduction cascade (Section 8), and from studies of embryonic eye development (Section 13 and Section 14).

5. Pre-vertebrate chordate C-opsins

As a result of recent work, it has become possible to track the changes that enabled an ancestral chordate C-opsin (that exhibited many properties in common with R-opsins) to evolve into the immediate pre-cursor of modern cone and rod opsins.

Thermal stability and photoreversal

Two ways in which cone and rod C-opsins differ substantially from their R-opsin cousins (including melanopsin) relate to the thermal stability of the photo-activated all-*trans* 'metarhodopsin' state and its ability to undergo photoreversal (Figure 18).

In R-opsins, the photo-activated metarhodopsin is thermally stable (Figure 18 right), with a half-life usually of hours or even days. This active form is rapidly inactivated by the binding of an arrestin molecule, but it remains stably in its all-*trans* configuration. In most cases this metarhodopsin has its peak absorption in the visible region of the spectrum, indicating that, in its enzymatically active configuration, the Schiff base bond of the all-*trans* retinaldehyde remains protonated. Furthermore, upon absorption of a further photon, this stable all-*trans* metarhodopsin (even when arrestin-bound) can undergo photoreversal back to its 11-*cis* rhodopsin form. Indeed, for most practical purposes this photoreversal is the only short-term mechanism available for the regeneration of visual pigment in many microvillar (rhabdomeric) photoreceptors.

In contrast, the photo-activated metarhodopsin II state of cone and rod opsins is thermally unstable (Figure 18, left), decaying with a half-life that is short (seconds) in cone opsins and somewhat longer (minutes) in rhodopsin (for values, see Table 2 of Imai et al (92)). Fast inactivation occurs as a result of arrestin binding, enabled by rapid phosphorylation. The active meta II absorbs in the UV (~380 nm), because the Schiff base is now un-protonated. Although the protonated meta I intermediate can undergo photoreversal to the 11-cis configuration, the active meta II state is incapable of undergoing such photoreversal, even if it absorbs a blue/UV photon (see Figure 7 of Ritter et al (93)), and this inability is apparently a consequence of an internal molecular rearrangement that accompanies activation.

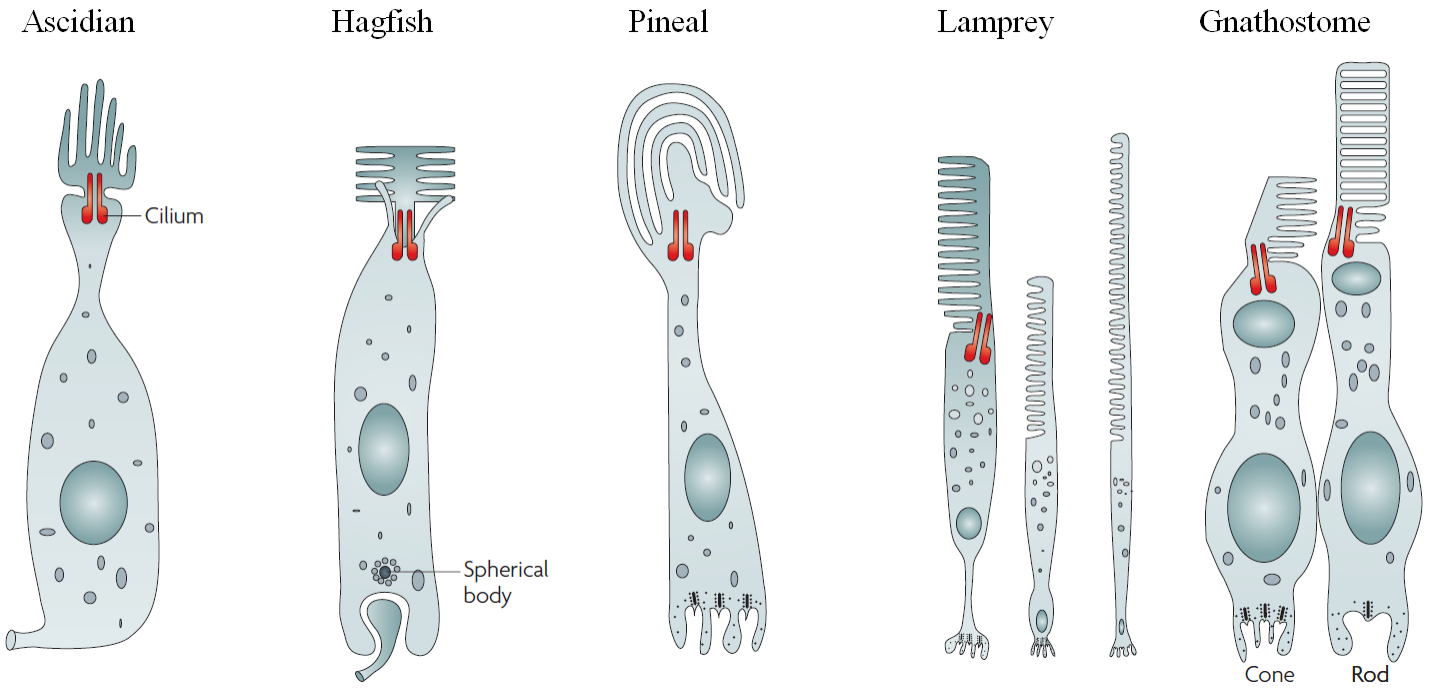

Figure 17. Schematic of transitions in ciliary photoreceptor morphology across chordates Schematic morphology of the ciliary photoreceptors of extant chordate species provides suggestive evidence of the remnants of a gradual transition in the morphology of ciliary photoreceptors during chordate evolution. Note the transitions, from left to right, towards (1) a highly organized laminar structure in the outer segment, and (2) the appearance of ribbons in the synaptic terminal. From Lamb et al (3).

Phylogeny, and gradation in properties, of chordate C-opsins

The C-opsins comprise a large family, with representatives in cnidaria and protostomes, as well as in deuterostomes (including chordates and vertebrates). Apart from the well-known retinal cone and rod opsins, vertebrates also express several additional categories of C-opsin, including: Opn3 (encephalopsin / TMT opsin), parietopsin, parapinopsin, VA (vertebrate ancient), and pinopsin. From their molecular phylogeny, as well as from the gradation (now to be described) in functional properties of the five groups that have been investigated, these C-opsins reflect an evolutionary sequence preceding the advent of the cone and rod opsins.

Figure 19 presents a shortened molecular phylogeny of opsins, together with a tabulation of the amino acid residues at a number of important locations (94). In the cladogram on the left, note that the lengths of the lines do not indicate evolutionary distance, and so the horizontal positions of the branch points do not represent timings of divergences. And in the tabulation on the right (as well as throughout this article), note that residues are numbered in accordance with the bovine rhodopsin sequence.

As indicated by the phylogeny in Figure 19, vertebrate C-opsins fall into the sequence (from most ancient to most recent) of: Opn3 (encephalopsin), parietopsin, parapinopsin, VA opsin, pinopsin, cone opsins, rhodopsin. For each of these C-opsins, the functional molecular properties are briefly described below and summarized in Item B; much of this information has come from recent studies of recombinant proteins.

In evaluating the relative properties of these C-opsins, comparison will be made with a 'typical' R-opsin, exhibiting photoreversible transitions between two stable states. As indicated above, vertebrate cone and rod opsins do not exhibit photoreversal, and instead release their all-*trans* retinoid. On the other hand they exhibit stronger activation of the G-protein. We will now see that the other vertebrate C-opsins exhibit properties intermediate between these.

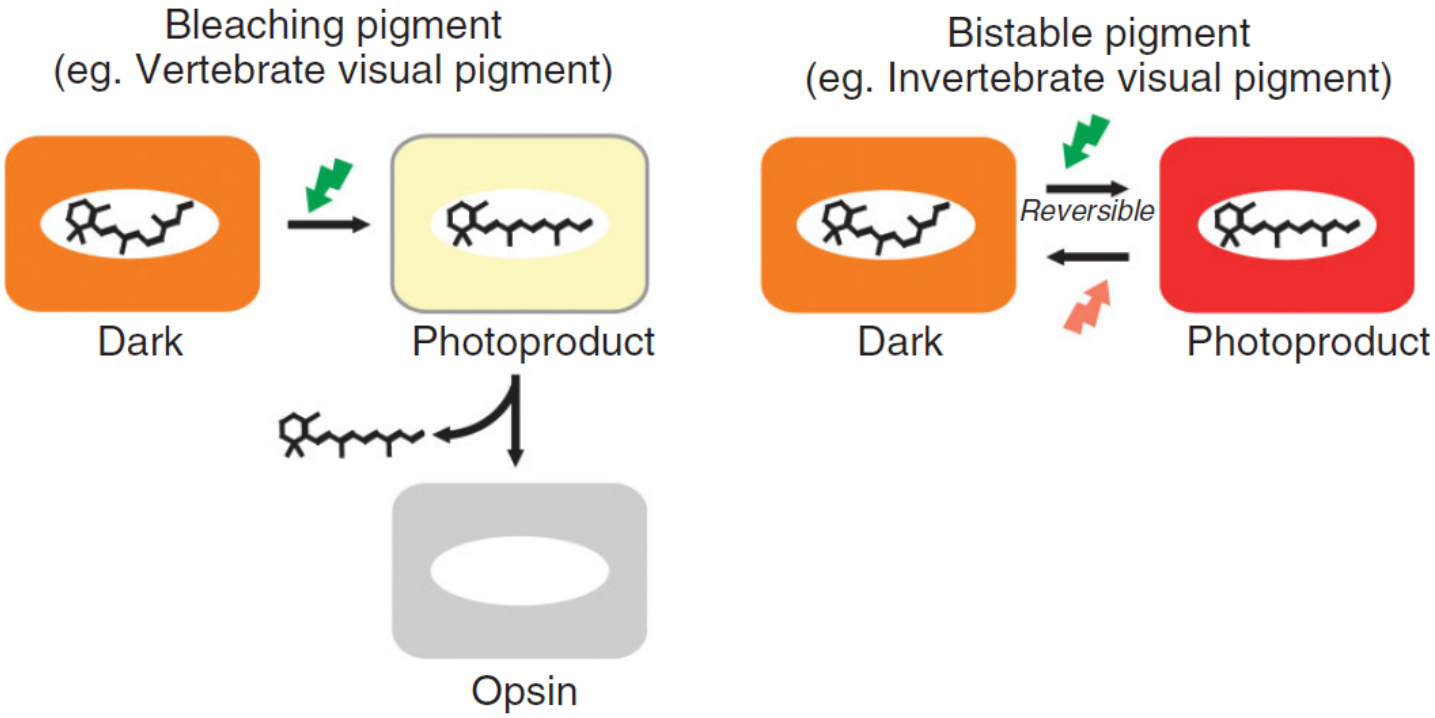

Figure 18. Thermally unstable pigment contrasted with bistable/photoreversible pigment Left: Cone pigments and rhodopsin are thermally unstable upon activation. The metarhodopsin photoproduct absorbs in the UV, so that it is colorless to human vision and hence the pigment is said to 'bleach' in the light. This metarhodopsin decays fairly rapidly, releasing all-trans retinal; cone metarhodopsin II decays in a matter of seconds, and rod metarhodopsin decays in minutes. Right: R-opsins and many C-opsins (other than vertebrate visual opsins) are bistable. The activated all-*trans* metarhodopsin is photoreversible; it absorbs in the visible part of the spectrum, and upon absorption of a photon is isomerized back to the 11-*cis* isomer. From Terakita et al (103).

Opn3. The Opn3 group of opsins includes mammalian Opn3 (formerly called encephalopsin or panopsin), TMT (teleost multiple tissue) opsin, insect pteropsin, and annelid C-opsin. This group clades near the base of C-opsins, and the sequences quite closely resemble those of R-opsins. For most members of the group, the two potential sites (113 and 181) for the counterion to the protonated Schiff base have the R-opsin form, Y113 and E181, indicating that E181 serves as the counterion; however, in mammals Opn3 has D113. Mammalian Opn3 is expressed in scattered cells in deep brain areas.

The molecular properties of Opn3 opsins have only very recently been studied (95), by expression in cultured cells. Pufferfish TMT opsin was shown to bind 11-cis retinal, to form a visual pigment absorbing in the blue (~460 nm); this pigment was bistable, being isomerized to a slightly red-shifted all-*trans* form by short-wavelength light, and isomerized back to the 11-*cis* form by long-wavelength light. The light- activated form could activate Gi and Go, though with only ~10% of the efficacy of activated rhodopsin, but it did not activate Gq, Gs or Gt (transducin). Similar results were found for a mosquito Opn3 homolog, though its activity was higher. Although mammalian Opn3 itself has not yet been successfully expressed in cultured cells, Koyanagi et al (95) suggest that it is likely to exhibit similar properties.

Parietopsin. Parietopsin was first identified in photoreceptors in the parietal eye of the lizard. Its functional properties have recently been explored by Sakai et al (96), who showed that the Schiff base counterion is located in the 'invertebrate' position of 181, consistent with the residues Q113 and E181. The expressed pigment had its absorption peak at 520 nm, and its photosensitivity and molar extinction coefficients were marginally lower than those of cone and rod opsins, as is often characteristic of invertebrate visual opsins. On the other hand, its photochemical properties resembled those of cone and rod pigments, with the formation of decaying metarhodopsin intermediates (I, II and III), rather than the typical invertebrate photoreversible metarhodopsin.

Parapinopsin. Parapinopsin was first identified in the catfish parapineal organ. It was subsequently identified in the lamprey pineal, where it was shown to be a UV-sensitive bistable opsin (97). Koyanagi et al (71) found parapinopsin to be expressed in the ciliary photoreceptors only on the distal side of the lamprey pineal and parapineal organs, and they examined its functional properties. They discovered that illumination of parapinopsin caused the conventional 11-*cis* to all-*trans* isomerization of the chromophore, to yield a product with a spectral peak at 515 nm. However, in contrast to the case for UV-sensitive (SWS1) cone opsins, this metarhodopsin was found to be stable, and to exhibit photoreversal upon absorption of a subsequent photon; indeed it was possible to repeatedly interconvert between parapinopsin and its meta state by illumination successively with UV and then orange light. Intracellular electrical recordings from pineal photoreceptors expressing parapinopsin showed that flashes of UV light elicited slow hyperpolarizing responses, consistent with a phototransduction cascade of the vertebrate style. The efficacy of activation of G-protein by activated parapinopsin was shown to be around 20-fold lower than that by activated rhodopsin (97).

VA/VAL opsin. VA opsin was first identified in salmon retina, and then soon after in other teleost retinas, where a longer splice variant (VAL) was also found, and then in other vertebrates. The functional properties of VAL opsin have recently been investigated by Sato et al (98). Like vertebrate visual opsins, VA/VAL has E113 at the usual site for the counterion to the resting state but, uniquely, the site of the ancestral counterion location is S181. Sato et al (98) found that light activation caused *cis* to *trans* isomerization, but that the activated intermediate absorbed in the visible region, at 455 nm, indicating that the Schiff base remained protonated. Although this intermediate absorbed visible light, it did not exhibit photoreversal (as for vertebrate visual opsins). This intermediate could activate the Gi G-protein, though with an efficacy around 5-fold lower than that of activated rhodopsin. Hence, they showed that several of the properties of VA/VAL opsin are intermediate between those of parapinopsin and pinopsin (see below).

Pinopsin. Pinopsin was first cloned from the chicken pineal, and was found to clade with the LWS cone opsin near the base of the phylogenetic tree of vertebrate visual opsins (99). However, there is no clear evidence as to exactly where or how it diverged from visual opsins, and there is a distinct possibility that it could be ancestral. Its functional properties were examined by Nakamura et al (100), and found to be closely similar to those of vertebrate visual opsins. The resting dark form absorbed at 465 nm, in the blue region of the spectrum, similar to the absorption of the SWS cone opsins (e.g. SWS2, Rh2). Light absorption triggered its progression through a sequence of photoproducts (batho, lumi, meta I, meta II, meta III) analogous to those triggered by activation of rhodopsin. The lifetimes of these intermediates were comparable to those of cone opsins, except for the meta II state, which exhibited a longer lifetime more typical of rhodopsin.

Improvements in the performance of C-opsins during chordate evolution

By comparing the sequences, structures, and functional properties of chordate C-opsins, Akihisa Terakita and Yoshinori Shichida and their colleagues have elucidated a set of transitions that occurred during evolution, that endowed chordate C-opsins with improved performance (reviewed by Tsutsui & Shichida (101); Tsukamoto & Terakita (102); Terakita et al (103)). These changes included the translocation of the counterion site (for the protonated Schiff base) from residue 181 to residue 113, as well as molecular rearrangements of the protein that provided enhanced tilt of helix 6 during activation, and hence led to much stronger activation of the G- protein.

Counterion relocation. To provide stability for the positive charge on the protonated Schiff base in the resting opsin, there is a requirement for a nearby negatively charged counterion. In most opsins (including R- opsins, Go-opsins, RGR-opsins, and photoisomerases) this counterion is located at position 181 (in bovine rhodopsin numbering) which is occupied by glutamate, E181, whereas in cone and rod opsins the counterion is located at position 113, occupied by glutamate E113. Terakita et al (97) found clear evidence that the E181 location represented the ancestral position, and showed that during the evolution of chordate C-opsins the counterion site had migrated to position 113 (Figure 20).

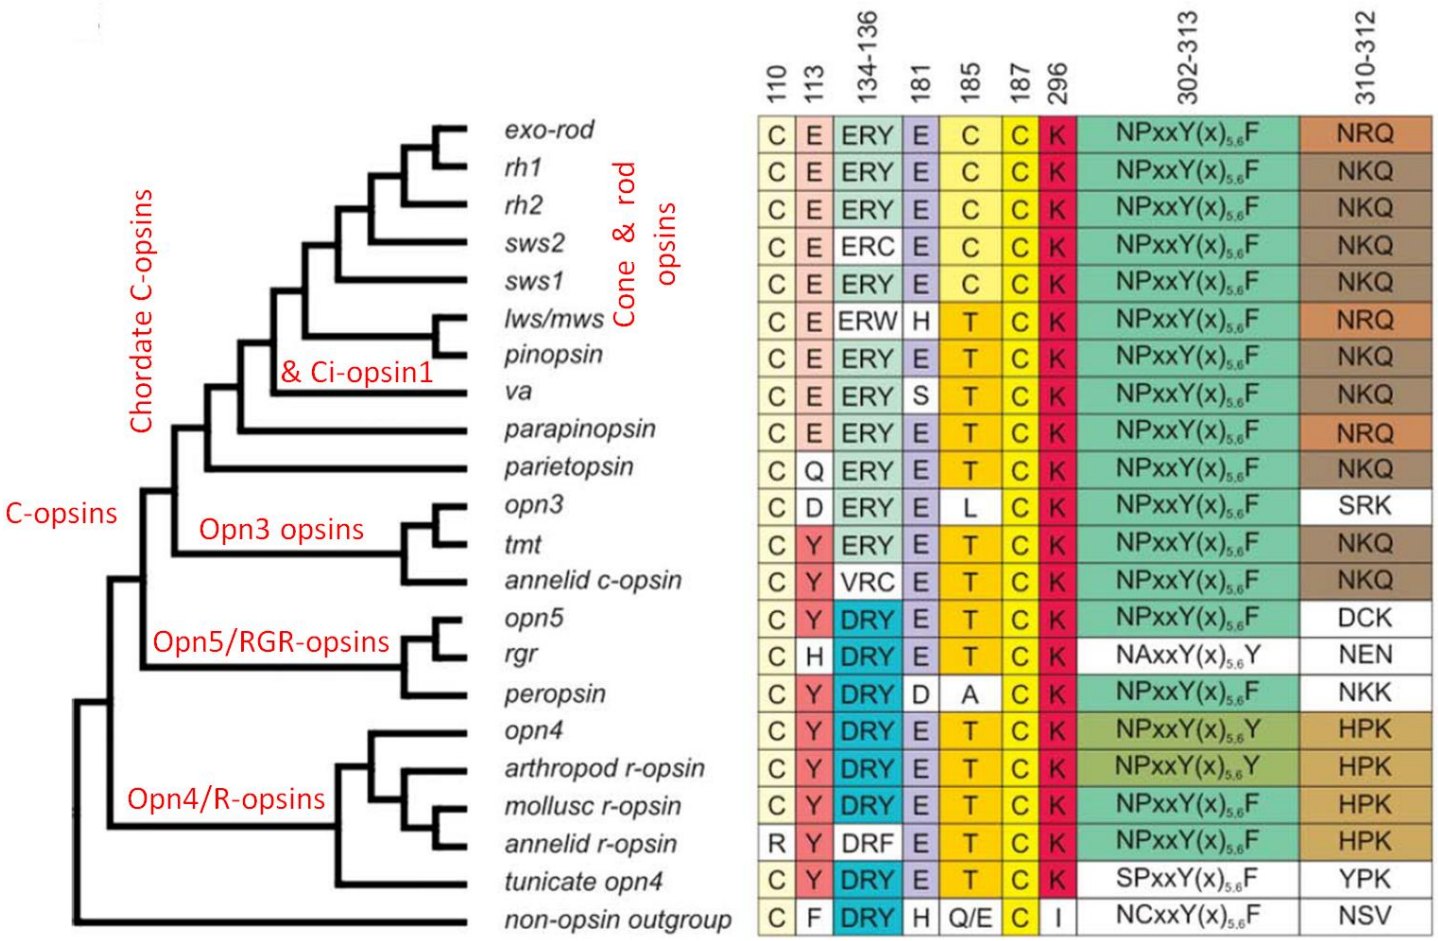

Figure 19. Abbreviated phylogeny of opsins, together with residues of interest Left: Phylogeny of a subset of opsins, comprising vertebrate C-opsins together with a selection of other opsins of interest. Note that the lengths of the lines do not indicate evolutionary distance, and so the horizontal positions of the branch points do not represent the timings of divergences. The C-opsin from *Ciona intestinalis* (Ci-Opsin1) is not included in this diagram, but its position in the tree is close to that of VA/VAL. Right: Residues at several locations that are known to be important for a variety of functions. Here and throughout the article, residue numbering is in accordance with bovine rhodopsin. From Davies et al (94).

Counterion functions. In addition to its role in stabilizing the protonated Schiff base in the resting state, the E113 counterion in cone and rod opsins has a number of other important functions (reviewed by Tsutsui & Shichida, (101)). Perhaps most importantly, it acts as an acceptor for the proton from the Schiff base during activation (see description of molecular mechanism below). Very recently it has been shown that it has two additional crucial functions, in enabling the rapid hydrolysis of the Schiff base bond after light absorption (which is important in cones) and likewise in enabling the rapid binding of 11-*cis* retinal (104)); these roles will be described below, and a comparison between cone and rod opsins will be made in Section 6. The counterion also exerts a powerful effect on the spectral tuning of the resting opsin state. Finally, it is also important in reducing the constitutive activity of the resting opsin; mutants that lack the E113 counterion typically exhibit substantial rates of G-protein activation in darkness. Thus, the acquisition of this alternative location for the counterion has proved enormously important in the evolution of vertebrate retinal opsins.

Increased efficacy of G-protein activation. It has been found (Item B) that the light-activated forms of cone and rod opsins exhibit much greater efficacy of activation of the G-protein than do the active forms of R-opsins, and furthermore that there is a gradation in this property amongst chordate C-opsins. Tsukamoto et al (105) used site-directed fluorescence labeling to examine the changes in the protein that occurred during light activation,

Table 2. Properties of chordate C-opsins

	113	181	λ_{max} (nm) Dark	λ_{max} (nm) Meta	Rev.	ε	G	Effic.	Reference
Cone/rod	E	E	vis.	~380	N	40.6	Gt	[1]	
Pinopsin	E	E	465	385	N		Gt		Nakamura et al (1999)
VA opsin	E	S	501	455	N		Gt	0.2	Sato et al (2011)
Parapinopsin	E	E	370	515	Y		Gt	0.05	Terakita et al (2004) Koyanagi et al (2004)
Parietopsin	Q	E	520	~380	N	31.7	Gt		Sakai et al (2012)
Opn3 opsins	D/Y	E	~460	~470	Y		Gi/Go	~0.1	Koyanagi et al (2013)
Box jellyfish C-opsin	A	E	500	455	N		Gs		Koyanagi et al (2008)
R-opsins	Y/F	E	vis.	vis.	Y	27-35	Gq	0.02	

Item B: For each of the chordate C-opsins, the columns give the following information, where known: 113, 181: Identity of amino acid residue at the two potential counterion sites. λ_{max} Dark: Wavelength of peak absorbance of the 11-*cis* configuration, 'rhodopsin'. λ_{max} Meta: Wavelength of peak absorbance of the all-*trans* configuration, 'metarhodopsin'. Rev: Photoreversal (Y or N). ε: Absorption coefficient of 'rhodopsin' at its peak wavelength (in units of 103 M^{-1} cm^{-1}). G: The class of G-protein that is preferentially activated. Effic.: Efficacy of G-protein activation, relative to efficacy of activated bovine rhodopsin.

and they found a strong correlation between the degree of movement of helix 6 relative to helix 5 during activation and the strength of the opsin's ability to activate the G-protein.

Pre-vertebrate duplication of the ancestral cone opsin. The 'improved' C-opsin that had emerged during chordate evolution, with a high efficacy of G-protein activation and with rapid release of all-*trans* retinal, became the ancestral cone opsin. Furthermore, there is strong evidence that, prior to the '2R' whole genome duplications at the base of the vertebrate lineage, this ancestral cone opsin had already duplicated into the ancestral pair of SWS and LWS cone opsins. However, it is more convenient to consider that evidence later, in Section 6 on vertebrate visual opsins.

Molecular mechanism of activation in vertebrate rhodopsin

The mechanism underlying activation of the metarhodopsin state in bovine rhodopsin is now understood at a molecular level, based to a large extent on examination of the crystal structure of the activated form (106, 107). It seems very likely that fundamentally the same mechanism applies for cone opsins, and therefore that it had arisen prior to the '2R' whole genome duplications. Figure 21 provides a schematic illustration of the events involved in activation (108). Within a few microseconds of photon absorption, a state (meta I) is reached, in which the excitation remains in the twist of the retinoid, and where there has been little movement in the protein. Within a few milliseconds, though, meta I relaxes thermally to the form known as meta II, which

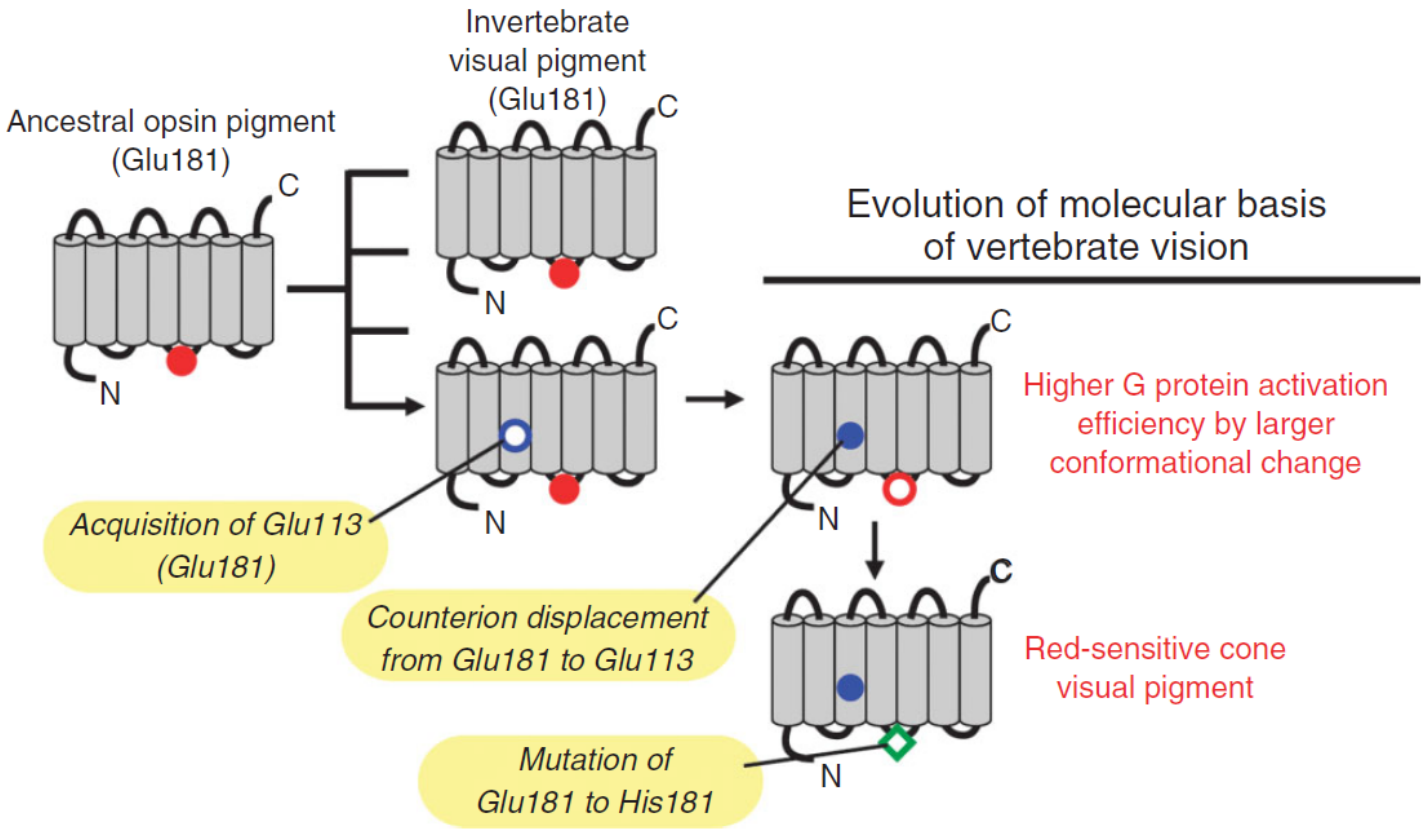

Figure 20. Counterion relocation and molecular rearrangements in chordate C-opsins. The ancestral opsin employed site 181 for the counterion (Glu181 = E181) that stabilizes the protonated Schiff base bond to 11-cis retinal. During the evolution of chordate opsins the site of the counterion relocated to position 113 following acquisition of a glutamate residue (Glu113 = E113) at that site. Both the new (Glu113) and former (Glu181) counterion residues could in principle facilitate the acquisition of new molecular properties for opsin photopigments. In vertebrate visual opsins the Glu113/Glu181 combination appears to have permitted a molecular rearrangement that led to a larger conformational change upon light activation. In one opsin lineage (LWS), mutation of site 181 from glutamate to histidine caused a significant red-shift in sensitivity through the formation a chloride binding site. From Terakita et al (103).

actually comprises an equilibrium between three different (though spectroscopically equivalent) forms. In the first step, a proton translocation occurs, deprotonating the Schiff base of meta I and protonating the E113 residue (109), creating meta IIa. In the second step, meta IIa undergoes an outward tilt of helix 6, opening up a crevice for interaction with the G-protein, creating meta IIb. In the third step, a proton is taken up onto E134 of the 'ERY' motif, which locks helix 6 in relation to helix 3. This form has been termed 'meta IIb H+' and is the enzymatically active form R* that activates the G- protein very efficiently. However, it is unable to undergo photoreversal back to the resting 11-*cis* configuration.

A schematic model for the configuration changes in the opsin/rhodopsin molecule during activation has very recently been proposed by Piechnick et al (110); see their Figure 4. On their model the protein can exist on the one hand in a 'compact inactive' configuration, either when it is ligand-free (as free opsin) or after binding 11–*cis* retinal (as rhodopsin), or alternatively it can exist in an 'opened-up active' configuration, either upon isomerization of rhodopsin to meta II (as R*) or when ligand-free (as Opsin*). Exit or entry of all–*trans* or 11–*cis* retinal is possible only from/to the opened-up active configuration, and such access appears to occur via a retinoid channel that opens between the retinoid binding pocket and the lipid membrane. A separate hydrophilic channel, that permits entry/exit of water during Schiff base hydrolysis/formation, is also proposed to open and close at the same times. This model appears capable of explaining many of the known features of retinoid entry/exit, Schiff base formation/hydrolysis, and switching of the protein's ability to activate the G-

protein. In Section 6 it will be suggested that one difference between rhodopsin and the cone opsins is that access by water is greater, and that it remains possible in the cone pigment's 'compact inactive' configuration.

Rapid hydrolysis of the Schiff base bond after light activation. Recently, Chen et al (104) have shown that the presence of the relocated counterion (the equivalent of E113 in bovine rhodopsin) is crucial in enabling rapid hydrolysis of the Schiff base bond in the light-activated metarhodopsin II state (which occurs ~200× more rapidly for the cone form than for rod metarhodopsin II). As described above, in meta II the Schiff base bond is deprotonated while the counterion site is protonated. However, hydrolysis of the Schiff base bond requires its transient protonation, and Chen et al (104) showed that the proton donor is the protonated counterion residue; water is then able to attack the protonated Schiff base, breaking the covalent bond and thereby leaving all-*trans* retinal non-covalently attached in the retinoid-binding pocket. Hence, we can conclude that the relocation of the counterion site was instrumental in generating a visual pigment that could rapidly release its all-*trans* retinal, thereby contributing to the rapid shut-off of activation needed for a rapid response in cones, and also rapidly readying the opsin for binding 11-*cis* retinal. As will be discussed in Section 6, at a subsequent stage in evolution the Rh1 opsin (rhodopsin) found a way to prevent this rapid decay of meta II, thereby enabling activated rhodopsin to integrate the photon-triggered signal for longer times than could be achieved with the rapidly decaying meta II.

Scenario for the pre-vertebrate evolution of C-opsins

In view of the information above, the following scenario can be hypothesized for the developments that occurred during the evolution of C-opsins in the chordate lineage (modified slightly from the interpretations of Terakita, Shichida, and colleagues):

C-1) An ancestral chordate possessed a C-opsin photopigment that exhibited close homology to extant Opn3 (encephalopsin and TMT-opsin), as well as to cnidarian and protostome C-opsins and even to R-opsins. E181 served as the Schiff base counterion, and site 113 was not negatively charged, and was instead probably either Y or F. This photopigment was bistable and could undergo photoreversal from its active state. It activated a Gi protein, though at a much lower rate than modern cone or rod opsins activate Gt.

C-2) This C-opsin gained a glutamate at position 113. Subsequently this E113 adopted the role of counterion to the Schiff base in the dark resting state, while the ancient E181 may have played a role in stabilizing the protonated Schiff base in the first metarhodopsin intermediate, metarhodopsin I.

C-3) Further mutations occurred, that permitted a larger tilt of helix 6 in the active state thereby improving interaction with the G-protein. This new configuration was stabilized by protonation of the ERY motif, creating the highly-active form metarhodopsin II that is unique to vertebrate 'visual' opsins. This metarhodopsin state exhibits very efficient activation of the G-protein in comparison with its predecessors, but is no longer capable of undergoing photoreversal upon absorption of another quantum (and it also has its absorption maximum in the UV).

C-4) Relocation of the counterion site also expedited hydrolysis of the Schiff-base bond in the activated state, providing a short lifetime of meta II and hence a more rapid photoresponse in those early cones.

C-5) The vertebrate C-opsins Opn3, parietopsin, parapinopsin, VA opsin, and probably pinopsin, represent modern versions of intermediate forms that occurred in this evolutionary progression, and show various degrees of modification of their functional properties from those of the ancestral chordate C-opsin, that remain useful for applications in different types of light-sensitive cell.

C-6) Hence, the ancestral opsin of the first cone photoreceptor in the lateral light-sensitive organs of the proto-vertebrate exhibited highly-efficient activation of the G-protein, along with rapid shut-off; it is also likely that by this stage the G-protein of the cone had evolved to become Gt (transducin).

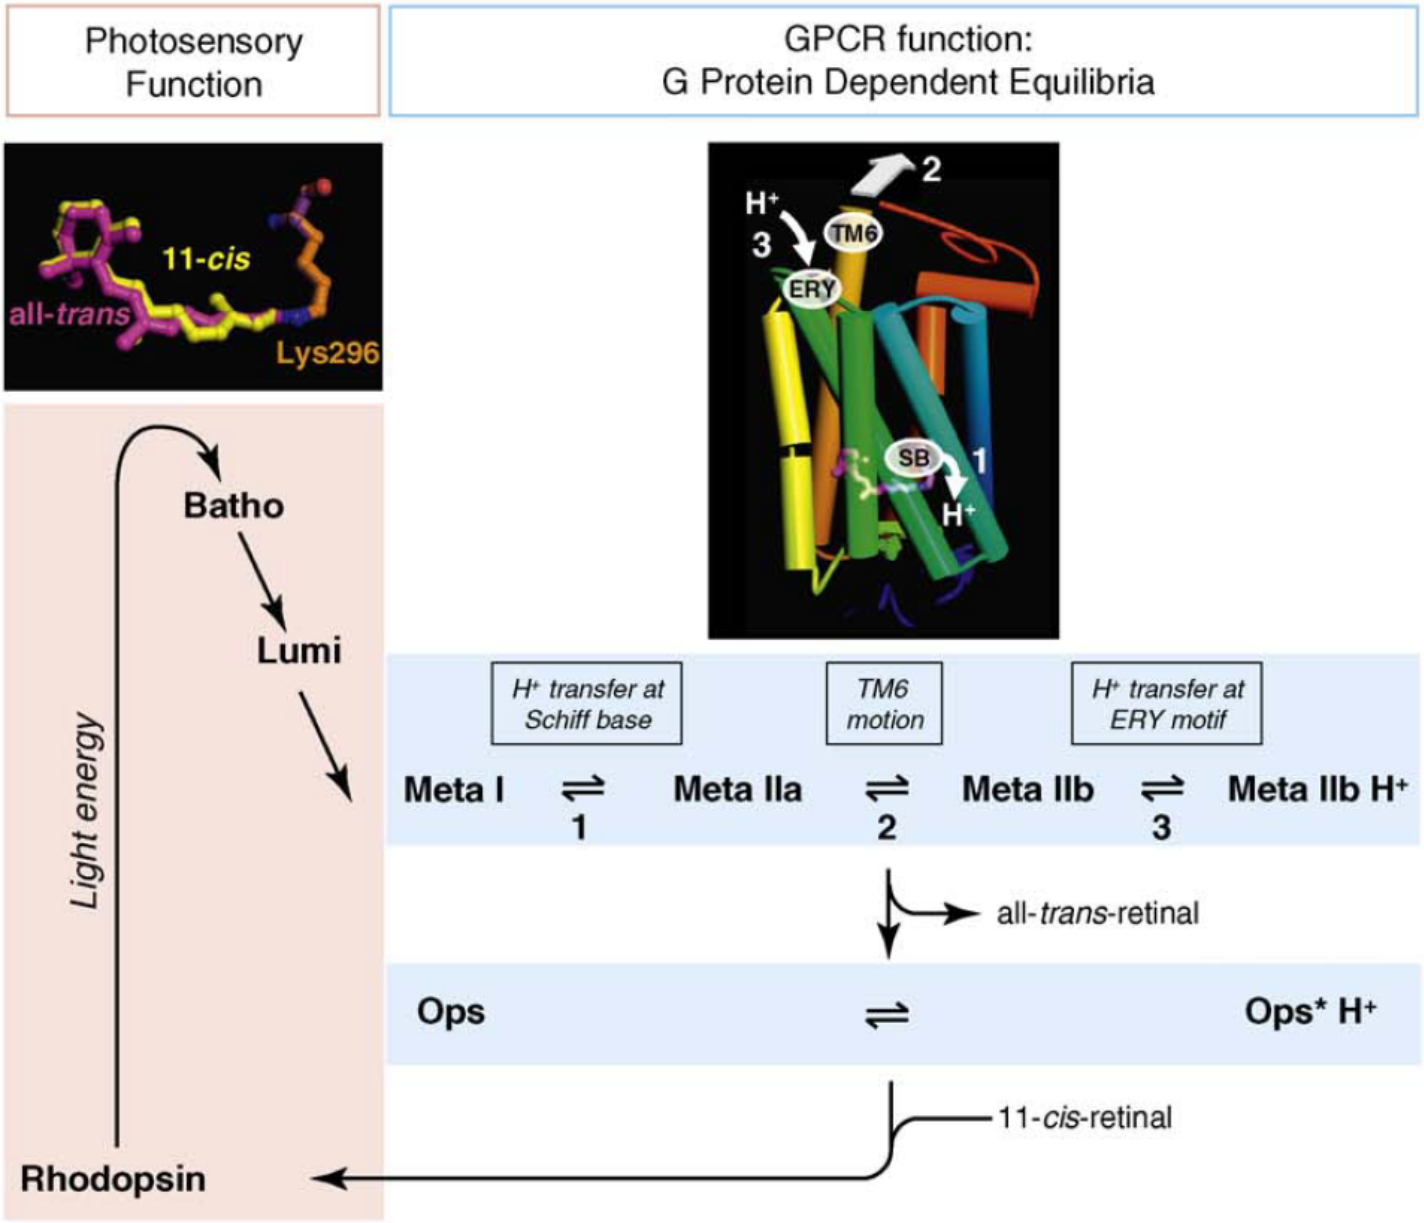

Figure 21. Molecular mechanism of activation of metarhodopsin II in vertebrate rhodopsin. Metarhodopsin II comprises three configurations that are indistinguishable spectroscopically, Meta IIa, IIb, and IIb H+. These are formed sequentially, from meta I: (1) by proton translocation from the Schiff base to E113; (2) by an outward tilt of helix 6; and (3) by protonation of E134 in the 'ERY' motif, that locks the molecule in its active form. From Hofmann et al (108).

C-7) As will be discussed in the next Section, this first cone opsin duplicated, giving rise to what became the SWS and LWS (short- and long-wave sensitive) divisions of cone opsins.

C-8) These events all occurred prior to the '2R' whole-genome duplications that occurred around the base of the vertebrate radiation.

6. Vertebrate 'visual' opsins

A characteristic feature of the retina of jawed vertebrates is its use of cone opsins and a cone-based pathway for intensities from twilight upwards (photopic vision) but rhodopsin and a rod-based pathway for the very lowest intensities (scotopic vision), in what has historically been termed a 'duplex' organization of the retina. It is of

considerable interest to understand how, when, and why this division arose. Along with many of the other advents that occurred in the stem vertebrate lineage, it seems that a major factor contributing to the duality of cones and rods was the occurrence of two rounds of whole genome duplication ('2R'), as proposed originally by Ohno (111) and subsequently confirmed in numerous studies.

By way of background, we will begin by reviewing the phylogeny of cone and rod opsins. Recently, substantial progress has been made in understanding the contribution of the '2R' duplications through studies of gene arrangements on chromosomes, and here we will examine results relevant to opsins. Then we will examine the differences in functional properties between cone opsins and rhodopsin.

In addition to the opsins expressed in cones and rods, the vertebrate retina also expresses a number of other opsins, including melanopsin and VA opsin. Furthermore, it has been shown that the intrinsically-photosensitive retinal ganglion cells (ipRGCs) that express melanopsin comprise a number of subtypes with diverse functions (112, 113). Different subtypes receive synaptic input from different sub-laminae of the inner plexiform layer, and project to different brain areas. Some subtypes are able to contribute to form vision in mouse. However, the following discussion of vertebrate 'visual' opsins will be restricted to the opsins of cones and rods.

Phylogeny of vertebrate 'visual' opsins

Phylogeny. The phylogeny of opsins, including vertebrate 'visual' opsins, has been reviewed in a number of publications, including Terakita (25), Bowmaker (114), Shichida & Matsuyama (8), Davies et al (94), and Porter et al (12), amongst others.

Cone opsins are ancestral to rhodopsin. One of the most important discoveries about the origin of vertebrate retinal opsins was made by Okano et al (115), who showed conclusively that the rod photopigment rhodopsin had evolved from one of the pre-existing cone photopigments. Furthermore, they showed that the first split in the ancestral vertebrate visual opsins had given rise to the SWS and LWS distinction; i.e. to the long-wave-sensitive (LWS) cone opsin on the one hand, and on the other hand to all the other cone opsins plus rhodopsin (the 'SWS' division, that now comprises SWS1, SWS2, Rh2 and Rh1). These fundamental results, which are illustrated by the more recent phylogeny in Figure 22, have been confirmed by all subsequent studies.

Timing of the SWS/LWS split. The evidence to be presented in the next Section (on paralogon arrangement of chromosomes) indicates that ancestral SWS and LWS opsins already existed prior to the '2R' whole genome duplications that occurred at the base of the vertebrate lineage. These two cone opsins already exhibited highly effective activation of transducin, as a result of the molecular rearrangements that had followed relocation of the site for the Schiff base counterion from position 181 to 113. The advent of LWS red-shifted-sensitivity appears to have occurred as follows.

LWS opsins: Red-shift through acquisition of a chloride binding site. As residue E181 was no longer required as the counterion to the resting state, mutations were not as constrained as previously. A mutation of E181 to H181 created a chloride ion binding site that permitted a substantial red-shift in the opsin's peak absorption, giving rise to the ancestral LWS cone opsin. (Note that this numbering is relative to bovine rhodopsin; in the frame of human OPN1LW the residues are H197/K200.) A history of investigations into the nature of this chloride-binding site is given in the recent study of Yamashita et al (116). Wang et al (117) showed that the two residues H181 and K184 contributed to the effect, with H181 being the primary residue contributing the red-shift; the K184 may contribute to enhancing the stabilization of chloride binding. Davies et al (118)and Yamashita et al (116) have recently shown that two other residues, 289 and 292, are also involved in the chloride effect.

As an aside, it is interesting that a handful of mammalian LWS cone opsins have subsequently reverted to a blue-shifted 'MWS' sensitivity through loss of the chloride binding site. One example is mouse 'MWS' opsin, which has the 181 position mutated to tyrosine (Y181); it shows no chloride effect because positions 289 and 292 have

both also mutated to serine (Yamashita et al, 2013). On the other hand, guinea-pig 'MWS' opsin (also with Y181) retains a partial chloride effect, as positions 289 and 292 both remain occupied by alanine.

SWS opsin duplications. The ancestral SWS pigment duplicated twice, to produce four opsins with peak sensitivities in the blue/green region of the spectrum; the next Section will present evidence suggesting that this quadruplication occurred as part of the vertebrate '2R' whole-genome duplications.

Vertebrate cone opsins. As a result of these duplications, the first vertebrates (jawless at that stage) possessed a complement of five distinct cone opsins, that are conventionally classified using the rather confusing terminology of SWS1, SWS2, Rh2, Rh1, and LWS (Figure 22). Those five classes have been inherited by all the descendants of the ancestral vertebrate, though some classes of opsin have been lost in different lineages. For example, monotremes lost the SWS1 opsin (119), while placental mammals lost the SWS2 and Rh2 opsins; for more complete information, see Davies et al (120).

Where they are retained in extant vertebrate species, the four opsin classes SWS1, SWS2, Rh2, and LWS, continue to be expressed in cones. At some subsequent stage (Section 11), the cone photoreceptor that expressed the Rh1 opsin evolved to become a rod. A second type of rod exists in amphibia, utilizing the SWS2 opsin, but the timing of its origin is unclear.

Paralogon arrangement of opsin genes

In order to help determine the role of whole-genome and other large-scale duplications in the evolution of the genes encoding the opsins and associated proteins of phototransduction, Larhammar and colleagues have studied the paralogon arrangement of the genes (7, 121). The term 'paralogon' applies to the (usually) quartet arrangement of related chromosome regions within the genome, that still persist (though often greatly modified) some 500 million years after the two rounds of genome duplication.

Chromosomal arrangement of opsins. The results of Nordström et al (121) and Larhammar et al (7) for the paralogon arrangement of the human opsin genes (as well as the genes for transducin alpha subunits) are shown schematically in Figure 23. The genes for rhodopsin (=RHO), SWS1 (=OPN1SW), and LWS (=OPN1LW) lie in corresponding positions on chromosomes 3, 7, and X. In view of the fact that phylogenetic trees for vertebrate visual opsins always have the SWS and LWS opsins as the most basal divergence (Section 6), they proposed that the locations of the ancestral genes (prior to quadruplication) had been as indicated in the top row. Following the two genome duplications, the ancestral SWS was proposed to have evolved into the SWS1, SWS2, Rh2, and Rh1 opsins of basal vertebrates, of which Rh2 and SWS2 have been lost in mammals (crosses in first column). In addition, it appeared that the LWS opsin had been preserved in only one member of the quartet (now on the X chromosome in humans).

The chromosomal arrangement of the genes for all the other proteins involved in the phototransduction cascade will be deferred to Section 8.

Discrepancy between observed phylogenetic tree and that predicted by '2R' duplications. It is important to recognize a discrepancy between the observed phylogenetic tree for vertebrate cone/rod opsins and the tree expected for whole-genome duplications. From first principles, one would expect that the pair of '2R' whole-genome duplications would have produced a 'forked' phylogenetic tree with a double bifurcation, of the form ((SWS1,SWS2), (Rh2,Rh1)), in contrast to the 'nested' tree (SWS1,(SWS2,(Rh2,Rh1))) that is always observed. In fact, a doubly bifurcating tree might be expected for all gene families that survived the quadruplication event, and the general absence of such forms was originally taken by some as evidence against the occurrence of '2R' duplications.

However, if (as is generally thought) the two duplication events occurred close together in time, relative to the time that has elapsed since, then a variety of influences could alter the form of the phylogenetic tree that is

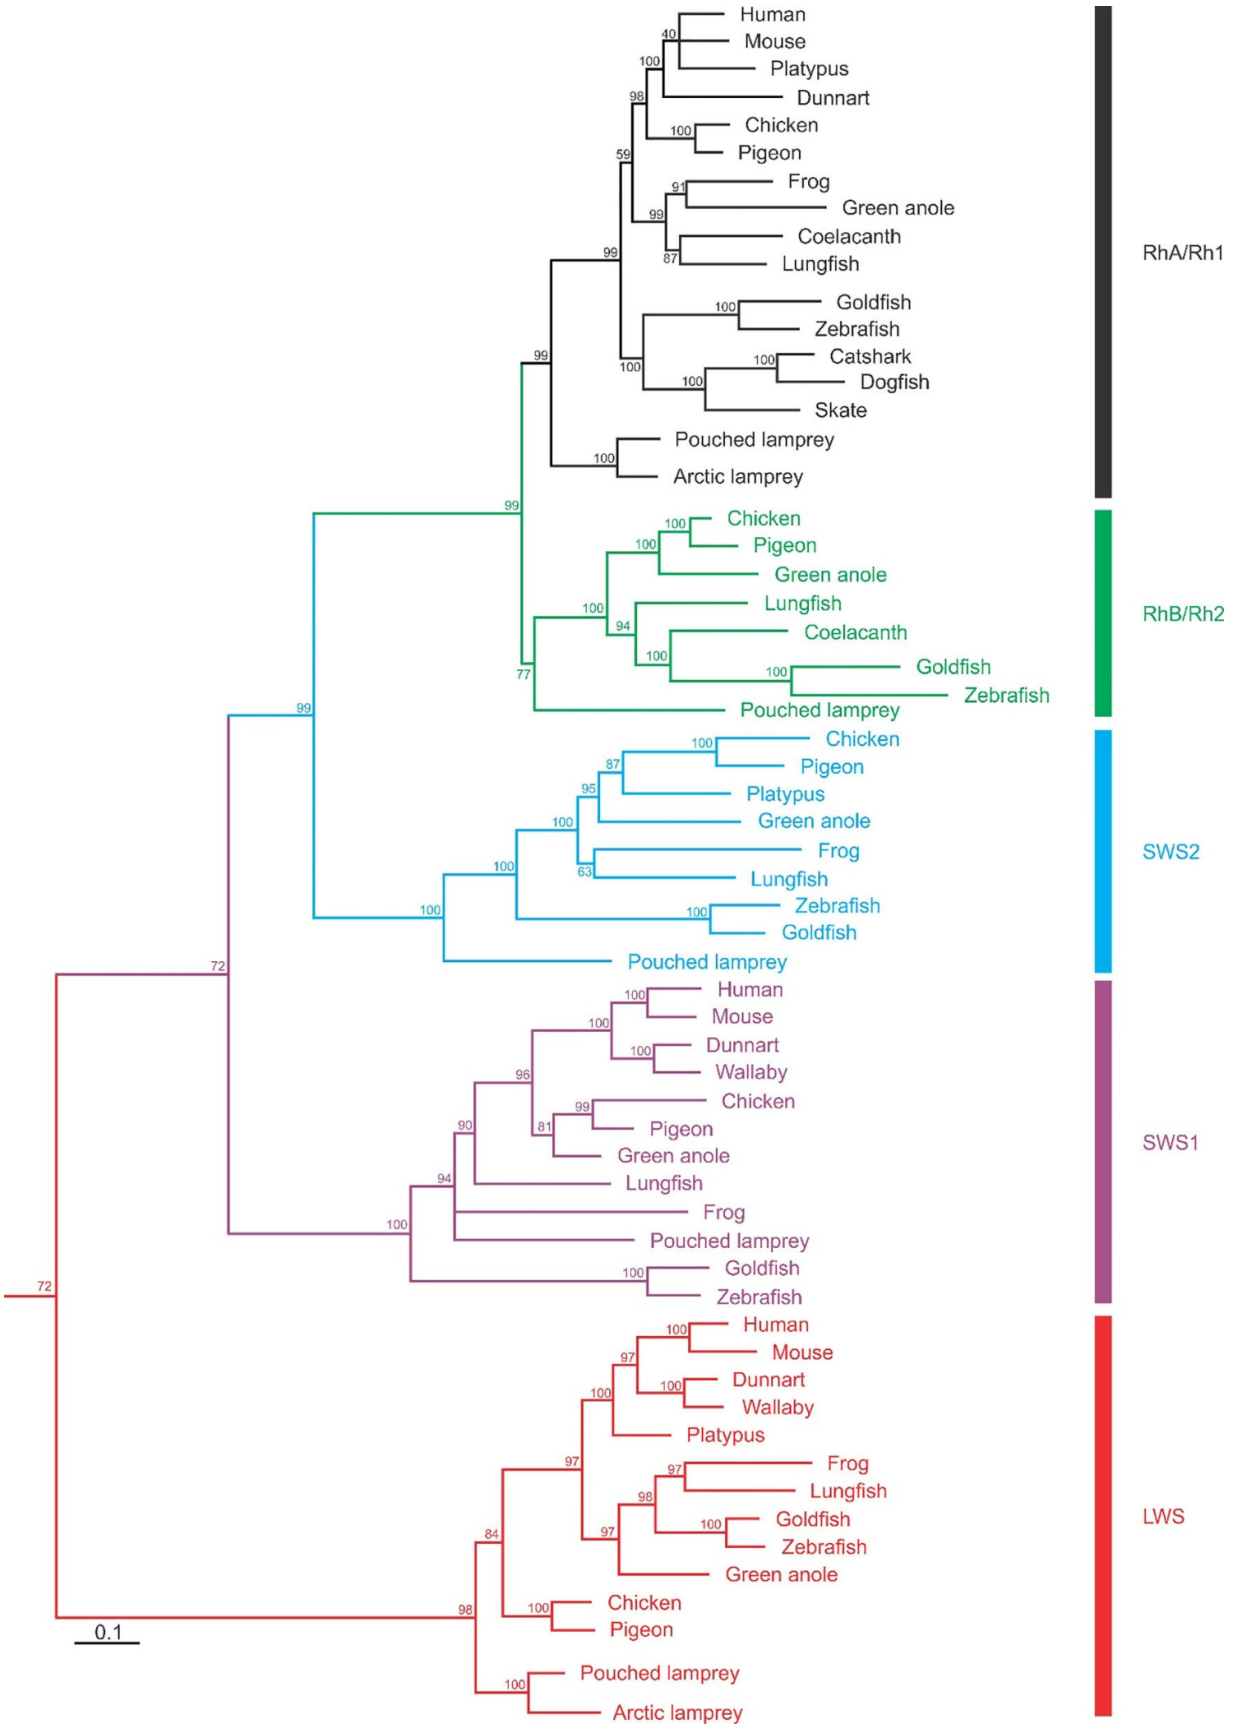

Figure 22. Phylogeny of vertebrate cone and rod opsins. Phylogeny of the gene families of vertebrate visual pigments (i.e. cone opsins and rhodopsin): LWS, SWS1, SWS2, RHB/RH2 and RHA/RH1. Posterior probability values (as percentages) are indicated at the base of each node. The scale bar indicates the number of nucleotide substitutions per site. Branch lengths reflect evolutionary distances. From Collin et al (10).

obtained. In general, any tendency towards different rates of incorporation of substitutions in the different branches could lead to a distortion of the extracted tree topology. For the visual opsins, which have adopted different spectral positions and different kinetic properties, it is plausible that there could have been competition between these (or other) properties, in the different branches, that in practice led to different rates of substitutions at residues in different branches.

As one example, consider what might have happened if the ancestral SWS opsin exhibited its peak absorption close to the UV, and underwent two successive duplications. After the first duplication, it seems likely that selective pressures would have caused a separation of peak wavelengths of the two opsins. However, this pressure is likely to have been asymmetric, because a shift of peak sensitivity further into the UV is unlikely to have been advantageous to the organism, whereas a shift of one of the opsins to longer wavelengths (to occupy the gap between SWS and LWS) is likely to have been advantageous. Comparable arguments would apply after a second duplication. Hence it is possible to envisage that selective pressures would initially have favored a general shifting *apart* of the spectral absorption peaks of the different opsins, though with a 'barrier' at the UV end. On this basis, whichever opsin was nearest to the UV end of the spectrum would have been under selective pressure not to alter its absorption peak, as a shift in either direction would have proved disadvantageous. As a result, it might be expected that the opsin that we now call SWS1 will have experienced a lower rate of substitutions at residues that affect its spectral tuning than have the other opsins. This could have the effect of distorting the extracted phylogenetic tree in a manner that would tend to make the SWS1 opsin appear more ancient than it really is.

It therefore seems that the observed nested phylogeny that is recovered for the visual opsins cannot necessarily be taken as a basis for rejection of the hypothesis that the four SWS opsins (SWS1, SWS2, Rh2, and Rh1) arose from the '2R' pair of whole genome duplications that occurred near the base of the vertebrate lineage. But on the other hand, neither has it been proven that '2R' does indeed account for the existence of the five classes of vertebrate cone and rod opsin.

Differences in functional properties between cone and rod opsins

Differences in functional properties between cone opsins and rhodopsin, and the dependence of these differences on amino acid sequence, have been reviewed by Imai et al (92). Three substantial differences involve: (*i*) the short lifetime of cone metarhodopsins, (*ii*) the rapid regeneration of cone pigments, and (*iii*) the high susceptibility of cone opsins to hydroxylamine attack.

Short lifetime of cone meta II. Many studies have shown that the lifetime of the meta II state is orders of magnitude shorter in cone opsins than in rhodopsin. Shichida's group (reviewed in Imai et al (92)) examined the properties of purified extracted opsins from native membranes or from cultured opsins with point mutations, using spectrophotometry, at a range of temperatures and other conditions. For WT chicken opsins, the meta II decay times were short for cone opsins (~2, ~1, 7 and 16 s for SWS1, SWS2, Rh2 and LWS) but far longer for rhodopsin (210 s), in each case at room temperature and with extraction in CHAPS. More recently, Chen et al (104) reported a similar difference in *Xenopus*, where the meta II for blue/violet-sensitive (SWS1) cone opsin decayed with a time constant of ~3 s compared with ~800 s for bovine rhodopsin (Rh1), both at 20 °C and pH 6 with extraction in 0.1% dodecyl maltoside. Their method involved fluorescence microscopy measurements to monitor the release of all-*trans* retinal, presumed to reflect the decay of meta II.

The large observed difference in speed of meta II decay (or retinal release) is not due to extraction/purification, because Golobokova & Govardovskii (122) found a similar effect in intact individual cones and rods of the goldfish using a fast-scanning dichroic microspectrophotometer. For both the red-sensitive (LWS) and green-sensitive (Rh2) cone opsins they found a meta II lifetime of ~5 s, compared with ~330 s for rhodopsin (Rh1). Hence each of these approaches shows that the decay of meta II occurs 100× (or more) faster for cone opsins than for rhodopsin.

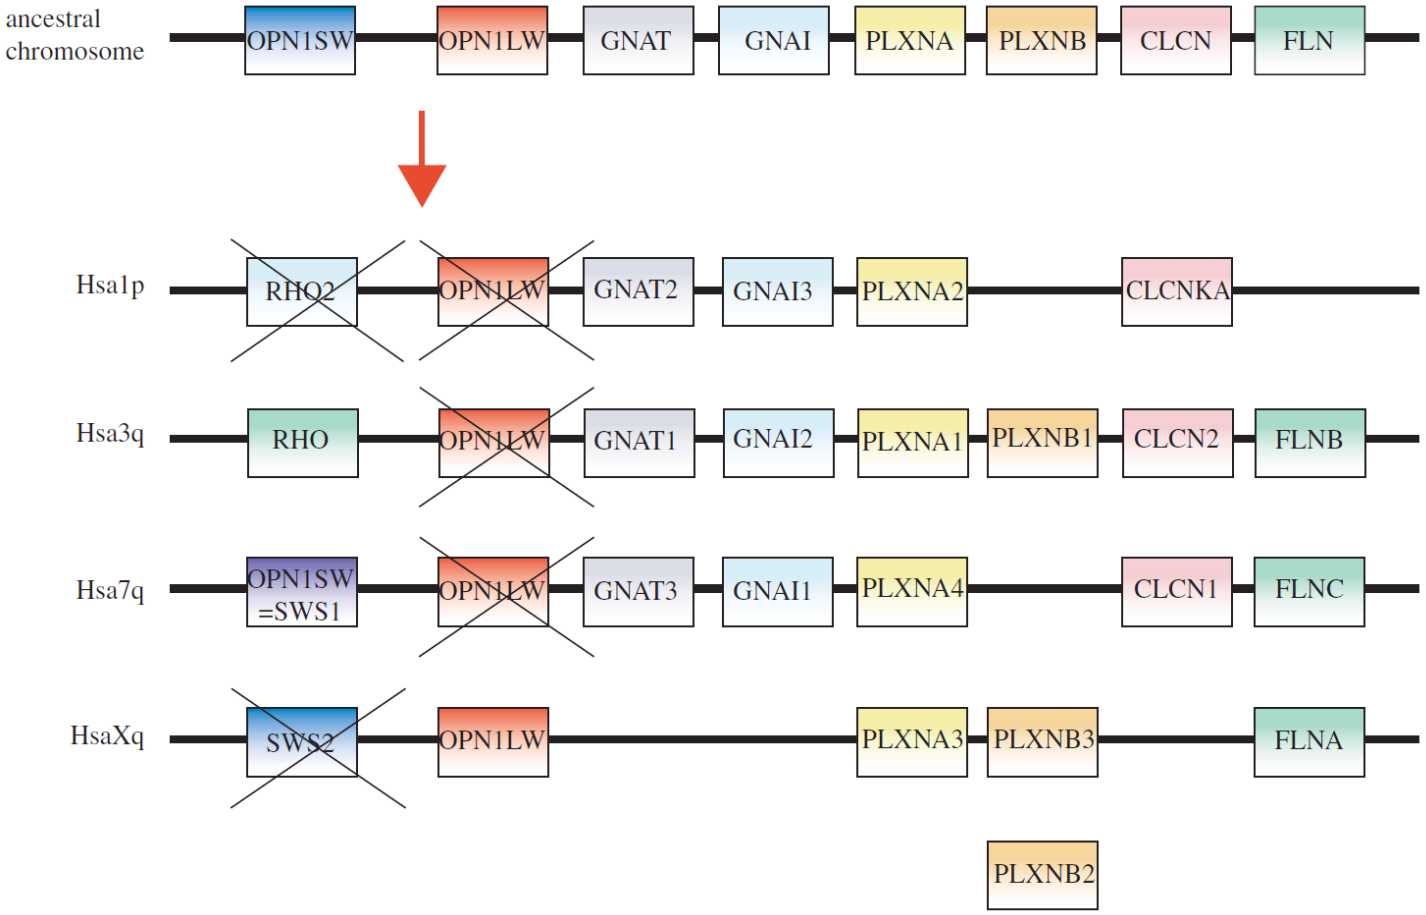

Figure 23. Paralogon arrangement of genes for opsins and transducin alpha subunits Chromosomal locations of vertebrate visual opsin gene family members in the human genome (Hsa for *Homo sapiens*) are shown in the lower four rows. The top row gives the arrangement postulated by Larhammar et al (7) for the ancestral genes, prior to quadruplication, and below, the crosses indicate the positions of the ancient blue- (SWS2) and green-sensitive (RHO2) opsins that have been lost in mammals. The proposed position for the ancient green-sensitive opsin (RHO2) is confirmed by the present location of its ortholog in the chicken genome, in a region with conserved synteny with Hsa1. The ancestral chromosome (top) was postulated to have possessed the SWS and LWS gene pair (OPN1SW and OPN1LW) before the chromosome quadruplication, because phylogenetic trees for vertebrate visual opsins always have SWS and LWS as the most basal divergence (e.g. see Bowmaker, 2008, and Figs. 19, 22). The transducin α subunit is located in the same paralogon, with GNAT1 expressed in rods and GNAT2 in cones (see Figure 26). From Larhammar et al (7).

Role of sites 122 and 189. Yoshinori Shichida's group has employed site-directed mutagenesis to determine the importance of the residues at sites 122 and 189 (in bovine rhodopsin numbering) for these differences in meta II lifetime, as well as for differences in pigment regeneration time (reviewed in Imai et al (92)). Residue 122 is conserved as E122 in all rhodopsins apart from those of deep-sea fish (see below), but in cone opsins it may be I, L, M or Q. Residue 189 is conserved as P in all cone opsins, but it is I in most rhodopsins. Mutations in these two residues act synergistically in determining both the lifetime of meta II and the rate of pigment regeneration. Thus, the presence of the rod forms (E122 and I189) both contributed to slow decay of meta II and to slow regeneration of visual pigment, whereas the presence of the cone forms (I/L/M/Q122 and P189) both contributed to faster kinetics. Together, the effects of these two residues accounted for all of the observed cone/rod difference in meta II kinetics. Although synergistic, the effects at the two locations were not equally strong, with the residue at position 122 being more effective in rods and the residue at position 189 being more effective in cones.

Role of the counterion site 113. The recent study of Chen et al (104) investigated the role of the counterion site in the speed of meta II decay. As mentioned in Section 5, they showed that all-trans retinal was released around 200× faster from the SWS1 cone opsin than from rhodopsin. In the *Xenopus* SWS1 opsin the counterion residue is aspartate (D108), and its removal (by mutation to alanine) led to extremely slow release of all-trans retinal; note that this visual pigment had an unprotonated Schiff base and hence was UV-sensitive so that it needed to be activated by UV rather than blue light. The re-introduction of aspartate at an alternative location (residue 85), also close to the Schiff base, restored absorption in the violet and in addition restored release of all-*trans* retinal. They also compared release of retinal from cone opsin and rhodopsin, when the counterion was removed from each (in bovine rhodopsin by mutation to glutamine); the measurements required higher temperature and longer monitoring times, but remarkably the release rate was equally slow in the two mutant opsins.

From these and further experiments Chen et al (104) concluded that the rate of hydrolysis of the Schiff base bond was similar in cone opsins and rhodopsin, and that what differed was the rate of release of retinal from the opsin after the covalent bond had been broken. This could result from either a difference in the chromophore's interaction with the retinal binding pocket or a difference in its ability to traverse the opsin protein (i.e. its accessibility). As mentioned in Section 5, they proposed a molecular model for hydrolysis of the Schiff base, in which the protonated residue at the counterion site acted as a proton donor to transiently protonate the bond and thereby render it susceptible to attack by water.

Susceptibility to hydroxylamine attack. Cone opsins are subject to degradation by hydroxylamine, whereas most rhodopsins are not. (This applies to rhodopsins of placental mammals, though some non-mammalian and monotreme rhodopsins have been shown to be slowly degraded; (123, 124).) Hydroxylamine attacks the Schiff base bond, and is able to do so in the resting cone opsin as well as in the metarhodopsin state of activated rhodopsin. Hydroxylamine is thought to attack the Schiff base in much the same way as occurs in the normal decay of meta II, by transient protonation of the bond, so that the cone/rod opsin difference in susceptibility to attack by hydroxylamine simply reflects the accessibility of the binding site to hydroxylamine.

Molecular mechanism limiting the speed of metarhodopsin II decay and formation of rhodopsin. Decay from the metarhodopsin II state involves hydrolysis of the Schiff base bond followed by release of all–*trans* retinal from the chromophore pocket, and there has been controversy as to which of these represents the rate-limiting step. By combining the recent work of Chen et al (104) and Piechnick et al (110), the following is proposed. The meta II state has to be transiently protonated, and the proton donor for this is the protonated counterion residue. Water access is required, and is relatively unhindered in cone opsins, but in rhodopsin can only occur via the hydrophilic channel that opens up in the meta II state. Likewise, when 11–*cis* retinal binds to form rhodopsin, a water molecule must be able to exit the binding site via this same route. In the molecular model of Piechnick et al (110), the hydrophilic channel in rhodopsin permits slow access/removal of water in the 'opened-up active' configuration, but very effectively protects the binding site in the 'compact inactive' state. For cone opsins it is simply necessary to postulate that access for water is much less restricted in both the active and inactive configurations.

Rhodopsin inaccessibility. Hence, the three major differences between cone opsins and rhodopsin (meta II lifetime, regeneration time, and hydroxylamine susceptibility) may all simply be manifestations of the fact that the rhodopsin molecule is much more effective at 'shielding' the retinal covalent binding site from small molecules, including water and hydroxylamine. Furthermore, it appears that this major cone/rod difference is contributed by the residues at sites 122 and 189. In other words, the acquisition of these residues may have permitted the rhodopsin molecule to adopt the more compact 'shielded' configuration that excludes water access in the resting state while permitting slow access in the meta II state (see Piechnick et al (110)). Thus, it seems entirely possible that essentially all of the important molecular differences between cone and rod opsins stem from this difference in accessibility, determined mainly by the residues at these two sites.

Evolution of this difference between cone opsins and rhodopsin. In terms of evolution, we can rationalize the above findings with the view (as explained in Section 5) that the ancestral C-opsin of cones had already evolved the relocation of its counterion site, which enabled both the increase in efficacy of G-protein activation and the release of all-trans retinal, with that latter contributing in part to a fast response. But subsequently (after the '2R' duplication) the pressure for increased sensitivity provided an advantage in attaining a longer lifetime of activated meta II for one of the opsins, and this was accomplished in the Rh1 opsin when site 122 mutated to glutamate and site 189 mutated to isoleucine, their present forms in rhodopsin.

The slow decay of metarhodopsin II may additionally have provided an advantage in reducing the toxicity that could have been elicited by a massive rapid release of all-*trans* retinaldehyde in intense light (e.g. sunlight); if so, this would have provided pressure for the retention of E122 and I189 in rhodopsins.

Residue 122 in deep-sea fish. Interestingly, in the rhodopsins of deep-sea fish, residue 122 is often occupied by glutamine (Q122), and this provides a significant blue-shift in the absorption spectrum (125). It is conceivable that the extremely low light intensities that are experienced at great depths lead to so little retinal being released that there is never a toxicity problem with E122Q in these species, whereas there is an advantage in the shift to a shorter wavelength of peak absorption.

Similarity. One interesting similarity, rather than difference, between cone and rod photopigments is that they are all remarkably stable against spontaneous thermal isomerization to the active state. The comparative details of this stability will be treated in Section 10.

Scenario for the evolution of vertebrate 'visual' opsins

From the information presented up to here, the following scenario is proposed for the sequence of evolutionary events that led to the emergence of four cone opsins plus rhodopsin in the vertebrate retina:

D-1) Prior to the large-scale duplication events that occurred at the base of the vertebrate lineage, the rostral region of the central nervous system (that would expand as the diencephalon) contained neurons (some of them ciliary photoreceptors) that expressed a range of C-opsins, including members of the classes parietopsin, parapinopsin, VA opsin, pinopsin, and an ancestral cone opsin.

D-2) In the ancestral cone opsin (and some of the earlier C-opsins), the counterion site had migrated to position 113. Subsequently, changes occurred that permitted greater movement of helix 6. The new meta II form exhibited a high efficacy of activation of the G-protein, and it decayed rapidly to release all-trans retinal.

D-3) This ancestral cone opsin duplicated to form two divisions, SWS and LWS opsins, that were expressed in two separate classes of cone photoreceptor in the part of the diencephalon that was expanding laterally.

D-4) In the LWS opsin, the ancestral counterion site E181 (in bovine rhodopsin numbering) had undergone mutation to H181, to create a chloride ion binding site, thereby giving a substantial red-shift in the pigment's peak absorption.

D-5) The genes for the SWS and LWS opsins were adjacent on a chromosome. Not far downstream were the genes for the alpha subunits of Gt (transducin) and Gi.

D-6) Two rounds of whole-genome duplication gave rise to four copies of the SWS gene, which underwent mutations to become the founding SWS1, SWS2, Rh2 and Rh1 opsins. When bound to 11-*cis* retinal, these visual pigments had peak spectral sensitivities ranging from the UV to the green region of the spectrum. Of the quartet of LWS genes that resulted from the duplications, only one copy survived, corresponding to the LWS (also sometimes called MWS) gene of all extant vertebrates.

D-7) Upon activation by a photon, all of these cone opsins exhibited a high efficacy of activation of the G-protein transducin; none exhibited photoreversal once they relaxed from the meta I state to meta II; and all underwent relatively rapid thermal decay from the active meta II state, releasing all-*trans* retinal.

D-8) In the Rh1 opsin, two mutations occurred (at residues 122 and 189) that led to slower decay of the meta II intermediate. This enabled the photoreceptor expressing the Rh1 opsin to integrate the photon signal for longer, thereby endowing it with higher sensitivity; but a trade-off was the slower re-binding of 11-*cis* retinal and hence slower regeneration of visual pigment. There was little else that distinguished this Rh1 'rhodopsin' from the other 'cone opsins'.

D-9) The thermal stability of these opsins against isomerization (i.e. their ability to avoid spontaneously entering the active all-trans state) was a function of the wavelength of absorption to which they were tuned (see subsequent Section 10), but all of these opsins were highly stable.

7. Vertebrate retinal cones and rods

The triumph of ciliary cells as the primary photoreceptors in vertebrates

In view of the fact that the image-forming eyes of most protostomes employ microvillar photoreceptors, it is natural to ask why vertebrate eyes instead opted for ciliary photoreceptors. Furthermore, given that a single type of fly rhabdomeric photoreceptor can reliably detect individual photons, and also respond very rapidly over an enormous range of intensities (reviewed in Yau & Hardie (126)), it is also appropriate to ask why vertebrates instead use a duplex retina with separate cone and rod divisions.

In considering the relative merits of ciliary and microvillar photoreceptors, and the likely reasons why one or other of these classes triumphed in different organisms, it is important to avoid the error of simply comparing properties between the photoreceptors of living organisms. For example, it is not appropriate to argue on the basis of a comparison between the properties of modern rhabdomeric photoreceptors in flies and modern cone and rod photoreceptors. Instead, one needs to take into consideration the properties of the photoreceptors, and the circumstances of the organisms, at the relevant stage in evolution when the cell type gained its dominance; i.e. at the time when the 'choice' of photoreceptor class was made. At the stage when ciliary photoreceptors first became dominant in the retinas of chordates, more than 500 Mya, the evidence suggests that rods had not yet evolved. Likewise, at the stage when microvillar photoreceptors gained their dominance in protostome compound eyes, possibly more than 550 Mya, it is unlikely that they had yet become true rhabdomeric photoreceptors or that they had yet evolved the highly specialized (and possibly unique) kind of phototransduction cascade of *Drosophila* eyes (127). Accordingly, one needs to investigate the relative merits of the rather simpler ciliary and microvillar photoreceptors that were likely to have existed in those ancient times.

With those points in mind, we can list a number of advantages that ciliary photoreceptors might have had over microvillar ones, at the time that the 'choice' between them was made:

E-1) Firstly, the polarity of response (hyperpolarizing to light and depolarizing to darkness) meant that ciliary photoreceptors would have been ideally suited for shadow detection in ancient organisms. The depolarization induced by a shadow could have triggered either an action potential or an increase in release of synaptic transmitter without additional logic, and this might have been advantageous for an animal with a simple nervous system.

E-2) Secondly, there may have been little difference in gain between the two classes of photoreceptor. Very recently, Ferrer et al (46) have shown that the gain of transduction in amphioxus microvillar photoreceptors is much lower than the gain in modern rhabdomeric photoreceptors. However, the extremely short duration of the quantal response in chordate microvillar photoreceptors (a few ms; (43)) may have been disadvantageous in comparison with the slower responses of ciliary photoreceptors.

E-3) Thirdly, it has been calculated that in a bright environment the energy consumption is lower for a hyperpolarizing ciliary photoreceptor, in which the ionic currents decrease in the light, than for a depolarizing microvillar photoreceptor, in which the ionic currents increase in the light; on the other hand the energy consumption of the two classes of photoreceptor is comparable in darkness (128). A duplex retina has a further advantage in a bright environment because the rods saturate, thereby reducing their energy consumption to a low level, and it is only the cones that continue to generate a circulating current with its consequent energy demand (11).

E-4) Fourthly, chordate ciliary opsins (but not other ciliary opsins) underwent intra-molecular changes that substantially increased the efficacy of their activation of the G-protein. As a consequence, though, they lost the ability to undergo photoreversal.

E-5) Fifthly, these new ciliary opsins exhibited quite rapid decay of the active metarhodopsin II state, releasing bound all-*trans* retinal, and thereby enabling the binding of 11-*cis* retinal. Such release would have been made essential by the inability of the pigment to undergo photoreversal; however it is also possible that this change preceded the increase in activation efficacy. In the case of bistable opsins (R-opsins and the early C-opsins), the activated pigment remains in the metarhodopsin state for an extended period after exposure to light, so that the pool of rhodopsin available to detect incident photons is depleted. In this respect, a bistable photopigment may have been severely disadvantageous when an organism moved from a bright environment to a dim environment and needed to dark-adapt rapidly. Chordate ciliary photoreceptors may thus have provided a distinct advantage under such conditions.

E-6) Finally, an additional benefit to the organism may have arisen not directly from the properties of the phototransduction process, but from the fact that the ciliary cells evolved synaptic transmission onto their microvillar counterparts (see Section 15), thereby constituting a dual photoreceptive system via a single afferent pathway.

In any case, as the discussion above shows, it is possible to point to several important ways in which ciliary photoreceptors may have proved superior to microvillar photoreceptors in ancient chordates. For one reason or another, ciliary photoreceptors did indeed triumph in the light-sensitive organs of proto-vertebrates.

Multiple classes of vertebrate retinal photoreceptor

For a review of the distribution of opsins and the variations in morphology and in transduction pathways across classes of vertebrate photoreceptors, see Ebrey & Koutalos (91).

As described in Section 6, the ancestral vertebrate possessed five classes of cone/rod opsin photopigment. In addition it possessed five morphological classes of cone/rod photoreceptor. On the basis of the norm in photoreceptors of jawed vertebrates, as well as circumstantial evidence from extant lampreys (Figure 15), it seems likely that each class of photoreceptor expressed a single class of opsin.

In jawed vertebrates, these photoreceptors comprise four classes of cone, expressing their individual cone opsins (SWS1, SWS2, Rh2, LWS), plus a single class of rod photoreceptor expressing the rod photopigment, rhodopsin (Rh1). However, at least in amphibia, the SWS2 'cone' opsin can additionally be expressed in another class of rods (called 'green rods' because of their greenish tint). In living lampreys, all five classes of photoreceptor appear cone-like, though the class that expresses 'rhodopsin' has some rod-like properties (Section 3). As a result, it is plausible that 'true' rods had not evolved prior to point #5 in Figure 1. The timing of the emergence of rods will be discussed in Section 11.

Currently it is not clear whether the initial driving force for the multiplicity of spectral classes of cone photoreceptor was simply in order to cover more of the 'visible' spectrum, given that each opsin absorbs over a relatively narrow region of the spectrum, or whether it was to provide 'color vision'. But it seems reasonable to

think that, almost as soon new spectral information became available to an organism, it would have been utilized by the nervous system to provide color information.

Morphological differences between cones and rods

Details of the morphology of cone and rod photoreceptors are given in Webvision Part I, Chapter 2 'Photoreceptors'; here we will simply concentrate on *differences* between the two classes of cell.

Sac versus disc structure. The most marked morphological difference between mammalian cones and rods relates to the topology of the outer segment membrane. In cones, the entire membrane is continuous with the plasma membrane of the inner segment, whereas in rods the bulk of the outer segment membrane is sealed off from the plasma membrane in the form of discs that resemble deflated balloons. These discs are not actually 'free floating', but appear to be tethered to the plasma membrane by proteins including peripherin/RDS, Rom1, and the GARP domain of the cyclic nucleotide-gated channel.

In both cell types, new outer segment membrane is continually being formed in the vicinity of the ciliary neck, and bulges outwards, so that new sacs are repeatedly formed beneath recently formed ones, in a mechanism that was documented experimentally by Steinberg, Fisher & Anderson (129); see Figure 16B above. They showed that a process of rim formation occurs between the membranes of adjacent sacs, though in cones it proceeds only part way around the circumference, so that the sacs are always open to the exterior (patent). In rods, however, this process of rim formation proceeds all the way around the circumference (bi-directionally), zippering together the apposed surfaces, and thereby forming a disc pinched-off from the plasma membrane.

As a result of this 'sealing over' of discs in rods, newly synthesized protein is trapped in the newly formed discs. As additional discs are created, those formed earlier slowly migrate outward along the length of the outer segment, over a period of weeks, before being phagocytosed by the RPE. This localization and migration of proteins can be demonstrated experimentally by autoradiographic examination at successive times after application of labeled amino acids (130). In contrast, what is seen in cones is a uniform distribution of label over the entire outer segment, as expected if protein is able to diffuse (even very slowly) throughout the continuous plasma membrane of the outer segment.

Other morphological differences. A further morphological difference between their outer segments is the existence of one or more incisure(s) in rods; these deep longitudinal indentations into the outer segments provide an increased cross-section of cytoplasmic space that increases the effective longitudinal diffusion coefficient for intracellular messengers (see also Section 11). At the level of the inner segment, cones exhibit specializations that do not occur in rods, including the paraboloid and sometimes spectral filters (an oil droplet or vesicles, in the ellipsoid). Probably because of its high refractive index, the inner segment of cones is very effective in funneling incident light into the outer segment, and this gives rise to a marked Stiles-Crawford directional effect in cones, and a weak one in rods. At their synaptic terminals, cones and rods differ substantially, with the cones exhibiting large pedicles and the rods exhibiting smaller spherules. In addition, there are other subtle morphological differences between cones and rods.

Overview of functional differences between cones and rods

The light response properties of cone and rod photoreceptors are remarkably similar to each other (see below), and the cells exhibit just a few major differences:

a. *Rods*. The defining feature in the response of the rod photoreceptor is its ability, under dark-adapted conditions, to respond reliably (i.e. with good signal-to-noise ratio) to the absorption of individual photons of light (131, 132). This single-photon detection performance is possible because the noise, expressed as 'dark light', is very low in rods; this dark light is many orders of magnitude lower in rods than in LWS cones, though the difference may be smaller in the case of SWS cones.

b. *Cones*. The defining features in the responses of the cone photoreceptor are its ability: (*i*) to respond rapidly, (*ii*) to function over an enormous range of intensities, so that (*iii*) it never saturates in steady light, no matter how bright the intensity, and (*iv*) its ability to recover much of its responsiveness almost instantaneously when an intense light is extinguished (reviewed in Lamb (133)).

Cone/rod similarities. In most other respects, the responses of cone and rod photoreceptors are remarkably similar to each other, as shown in Item C for human LWS cones compared with rods. For example, the amplification of the phototransduction cascade appears to be reasonably similar in mammalian cones and rods. The observed difference in sensitivity between them (of around 20-fold) results in large part from the more rapid shut-off of the cone response, which is typically around 5-times faster than in rods under dark-adapted conditions. As illustrated in Figure 24, cone and rod responses begin rising with broadly similar gain, but the cone responses recover much sooner. It has also been shown that the shapes of the light responses (i.e. their kinetics) are closely similar, apart from an overall scaling of the time axis.

However, the gain of transduction and the rate of activation of G-protein by activated opsin are probably not exactly equal in cones and rods, and indeed there are several reports of a lower gain in cones. Kawamura & Tachibanaki (134) reviewed measurements from isolated cones and rods of fish and salamander, and concluded that the gain in the cones was considerably lower. More recently, Tachibanaki et al (135) conducted careful experiments on the rate of G-protein activation by light-activated visual pigment, and found this rate to be ~5× lower in cones than in rods. Nevertheless, a recurring difficulty in measurements of cone biochemistry is that the shut-off reactions are so fast that this creates problems in determining activation rates. Overall, it seems likely that the gain of transduction in cones lies somewhere in the range 0.2-1× that in rods.

The responses in Figure 24 also illustrate the general observation that cone photoreceptors expressing blue/green-sensitive opsins (i.e. those with the SWS1, SWS2, or Rh2 opsin) typically tend to display response properties intermediate between those of LWS cones and rods; thus, blue/green-sensitive cones are slower and more sensitive than red-sensitive cones.

Major cone/rod differences in performance. In Item C the parameters exhibiting major differences between cones and rods are indicated in red. Firstly, although cones and rods both exhibit classical Weber-law light adaptation, for rods this occurs only over a restricted range of intensities before they saturate, whereas for cones the adaptation continues up to indefinitely high intensities so that they never saturate in steady light. Secondly, rods typically display a very low rate of photon-like events in darkness, of the order of one event per tens or hundreds of seconds, whereas in LWS cones the 'dark light' may typically be of the order of hundreds of photon events per second. Although much of this difference in dark light stems from the difference in wavelength of peak absorbance (Section 10), a small part appears to be due to intrinsic differences between rhodopsin and cone opsins. Finally, following extinction of a steady light that bleaches more than 90% of the photopigment, human cones recover their circulating current within ~20 ms (136), whereas for human rods comparable recovery of circulating current may take 20 mins, which is slower by a factor of ~60,000×.

These differences will be treated according to the photoreceptor class that exhibits the superior performance. Thus, the avoidance of saturation and the speed of response will be dealt with in Section 9 on cone photoreceptors, while transduction noise and the ability to resolve individual photons will be treated in Section 10 and Section 11.

8. Evolution of the vertebrate retinal phototransduction cascade

In this Section we will investigate the evolution of the 'vertebrate-style' phototransduction cascade that is employed in chordate ciliary photoreceptors, with emphasis on those of the vertebrate retina. The similar cascades utilized in protostome and cnidarian ciliary photoreceptors will be mentioned only in passing. The aims will be (1) to determine the nature of the phototransduction cascade that existed in a chordate ancestor of

	Parameter	Cone	Rod	Units	Qualitative effect	Ratio
Adaptational range and dark noise	Saturating intensity	–	100	Td	**Low in rods, but unlimited in cones**	**>10,000×**
	Weber fraction	0.5	10	%	Better in cones	~20×
	'Dark light'	>100	0.01	R*/s	**Enormously lower in rods**	**~10,000×**
Response kinetics and sensitivity (dark-adapted)	Response time-to-pk	25	125	ms	Faster in cones	~5×
	Sensitivity	0.1	2	pA/R*	Higher in rods	~20×
	Gain of transduction	5	10	s^{-2}/R*	Slightly lower in cones	~0.5×
Speed of reactions (dark-adapted)	R* lifetime	3	40	ms	Faster in cones	~10×
	G*/PDE* lifetime	10	200	ms	Faster in cones	~20×
	cGMP turnover time	350	250	ms	Similar	~1×
	Ca^{2+} turnover time	3	50	ms	Faster in cones	~20×
Dark adaptation after very large bleach	Time for recovery of circulating current	0.02	1200	s	**Enormously faster in cones**	**~60,000×**
	Time for regeneration of visual pigment	3	15	min	Faster in cones	~5×
	Time for full recovery of visual sensitivity	5	50	min	Faster in cones	~10×

Item C: Comparison of light response properties of human LWS cones and rods. Parameter values are representative, and have been taken from numerous different sources. The parameters with very large cone versus rod differences are shown in bold red. Note that the turnover time for cGMP in cones is effectively much shorter than shown, even for the dim-flash response, because of the combination of the flash-induced activation of PDE within each sac and the calcium feedback loop.

ours, just prior to the '2R' rounds of whole-genome duplication, and (2) to determine the manner in which that cascade became specialized in cones and rods. Thus, we will be examining the co-evolution of components of the cascade, initially in pre-vertebrate chordates, and thereafter in the earliest vertebrates.

Evolution of bilaterian phototransduction cascades

In Figure 25A, the major components of several phototransduction cascades are contrasted, for vertebrate photoreceptors (top), for other ciliary photoreceptors, and for microvillar photoreceptors (103). Each of these cascades appears to have evolved from a common ancestral form.

Co-evolution of cascade components. The co-evolution of molecular components across phototransduction cascades was investigated by Arendt & Wittbrodt (137), who compared the phylogenies of the genes for opsin,

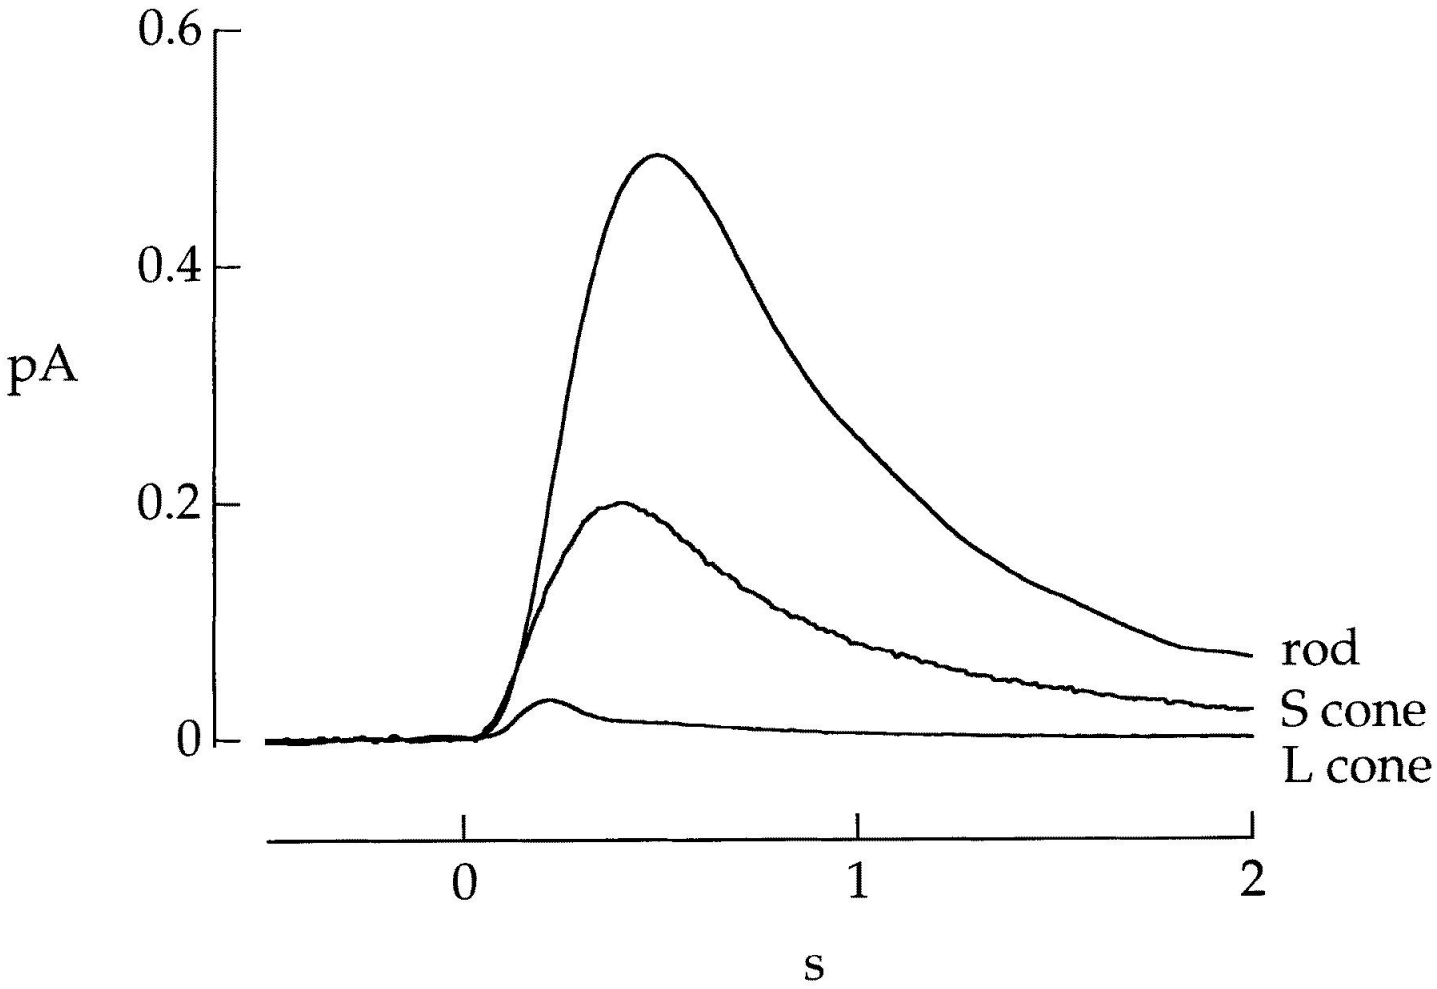

Figure 24. Comparison of single-photon responses in LWS and SWS cones and a rod. Averaged responses to a single photoisomerization in representative dark-adapted photoreceptors of the salamander. The photopigments in these cells are: L cone, LWS; S cone, SWS2; rod, Rh1. The responses reach peak in approx. 200, 400 and 600 ms, and their amplitudes are roughly in the ratio 1 : 6 : 12. From Rieke & Baylor (270).

plus its G-protein, kinase, and arrestin, across protostomes and deuterostomes. They found clear evidence that all four of these components must have been present in the common bilaterian ancestor.

Coupling to G-proteins. The coupling of opsin type with G-protein type was examined by Koyanagi et al (138) and has recently been reviewed by Terakita et al (103). They categorized opsins into four groups according to the G-proteins to which they coupled. Chordate C-opsins couple to Gi/Gt; at least one cnidarian C-opsin couples to Gs; invertebrate 'Go-opsins' couple to Go; while all R-opsins couple to Gq.

Origin of cascades using CNGCs. The evolution of the coupling of opsin via its G-protein to an ion channel was investigated by Plachetzki et al (26, 27). For the downstream effector mechanism, at the level of the cell's electrical response, Plachetzki et al (27) provided evidence that the ancestral cascade had employed CNGCs (cyclic nucleotide-gated channels), as illustrated in Figure 25B. Furthermore, the alternative TRP/TRPL (transient receptor potential-like) channel mechanism appeared to have arisen at a later stage, probably in bilaterians, and was employed in microvillar photoreceptors, where the R-opsin couples via Gq.

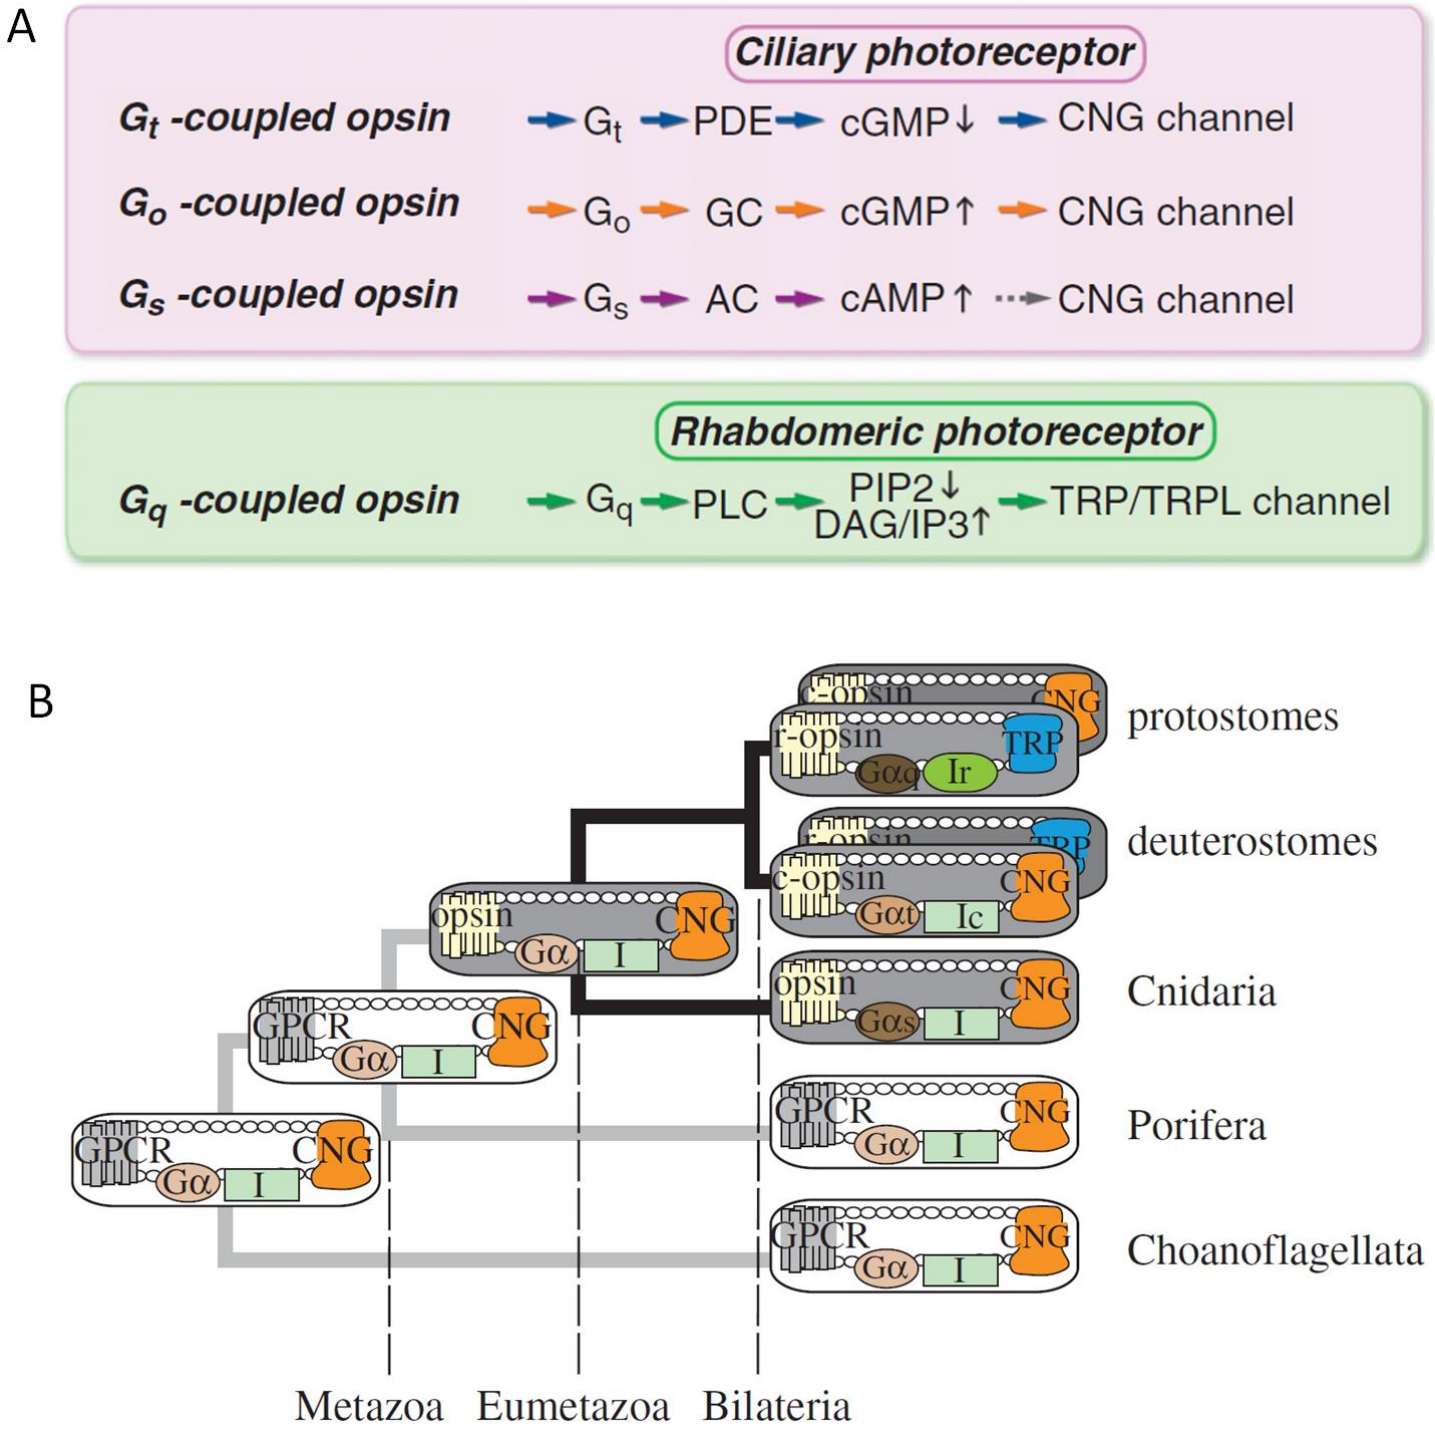

Figure 25. Co-evolution of components of phototransduction cascades. A, Components of the phototransduction cascades in ciliary and microvillar (rhabdomeric) photoreceptors. From Terakita et al (103). B, Sequence of evolution for the components of phototransduction cascades proposed by Plachetzki et al (27). Bottom left: The ancestral (non-photosensitive) G-protein cascade utilized a GPCR that coupled ultimately to a CNG (cyclic nucleotide-gated) channel. Third from left: The mechanism in the ancestral light-sensitive cell was similar. Top right: Early in the bilaterian lineage two variants of this scheme arose, both of which have been preserved in protostomes and deuterostomes. (Note that the obscured rear diagram for protostomes is the same as the front diagram for deuterostomes, and vice versa.) The ancestral mechanism was retained only slightly modified in the ciliary variety of photoreceptors, that expressed C-opsins. But the microvillar variety of photoreceptors, that expressed R-opsins, instead coupled via a Gq G-protein (and unknown intermediaries) to a TRP (transient receptor potential) channel. Additional abbreviations: I, intermediary molecules; Ic, ciliary intermediaries such as phosphodiesterase (PDE) and guanylyl cyclase (GC); Ir, rhabdomeric intermediaries such as phospholipase C (PLC), DAG (diacylglycerol) and PIP2 (phosphatidylinositol-4,5-biphosphate). From Plachetzki et al (27).

Molecular components of the vertebrate phototransduction cascade

The molecular and cellular mechanisms underlying activation and recovery of the (modern) vertebrate phototransduction cascade are dealt with in detail in Webvision 'Phototransduction in Rods and Cones', as well as in numerous reviews, including Lamb & Pugh (139), Wensel (140), Yau & Hardie (126), etc. The principal proteins involved, both in cones and rods, are shown schematically in Figure 26. For an overview of these proteins and their functions, see Wensel (140); for a review of the proteins mediating shut-off of R*, see Gurevich et al (141).

Summary of molecular mechanisms. The molecular mechanisms of phototransduction are almost identical in cones and rods. Photoisomerization of a molecule of visual pigment to its active form R* triggers the catalytic activation of the G-protein (Gt, transducin) to G*, which in turn activates the cGMP phosphodiesterase (PDE6) to E*. The increased hydrolysis of cGMP lowers its cytoplasmic concentration, causing closure of cyclic nucleotide-gated channels (CNGCs). This suppresses the circulating electrical current that had been flowing in darkness, hyperpolarizing the cell; in addition, it leads to lowered cytoplasmic Ca^{2+} concentration through the continued activity of a $Na^{+}/Ca^{2+},K^{+}$ exchanger, and this drop in Ca^{2+} level is important for response recovery. Response shut-off requires inactivation of each of the activated forms, as well as restoration of cGMP levels. R* is rapidly inactivated by the binding of arrestin, but this step first requires the R* to have been phosphorylated by a G-protein receptor kinase (GRK). The G*/E* complex is rapidly inactivated by hydrolysis of the terminal phosphate of the GTP bound to G*, through the action of the GTPase accelerating (GAP) activity of the RGS9-Gβ5-R9AP complex. The drop in Ca^{2+} concentration permits Mg^{2+} to bind to guanylyl cyclase activating proteins (GCAPs), thereby activating guanylyl cyclase (GC), restoring cGMP levels, and hence causing the re-opening of ion channels. This action of Ca^{2+} endows the photoreceptor with a powerful negative feedback loop that helps stabilize the electrical current.

Differences in isoforms and activities between cone and rod proteins

The proteins mediating the light response in cones and rods are closely similar; indeed a few of the proteins are identical in the two classes of photoreceptor, though in most cases distinct but closely related isoforms are expressed, as indicated by the gene names shown in Figure 26 and listed in Item D. A number of online resources exist for examining the genes involved in the eye, and two useful resources are RetinaCentral.org (with the 'retinome', or transcriptome of the retina/RPE; (142)) and RetNet, sph.uth.edu/retnet (with retinal disease genes).

When we come to compare the functional properties of cones and rods in Sections 9 to 11, we will see that it is possible to view the rod transduction cascade as a variant of the cone transduction cascade, in which the main difference is that each of the shut-off steps in the dim flash response has been slowed down. For several of the phototransduction proteins, the expression levels in cones are much higher than in rods, and this probably accounts for several instances of more rapid shut-off of the light-activated molecules. A notable example is the 10-fold higher expression level in cones of the molecular complex RGS9/Gβ5/R9AP that shuts off the activated G-protein, transducin, when it is bound to the PDE. For shutting off activated rhodopsin, cones and rods in many species employ different isoforms of the GRK (G-protein receptor kinase): in cones it is typically GRK7 whereas in rods it is GRK1; in this case, the difference in isoform probably contributes substantially to slowing the shut-off of activated rhodopsin and therefore in increasing the sensitivity of the response (134, 143, 144). For dim flashes the recovery kinetics are also determined by the turnover time in darkness for cGMP, and in rods this turnover time is slowed as a result of a lower basal activity of the rod PDE6 (145).

The overall effects of the differences in activities and expression levels of the different isoforms of phototransduction proteins have been analyzed and modeled by Kawamura & Tachibanaki (134) and Korenbrot (144), who have been able to account well for the observed differences in kinetics and sensitivity between cones and rods.

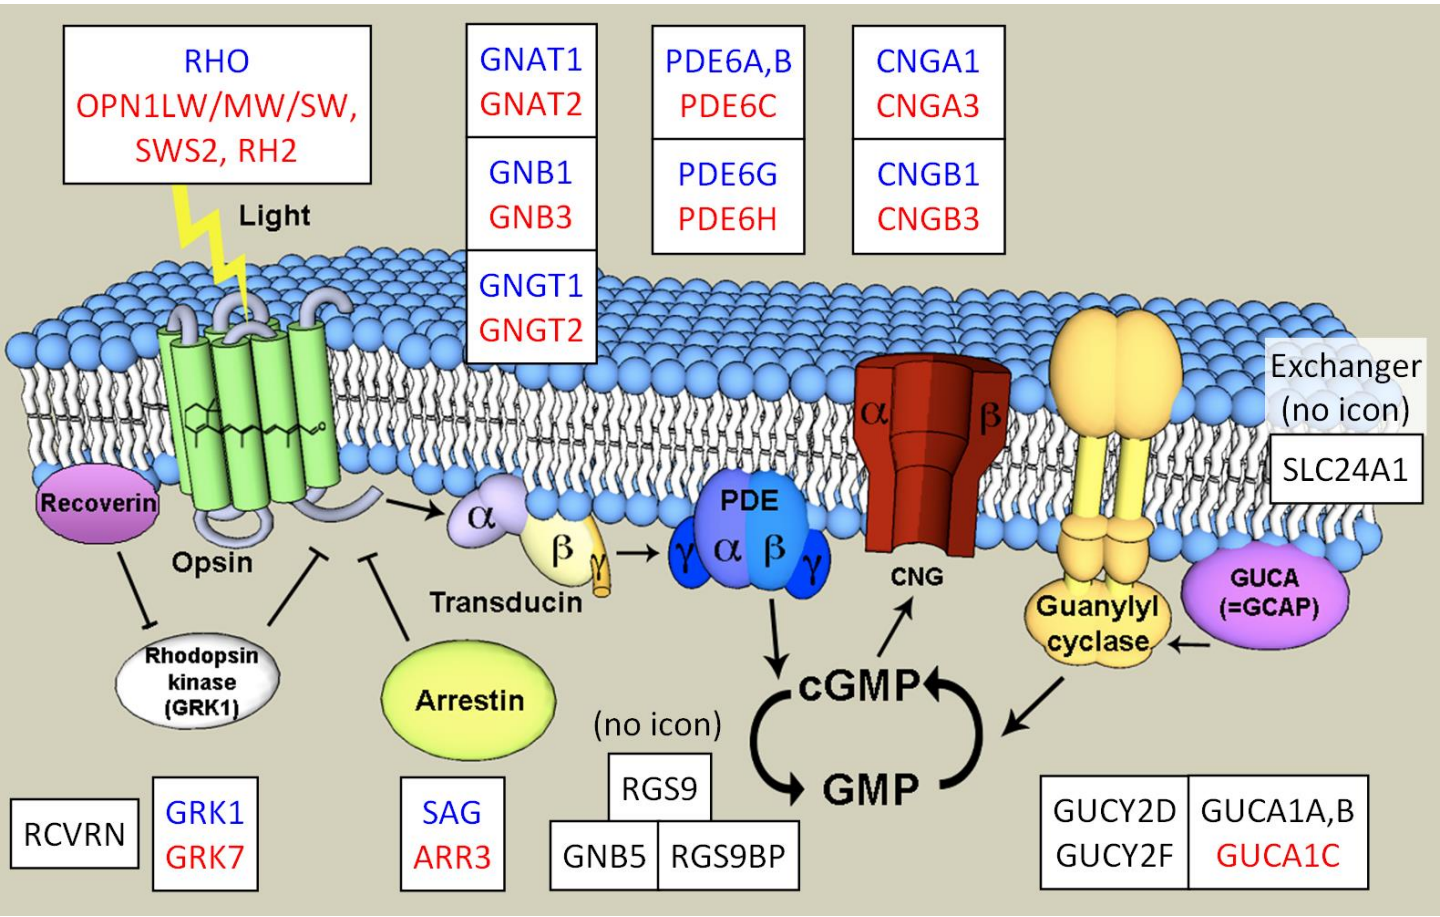

Figure 26. Molecular components of the vertebrate phototransduction cascade. The proteins underlying the activation phase of the phototransduction cascade in a cone are illustrated schematically; because the membrane configuration of a cone rather than a rod is illustrated, the ion channel and ion exchanger are in the same membrane as the other proteins. From Larhammar et al (7). The names of the corresponding genes are listed nearby, with those for activation above and those for recovery and regulation below or to the right. Note, though, that icons for the RGS9/Gβ5/R9AP complex and the Na+/Ca2+,K+ exchanger (SLC24A1) are not included in this diagram. Where there is a clear distinction between expression in cones and rods, the genes are colored red for cones and blue for rods, while black indicates expression in both cones and rods; see Nordström et al (121) for references. A more complete list of the proteins/genes involved in phototransduction, as well as those involved in the recycling of retinoid, is given in Item D. Note that the arrestin gene SAG (retinal S-antigen) is sometimes known as ARR1, and that ARR3 is sometimes known as ARRX. The ion channel is a tetramer, composed of both α and β subunits, and is permeable to monovalent and divalent cations. In cones, it comprises two CNGA3 and two CNGB3 subunits; in rods, it comprises three CNGA1 subunits and a single CNGB1.

Evolution of components of the vertebrate phototransduction cascade

For vertebrate phototransduction, Hisatomi & Tokunaga (146) compared the phylogenies of the genes for eight families of the proteins involved (transducin, PDE, CNGC, GRK, arrestin, recoverin, GC, GCAP). They noted close similarity in the branching patterns of the gene dendrograms, and concluded that each of these families appeared to have evolved 'cone' and 'rod' branches, though in two cases (PDE and GCAP) there had been a further duplication in the rod branch. More recent results, examining the evolution of individual components of the phototransduction cascade, will now be presented.

Transducin. The origin of transducin alpha subunits was investigated by Muradov et al (87), who identified two isoforms in lamprey, that they named GαL and GαS, for their expression in the long (cone-like) and short (rod-like) photoreceptors, respectively. GαL is roughly equally distantly related to cone and rod transducin alpha subunits of jawed vertebrates, and might represent the ancestral form, whereas GαS clades with the rod version, though it retains certain cone-like characteristics such as the presence of the 'hallmark' four-residue sequence

Protein name	Gene name in human	Has role in:	Cell	Protein description
Rh (Rh1)	RHO	Activation	Rod	Rhodopsin
LWS	OPN1LW OPN1MW	Activation	L-cone M-cone	Long-wave-sensitive opsin
SWS1	OPN1SW	Activation	S-cone	Short-wave-sensitive opsin
SWS2	–	Activation	Cone (or rod)	Blue/green-sensitive opsin
Rh2	–	Activation	Cone	Blue/green-sensitive opsin
Gα	GNAT1 GNAT2	Activation	Rod Cone	Transducin α subunit
Gβ	GNB1 GNB3	Activation	Rod Cone	G-protein β subunit
Gγ	GNGT1 GNGT2	Activation	Rod Cone	Transducin γ subunit
PDEα PDEβ PDEα'	PDE6A PDE6B PDE6C	Activation	Rod Rod Cone	PDE6 hydrolytic subunits
PDEγ PDEγ'	PDE6G PDE6H	Activation	Rod Cone	PDE6 inhibitory subunits
CNGCα	CNGA1 CNGA3	Activation	Rod Cone	Cyclic nucleotide-gated channel α
CNGCβ	CNGB1 CNGB3	Activation	Rod Cone	Cyclic nucleotide-gated channel β
GRK	GRK1 GRK7	Recovery	Rod Cone	G-protein receptor kinase
Arr	ARR1/SAG ARR4	Recovery	Rod Cone	Arrestin
Rec	RCVRN	Recovery	Both	Recoverin
RGS9	RGS9	Recovery	Both	Regulator of G-protein signaling 9
Gβ5	GNB5	Recovery	Both	G-protein β subunit 5
R9AP	R9AP	Recovery	Both	RGS9 anchor protein
GC	GUCY2D GUCY2F	Recovery	Both	Guanylyl cyclase
GCAP	GUCA1A,B GUCA1C	Recovery	Rod Cone	GC activating protein
Exchanger	SLC24A1	Recovery	Both	$Na^+/Ca^{2+},K^+$ ion exchanger
at-RDH	RDH8, 12	Retinoid	Both	all-*trans* Retinol dehydrogenase
ABCR	ABCA4	Retinoid	Both	ATP-binding cassette transporter
IRBP	RBP3	Retinoid	RPE	Interphotoreceptor retinoid-binding protein
CRBP	RBP1	Retinoid	RPE	Cellular retinol-binding protein
LRAT	LRAT	Retinoid	RPE	lecithin:retinol acyltransferase
RPE65	RPE65	Retinoid	RPE	Isomerohydrolase, RPE65
11c-RDH	RDH5	Retinoid	RPE	11-*cis* Retinol dehydrogenase
CRALBP	RLBP1	Retinoid	RPE	Cellular retinal-binding protein

Item D: Genes for proteins with known function in phototransduction or retinoid cycling. List of proteins with known functions in activation and recovery of the phototransduction cascade, and in the RPE retinoid cycle. Names of the human genes are given in column 2. Where there is a clear distinction between expression in cones and rods, the genes are colored red for cones and blue for rods, while black (and 'Both') indicates expression in both cones and rods, as in Figure 26 and Figure 27. Not enough is known about the intra-retina retinoid cycle in order to list its components. Many additional proteins have important functions in cones, rods, and RPE cells, apart from involvement in phototransduction and retinoid cycling, but are not listed here. Likewise, numerous other proteins are involved in signal transmission and neural processing within the retina

near the N-terminus. In order to determine the timing of the duplication that gave rise to these two transducin alpha subunits, there is additional information that can be obtained from analysis of the location of genes on chromosomes (see Section 8 below).

Phosphodiesterase. The phosphodiesterase (PDE6) used in vertebrate phototransduction is unique in its ability to be regulated by the gamma subunit (Pγ), and the co-evolution of these two components has been investigated by Muradov et al (86) and Zhang & Artemyev (147). Muradov et al (86) cloned both components from lamprey. For the PDE6 catalytic unit, they found that lamprey has a single isoform (as in cones), with high homology to jawed vertebrate PDE6 catalytic units, though equally distantly related to those of cones and rods, and their results were consistent with the notion that PDE6 arose from a common PDE5/6/11 ancestor in the chordate lineage. They identified a tunicate PDE that grouped with vertebrate PDE6, but they could find no other non-vertebrate sequences grouping with PDE6.

For the regulatory Pγ subunits, they found two isoforms, one cone-like and the other intermediate between cone and rod sequences; no sign of similar sequences was found in tunicate databases. Their evidence suggested that these regulatory subunits arose in the stem vertebrate lineage, and that the common ancestor of lampreys and jawed vertebrates was likely to have already possessed two isoforms. This analysis was extended by Zhang & Artemyev (147) who provided evidence that, although Pγ is a strictly vertebrate invention, the capacity of the PDE catalytic units to bind Pγ predated the emergence of the inhibitory subunit; indeed their analysis predicted that the PDE5/6-like enzymes of cnidaria should interact with vertebrate Pγ.

CNGCs. In cones the cyclic nucleotide-gated channel comprises two α subunits (CNGA3) and two β subunits (CNGB3), configured as A3-A3-B3-B3 (148), whereas in rods the channel comprises three α subunits (CNGA1) and a single β subunit (CNGB1). Nordström et al (121) found strong evidence that the duplication that gave rise to the α and β subunits of the cyclic nucleotide-gated channel took place prior to the divergence of protostomes and deuterostomes, and they also found suggestive evidence that the multiple versions of α and β subunits may have arisen in the '2R' duplications.

GRKs. Mushegian et al (149) have recently investigated the origin and evolution of G-protein receptor kinases (GRKs). They found evidence that GRKs originated prior to metazoa, through the insertion of a kinase (similar to a ribosomal protein S6 kinase) into a loop in a domain with homology to RGS (regulator of G-protein signaling). During chordate evolution an ancestral GRKa split into the GRK1/7 and GRK4/5/6 lineages. Mushegian et al (149) suggest that this coincided with the first round of '2R' whole-genome duplication, though it is possible that the split may have occurred earlier, as an apparently ancestral GRK1/7 is present in the tunicate *Ciona intestinalis.* The results of Larhammar et al (7) (see next Section) suggest that the distinction between GRK1 and GRK7 arose during the '2R' duplications. However, further work is needed to resolve the origin of these isoforms.

Arrestin. The phylogeny of arrestins (including 'visual' arrestin) has been studied by Gurevich & Gurevich (150) and Alvarez (151), and the function of these proteins has been comprehensively reviewed by Gurevich et al (141). Arrestins arose very early in metazoan evolution, with the family comprising both the β-arrestins (named after their interaction with the β-adrenergic receptor) and the 'visual' arrestins, having diverged from a much larger family in pre-bilaterian times (151). A clue to the nature of the much more recent split between vertebrate visual arrestins and β-arrestins has been provided by Kawano-Yamashita et al (152) who reported that the pineal non-bleaching opsin, parapinopsin, appeared to be inactivated by a β-arrestin through a process of internalization (as in other β-arrestins). They noted that *Ciona intestinalis* photoreceptors apparently use a β-arrestin, and they proposed that the vertebrate-style visual arrestin had evolved specifically for use in shutting-off opsins that release their retinoid; i.e. specifically in the case of vertebrate visual opsins.

Chromosomal arrangement of phototransduction genes

The paralogon arrangement of the opsin genes was presented in Section 6. Here we consider the results of Larhammar et al (7) relating to the paralogon arrangement of other components of phototransduction.

Transducin alpha subunits. Interestingly, Larhammar et al (7) showed that the gene for the transducin alpha subunits was in the same paralogon as the opsins, and close by (see Figure 23). Recently, Lagman et al (153) have combined an analysis of the gene arrangements for each of the three subunits of the trimeric transducins with sequence-based analyses, and they have provided evidence that all three families of transducin subunit expanded during the early vertebrate tetraploidizations. They concluded that the early vertebrate tetraploidizations provided the basis for the subsequent specialization of transducin subunits leading to differential expression between cones and rods.

The original GNAT gene may have arisen by duplication within the deuterostome lineage of the ancestral GNAI/GNAT gene present in bilaterians, as some protostomes have homologs of GNAI, but none have homologs of GNAT; alternatively, the duplication could have occurred earlier, but with GNAT being lost in protostomes.

Other components of the phototransduction cascade. Larhammar et al (7) also found apparent remnants of a paralogon arrangement in a local grouping of the genes for the transducin beta subunits, for the GRKs, and for the arrestins (their Fig. 5). In addition they found evidence for '2R' expansion of the genes for PDE6, and for both the alpha and beta subunits of the CNGC channel, as well as for arrestin and the GRKs.

Interpretation. For many of the proteins involved in the phototransduction cascade, there is a difference (either partial or complete) in the distribution of isoforms between cones and rods, and for at least 10 of the 13 protein components studied by Larhammar et al (7) the differentially-distributed isoforms arose as a result of the '2R' duplications at the base of the vertebrate lineage. Accordingly, there seems little doubt that much of the distinction between the cone and rod transduction cascades can be traced to the reduction in constraints on gene mutation that resulted from the two whole-genome duplications.

Hypothesized nature of pre-vertebrate ciliary photoreceptor and transduction cascade

From the available evidence, it does not yet seem feasible to paint a scenario for the detailed sequence of events that transformed an ancestral bilaterian photoreceptor into a vertebrate photoreceptor. However, it is possible to propose the following for the state that had been reached, in the evolution of the 'proto-cone' photoreceptor and its phototransduction cascade, just prior to the '2R' whole-genome duplications that occurred near the base of the vertebrate lineage:

F-1) The ancestral cone opsin of the 'proto-cone' photoreceptor was broadly similar to modern pinopsin and SWS and LWS cone opsins, and in particular it had evolved a high efficacy of activation of the G-protein.

F-2) Duplication of that ancestral cone opsin created a pair of retinal cone opsins: an SWS opsin with the standard E181 residue, and an LWS opsin with the H181/K184 combination that provided a chloride-binding site giving a substantially red-shifted absorption. The SWS and LWS opsins were expressed in separate, but closely similar, cones. The output signals from those cones could potentially have been utilized to provide dichromatic color vision.

F-3) The primary additional proteins involved in activation of the cascade had evolved to become: (*i*) the ancestral transducin Gt, with unique alpha, beta and gamma subunits; (*ii*) the ancestral PDE6 cyclic GMP phosphodiesterase, comprising a pair of identical catalytic subunits and a pair of identical regulatory (gamma) subunits; and (*iii*) a tetrameric cyclic nucleotide-gated channel composed of two classes of subunit, alpha and beta.

F-4) The Gαt had probably arisen from a common ancestral Gαi / Gαt during chordate evolution. The PDE6 had arisen from a common ancestral PDE5/6/11 during chordate evolution. The PDE regulatory subunit had arisen late in chordate evolution, after the divergence of tunicates (i.e. after #4 in Figure 1).

F-5) The primary proteins involved in response recovery and regulation had evolved to become the ancestral 'cone' components, specified by the genes GRK7, ARR3, RGS9, GUCY2D/F, GUCA1C, SLC24A1 and RCV1, in addition to the cone opsins themselves.

F-6) The presence of all these components suggests that response shut-off occurred in a manner fundamentally similar to that in modern vertebrate photoreceptors.

F-7) In particular, the co-existence of the components required for the Ca^{2+} feedback loop (GUCA1C, GUCY2D/F, CNGA3/B3) provides strong circumstantial evidence that the negative-feedback loop that stabilizes the circulating current, and assists in light adaptation, was already present.

F-8) All the components of the transduction cascade were expressed in the membranes of the lamellar sacs that radiated laterally from the cilium of the proto-cone.

F-9) Because of the release of all-*trans* retinoid from activated opsin, the photoreceptor's outer segment required a source of 11-*cis* retinoid, and this may have been provided by the glial (Müller) cells.

F-10) The cell had evolved a simple glutamatergic synapse, permitting synaptic transmission.

9. Cones: Photoreceptors with exceptional performance

Cones exhibit high sensitivity, high speed, and high contrast sensitivity

High sensitivity. Despite frequent claims to the contrary, cone photoreceptors are highly sensitive, and the amplification of transduction appears to be quite similar to that of rods. Indeed, when one views a dim star at night, it is the cones (and the photopic system) that detect the star. For example, in viewing the Pleiades (Seven Sisters), although one will be aware of the cluster as a blur in the parafoveal field by means of scotopic vision, when one fixates the individual stars then it is the cones that are detecting them. The rod system is much better for the diffuse cluster, because of its wide spatial summation, but the cone system is better at detecting individual stars, because of its higher spatial resolution. The sensitivity of individual cones is sufficient to detect quite dim stars, though for very dim stars one may be better off using parafoveal rod vision.

High-speed response. The speed of response in cone photoreceptors is far higher than in rods, and this speed increases with increasing background intensity. In bright illumination, the human photopic visual system is able to resolve sinusoidal or square-wave flicker at frequencies of around 100 Hz (154), for which the brighter/dimmer periods are ~5 ms each. Thus, it seems that light-adapted cones are able to generate a resolvable signal when the illumination is extinguished for as short a duration as about 5 ms.

High contrast sensitivity. The human photopic (cone) system is able to detect very small fractional changes in intensity. Thus, under light-adapted conditions, an observer can detect a contrast of 0.5%; for comparison the contrast sensitivity of the scotopic (rod) system is at least an order of magnitude poorer, at >5%.

Hence, the cone system is extremely sensitive, extremely fast, and it has excellent contrast sensitivity.

Avoidance of saturation by cones: Unlimited upper operating intensity

In contrast to rod photoreceptors, which saturate at quite low intensities, cone photoreceptors are remarkable for their ability to function well during steady illumination - no matter how intense that steady background is made (155, 156). Although cones may saturate transiently at the onset of intense illumination, they rapidly recover and are able to signal increments and decrements, even when the illumination is so bright that it bleaches a large

proportion of the photopigment. To account for this, Lamb & Pugh (139) compared the shut-off reactions in human cones and rods; they showed that the ability of the cones to avoid saturation can be explained in terms of the combination of the ~20-fold faster shut-off of the activated cone photopigment, and the ~20-fold faster shut-off of the activated cone Gt/PDE complex.

In human rod photoreceptors *in vivo,* the circulating current is halved at a steady intensity of ~70 scotopic trolands (600 $R^* s^{-1}$), with complete saturation occurring at ~1000 scotopic trolands (~10^4 $R^* s^{-1}$). If the activation gain of transduction is comparable in human cones and rods, then the two very short cone time constants would elevate the intensities required for half and full saturation by some ~400×, to levels of ~240,000 and ~4×10^6 $R^* s^{-1}$ in cones. Two additional factors are that the gain of transduction may be slightly lower in cones, and that the cGMP-gated channels of mammalian cones (in contrast to those of rods) show increased affinity for cGMP when Ca^{2+} falls (157); these factors would further increase the R* rate required to saturate the cone. Now, the highest *steady* rate of photoisomerization that can ever be reached in a human cone, *by exposure to steady light,* corresponds to the maximal rate of pigment regeneration, which has been shown by Mahroo & Lamb (158) to be 0.75%/s, which in a cone containing 40 million molecules of cone opsin corresponding to ~300,000 $R^* s^{-1}$. Hence, this maximum possible rate of steady photoisomerizations is lower than the isomerization rate calculated above to be needed to saturate the cone, meaning that the cone can never be saturated by steady light.

A more intuitive way of understanding this is to say that very high steady intensities cause the cone opsin to bleach to a level low enough to prevent saturation of the response by the steady light. As a result, the photopic visual system is able to function over (i.e. to adapt to) an enormous range of intensities, from moon-lit conditions to the brightest sun-lit scenes.

Extremely rapid recovery of cone circulating current

When the human eye is exposed to steady light sufficiently intense to bleach 90% of the photopigment in the rods, full recovery of the rod circulating current takes around 20 mins after extinction of the light (159). In contrast, a steady light that bleaches 90% of the LWS/MWS cone photopigment does not saturate the cone response (see above), and around half the circulating current remains. Upon extinction of that light, the cone circulating current recovers fully within ~20 ms, around 60,000-fold faster than for the rod (136).

As in the case of the cone's avoidance of saturation, the molecular mechanisms that enable this extremely rapid recovery of circulating current lie in the rapidity of the inactivation steps. Kenkre et al (136) estimated that in the presence of bright light the time constants for the shut-off reactions were as follows: for R*, ~5 ms; for G*/E*, ~13 ms; and for cGMP turnover, ~4 ms. Using these parameters in a simple model of cGMP kinetics and channel activation, they were able to accurately fit their experimental measurements of the time-course of recovery of cone current. In rods, the extremely slow recovery of current is caused not by the slowness of inactivation/shut-off steps in the G-protein cascade, but instead by the slowness of the regeneration of visual pigment, combined with the fact that unregenerated opsin activates the cascade; for a full account of this slow recovery, see Lamb & Pugh (160).

Morphological features required by a cone

The operational requirements of cone photoreceptors place certain constraints on the morphological features of the cells.

High surface to volume ratio of outer segment. In order to achieve rapid response kinetics, all the recovery reactions must be fast, including the Ca^{2+}-mediated acceleration of guanylyl cyclase activity that permits rapid re-opening of the cyclic nucleotide-gated ion channels. This means that the time constant for equilibration of cytoplasmic Ca^{2+} concentration (τ_{Ca}) must be short. In mammalian (including human) cones, τ_{Ca} has been estimated as ~3 ms (161, 162), in contrast to its value in amphibian rods of the order of 400 ms or more.

Simulations showed that if τ_{Ca} was not kept as short as the longest of the other shut-off time constants, then the responses became strongly biphasic or even oscillatory.

Straightforward analysis shows that τ_{Ca} should be inversely proportional to the activity of the $Na^+/Ca^{2+},K^+$ exchanger, but directly proportional to cytoplasmic volume (see eqn 15 of Lagnado et al (163)). Accordingly, a high surface-to-volume ratio for the outer segment, that allows a large number of molecules of exchanger per unit volume of cytoplasm, will provide a short time constant τ_{Ca} for Ca^{2+} and will therefore be advantageous for cones. In addition, the calcium buffering power of the outer segment will need to be kept low for cones.

Function of open sacs. The above requirement for a high surface-to-volume ratio no doubt provided a powerful driving force for the opsin-containing membrane of cones to remain in contact with the extracellular medium, and hence for the outer segment membrane not to seal over in the way it does in rods. In LWS cones, an additional driving force for the retention of open sacs may relate to the chloride-binding site, H197 (=H181 in the bovine rhodopsin frame), that confers a substantial red-shift in spectral sensitivity. This site is in the second extracellular loop, and in order to provide a high (and stable) chloride ion concentration on this side of the membrane, it is probably necessary for this region to remain extracellular, instead of transforming to become intradiscal as occurs in the discs of rods.

The existence of the sac structure in cone photoreceptors would appear likely to restrict both the membrane-based reactions and the cytoplasmic reactions resulting from a single photoisomerization to the domain of just a single sac; this could conceivably be either advantageous or disadvantageous, depending on the response property under consideration.

Synaptic release constraints. In order for cone photoreceptors to be able to transmit their graded (i.e. analog) signals rapidly, it is essential that the rate of release of synaptic vesicles be extremely high. This is necessary because the post-synaptic signal needs to be detected above the noise that is intrinsic to the quantal release of neurotransmitter vesicles. In order to be able to detect a change of (say) 1% in the release of vesicles, it is necessary that the mean number of vesicles released should be of the order of $1/(0.01)^2$, or 10,000. And in order for this to be achievable in (say) 100 ms, the rate of vesicle release would need to be around 100,000 vesicle s^{-1} which is enormously high. Accordingly, the cone's synaptic terminal requires a very large area for the active release zone, in order to achieve this kind of rate of vesicle release. For comparison, in a rod the response to a single photoisomerization is considerably larger than the cell's baseline noise, so that it may be adequate to be able to detect a change of the order of (say) 10%; in addition the rod's response is a much slower than the cone's. Hence, a far lower rate of vesicle release (and hence a smaller synapse) would suffice to provide a sufficiently reliable post-synaptic signal from a rod.

Scenario for the refinement of vertebrate phototransduction in cones

The following scenario is proposed for the refinement of the phototransduction cascade in chordate ciliary photoreceptors, that occurred during the early evolution of the vertebrate retina:

G-1) By the time that the chordate lateral retinas began signaling spatial (i.e. visual) information (see Section 17) there was great evolutionary pressure for rapid responses, for high sensitivity, for the ability to adapt to different intensities, and for high contrast sensitivity.

G-2) Those pressures led to acceleration of each of the recovery steps in the cascade; i.e.: shut-off of activated opsin, shut-off of G-protein/PDE, turnover time for Ca^{2+} concentration, and Ca^{2+} feedback to the re-opening of ion channels.

G-3) To compensate for the reduced sensitivity that would inevitably have accompanied the faster responses, there would have been a continuation of the pressure for increased efficacy of activation of the G-protein by the activated opsin.

G-4) Given the existence of multiple classes of cone, not all of these needed to be equally fast or equally sensitive. The systems with shorter wavelength (and hence more thermally stable) opsins could afford to become slower, in order to achieve higher sensitivity. The LWS system, with its high intrinsic noise, was better suited to achieving the fastest performance.

G-5) In response to the intense pressure to be able to transmit responses rapidly, and also to be able to signal small changes in light level (low contrasts), changes took place in the synaptic terminal that led to very high rates of release of synaptic transmitter. In this way, even brief and small changes in cone intracellular voltage led to changes in post-synaptic transmitter concentration that could be detected above the noise inherent in the vesicular nature of release.

G-6) By the time that the first (jawless) vertebrates evolved, their lateral retinas possessed five spectral classes of cone photoreceptor that exhibited exceptional responses properties, broadly similar to those of modern vertebrate cones.

10. Noise: Thermal isomerization and other sources of noise

This Section examines sources of noise (fluctuations) in the responses of photoreceptors, beginning with intrinsic properties of the opsins and then within the transduction cascade.

Thermal isomerization of cone opsins and rhodopsin

In considering the differences between cones and rods, one major disparity relates to the level of noise: LWS cones are many orders of magnitude noisier than rods (Item C). Here we will examine the extent to which this difference in noise is a function of the stability of opsin molecules with different peak wavelengths.

More than 60 years ago, Stiles (164) developed a model describing the long-wavelength decline in spectral sensitivity of visual pigments, later expanded by Lewis (165), invoking the concept that the thermal energy of vibration in the molecule could add to the energy of a photon in order to trigger activation. Barlow (166) extended this concept, with the proposal that spontaneous thermal activation could occur, at a very low rate, even in the absence of light, and he predicted reduced stability (greater noise) for pigments of longer wavelength. Barlow's prediction has been borne out in numerous experimental studies (167, 168), and theoretical models of varying complexity have been proposed to account for the exact relationship between peak wavelength and rate of thermal activation (165, 168-170).

One important observation is that 'cone' opsins can be incredibly stable, and this is most obvious when that particular opsin is expressed in a rod. In amphibia, the so-called 'green rods' (that absorb in the blue, and hence appear green) express a blue-sensitive pigment, which has been shown to be the SWS2 opsin that is also expressed in blue-sensitive cones in the same retina (171). Early electrophysiological experiments showed that green rods of the toad exhibit a very low rate of spontaneous thermal isomerizations (172), and more recent experiments have shown this rate to be amazingly low, at $<10^{-14}$ s^{-1} at 23 °C (168). This means that the SWS2 (cone) pigment, when expressed naturally in a toad rod, only activates spontaneously on average once every ~10^{14} s, or ~4000 years. Thus, this 'cone' pigment is the most stable of all known opsins, including conventional rhodopsins!

Cones: Dark noise

Intracellular voltage recordings from LWS cones in turtle have shown very high levels of noise (173). Usually, this noise is reduced in amplitude by the 'averaging out' that results from the extensive lateral spread of signals across the electrically coupled network that is created by the gap junctions that link neighboring cones (174). But in a cone that is not coupled to its neighbors (an 'electrically isolated' cone), the observed amplitude of dark noise, of around 3000 μV peak-to-peak, is truly enormous when compared with the mean single-photon

response amplitude of only 25 μV, and utterly precludes the resolution of individual photon events. Calculations indicate that this dark noise is equivalent to the quantal fluctuations that would be produced by a real light of a little over 2000 photoisomerizations s^{-1}; this parameter is termed the 'dark light' experienced by the cone. Experiments with backgrounds showed that application of a real light of this intensity roughly halved the flash sensitivity of the cone. Subsequently, in intracellular measurements from macaque LWS/MWS cones, Schneeweis & Schnapf (175) found dark noise that they calculated to be equivalent to >3000 R^* s^{-1}per cone.

The source of these dark fluctuations in the intracellular voltage of LWS cones has not been established. In turtle cones, a significant contribution would be expected to come from thermal activation of the opsin (see above), because the wavelength of peak absorption is exceptionally long, at around 620 nm; indeed this appears to be the longest known wavelength of peak sensitivity of any opsin. If all the dark noise originated from thermal isomerizations, then the cone's opsin content of ~10^8 molecules divided by the event rate of 2000 s^{-1} would yield a mean thermal lifetime of 0.5 × 10^5 s, which is not far from the prediction of Luo et al (168); their Fig. 4C) for a cone opsin of this wavelength. In addition to photopigment noise, the transduction process is also expected to contribute noise (see below). And finally, the chattering activity of ion channels in the synaptic terminal should contribute additional noise. To date, the relative contribution of these potential sources has not been evaluated. One way to investigate the contributions would be to use suction pipette experiments, though a potential drawback is that separation of the cone outer segment from its normal enmeshment amongst the processes of the RPE cells might conceivably alter the cone's performance compared with that in the intact retina.

Rods: Transduction noise and variability of the single-photon response

Transduction noise in rods. In rods, it is possible to separate noise in the transduction process (and subsequently) from the noise caused by thermal isomerization of rhodopsin, because of the fact that the spontaneous photon-like events are individually resolvable (at least, under dark-adapted conditions). In dark-adapted toad rods, Baylor et al (176) reported that the residual 'continuous' noise corresponded to shot events with an amplitude around 1/400 of the single-photon event and occurring randomly at a mean rate of around 6000 events s^{-1}. In functional terms, this source of noise can be considered low, simply on the basis that the great majority of single-photon responses are resolvable despite its presence. It seems likely that the proteins of the rod transduction cascade have evolved greater stability against spontaneous activation than have those of the cone cascade, as exemplified by the results of Muradov et al (145) for PDE6, which showed that the rod form has a lower basal hydrolytic activity in conjunction with a weaker affinity for transducin (see also Section 8).

Variability of the rod single-photon response. Despite the contrary view that is painted in most publications on the subject, the single-photon response of rods is quite variable, especially in terms of its time-course, yet most authors describe the kinetics as 'reproducible'. For toad rods, Whitlock & Lamb (177) illustrated the wide variability in time-course of the single-photon response visually, by matching individual responses that began rising with a similar slope, and showing how different the peaks and falling phases could be. When they estimated the variation in a single shut-off step that was needed to account for the experimental measurements, they found a coefficient of variation (standard deviation divided by mean) of ~0.4. This is sufficiently high that it is not reasonable to describe the quantal responses as exhibiting 'reproducible' kinetics. The substantial variability in time-course, and also in amplitude, is a perfectly normal (and expected) feature of the known shut-off steps in the rod photoresponse, and has been accurately modeled by Hamer et al (178, 179) and Gross et al (180).

Magnitude of the rod single-photon response. It has recently been shown that mouse rods in the retinal slice preparation exhibit considerably larger single-photon responses than reported previously using the suction pipette approach, with mean amplitudes of 2-3 mV in cells with ~20 mV maximal responses (181). With a single-photon response as large as this, reliable synaptic transmission of that response to rod bipolar cells is far less problematic than has frequently been suggested in the literature.

11. Rod specializations and the origin of rods

As discussed in Section 7, the defining feature that distinguishes a rod photoreceptor from a cone photoreceptors is its ability, under dark-adapted conditions, to respond reliably (i.e. with good signal-to-noise ratio) to the absorption of individual photons of light (131, 132). Although numerous differences between cones and rods have been catalogued, in terms of morphology, molecular components, and response properties, there has never been a compelling account of what it is that enables vertebrate rods to achieve their photon-resolving performance.

This Section first analyzes structural features that contribute to the ability of rods to reliably signal individual photoisomerizations. It then examines two unusual types of 'rod': those of the nocturnal gecko, where the photoreceptors exhibit rod-like properties, yet are relatively recently descended from cones; and those in the all-rod retina of the skate, where the rods exhibit certain cone-like properties. Thereafter the emergence of rods in early vertebrates is considered, and finally a scenario is painted for the evolution of rod photoreceptors.

Structure as a factor in the rod's ability to signal individual photoisomerizations

In order to achieve a single-photon response amplitude of reasonable amplitude (say 5% of the circulating dark current), ion channels must be affected over a moderate length of the outer segment, and this necessitates longitudinal spread of the cytoplasmic messenger cGMP along the outer segment. The situation in a typical cone, where the cytoplasmic message is restricted primarily to the interior of a single sac during the short duration of the cone response, cannot provide a single-photon signal of more than 1/N of the circulating current, where N is the number of sacs in the outer segment (typically >500).

More effective longitudinal spread (a higher longitudinal diffusion coefficient) can be achieved by increasing the cross-sectional area available for longitudinal diffusion, as was originally modeled by Lamb et al (182). In a cone outer segment, only a tiny proportion of the circumference of the sac is available as an intracellular route for longitudinal communication, and hence the effective longitudinal diffusion coefficient is low. But, by enclosing the sac membranes within the plasma membrane, through the formation of pinched-off discs, then essentially the entire circumference is available as a longitudinal conduit. The longitudinal diffusion coefficient can be further increased by the use of one or more incisures (longitudinal infoldings of the outer segment membrane), as this will increase the total length of the gap that encircles the discs, and hence will increase the cross-sectional area of the cytoplasmic path along the outer segment.

In the large rods of toads, Lamb et al (182) measured the longitudinal spread of activation to have a length constant of the order of 3 μm at the time of the peak of the single-photon response, and they measured the steady-state spread of desensitization during light adaptation to have a length constant of around 6 μm. Subsequent studies have confirmed and extended these observations to mammalian rods.

With this extent of longitudinal spread of cytoplasmic messenger in the outer segment, the rod is readily able to achieve an amplitude for the single-photon response of 5% of the circulating dark current (provided that its shut-off reactions have been made sufficiently slow). The effect of such longitudinal diffusion on the time-course of the single-photon response was modeled by Lamb & Pugh (70); their Appendix B).

Nocturnal gecko: Cones exhibiting rod-like properties

The photoreceptors of nocturnal species of gecko provide an important test of what is needed to make a 'rod', because in essence they are cones with a few rod-like features, yet they exhibit rod-like response properties. Walls (183, 184) proposed that the photoreceptors of nocturnal geckos had been 'transmuted' from cones into rods. He suggested that extant geckos were derived from a diurnal ancestor that had possessed an all-cone retina

(i.e. one from which the rods had been completely lost). He suggested that nocturnal species of gecko had adapted by evolving rod-like outer segments, while retaining other morphological features of cones together with the organization of an all-cone retina. In more recent literature, most authors have referred to the retina of the nocturnal gecko (e.g. *Gekko gekko*) as being 'all-rod', and the photoreceptors as being 'rods', but this is *not* the case (see below).

Light responses. Intracellular recordings of light responses were made from photoreceptors of *Gekko gekko* by Kleinschmidt & Dowling (185), who reported response properties broadly similar to those found in the rods of other species. The responses to dim flashes had a slow time-to-peak, of around 700 ms at 25 °C. Although those responses appeared very sensitive (and hence rod-like), I have not been able to extract a quantitative value for their sensitivity. The family of responses to flashes of increasing intensity is reminiscent of rod families. The response to a bright flash had an amplitude of ~20 mV, and exhibited a rapid sag from a peak to a plateau; this sag was eliminated by treatment with 100 mM aspartate, suggesting that it arose through feedback from horizontal cells; if so this aspect would be cone-like rather than rod-like, because rods typically display a rapid sag originating in the inner segment. In the presence of steady backgrounds, the photoreceptor's response light-adapted, over a range of ~4 $\log_{10}$ units, before saturating; such saturation is rod-like.

Rispoli et al (186) reported voltage-clamp electrical recordings from isolated outer segments of *Gekko gekko* photoreceptors, that had been detached at the connecting cilium and then dialyzed with an energy-rich intracellular solution. The mean dark current was ~67 pA, and the family of responses to flashes of increasing intensity was remarkably similar to that seen in rods of other species. Responses to dim flashes had a time-to-peak of ~1.1 s at 17 °C, with kinetics of the form reported for rods. The dark-adapted flash sensitivity was calculated (from intensity measurements) to correspond to a single-photon response amplitude of ~0.8 pA, while fluctuation analysis (ensemble variance divided by mean) gave a marginally smaller value of ~0.6 pA. This indicates that the single-photon response corresponded to ~1% of the dark current, far larger than in conventional cones though somewhat smaller than in most rods.

Taken together, the results of these two studies indicate that the electrical responses of *Gekko gekko* photoreceptors to illumination exhibit predominantly rod-like properties, though the amplitude of the single-photon response may not be as large as in true rods of other species.

Photoreceptor morphology. In an ultrastructural study, Röll (187) showed conclusively that almost every morphological feature of the photoreceptors of nocturnal geckos is actually cone-like, confirming the original view of Walls (183, 184), and contradicting more recent assertions that they are rods. The only features that are rod-like relate to the outer segment, and are: (1) the large size of the outer segment, (2) the existence of outer segment 'discs' that for the most part are enclosed by the plasma membrane, and (3) the existence of an incisure. The cone-like features that she demonstrated in the photoreceptors from all species of gecko studied (both nocturnal and diurnal) were as follows: the connecting cilium was short; the inner segment contained a glycogen-rich paraboloid, and an ellipsoid (with oil droplets in diurnal species); the nuclei contained dispersed chromatin; and the synaptic terminals closely resembled cone pedicles. She concluded that "the retinae of nocturnal geckos have definitely to be classified as cone retinae".

The disc-like structure of the photoreceptor outer segment in the nocturnal gecko had previously been reported by Yoshida (188), and the study of Röll (187) was in close agreement. Yoshida (188) stated that "as in other vertebrate rods, the stack of double membrane discs of the outer segment of the photoreceptor cells in the retina of adult [nocturnal] geckos is enclosed by the plasma membrane, except for the proximal zone of the outer segment". Both studies found the great majority of discs to be enclosed by plasma membrane, but both also reported frequent cone-like openings to the exterior, scattered along the length of the outer segment. Both also reported the existence of one (or rarely two) rod-like incisures.

Gekko opsins. The differences between cone and rod opsins were presented in Section 6. The two primary opsins of *Gekko gekko* have been shown to clade with the LWS and Rh2 cone opsins of other vertebrates, and to exhibit cone-like biochemical properties (189). In particular, the gecko Rh2 opsin has the Q122 and P189 that have been reported to underlie the cone visual pigment properties of fast meta II decay and fast pigment regeneration (92), Section 6).

Gecko phototransduction cascade. The proteins of the transduction cascade in *Gekko gekko* were investigated by Zhang et al (190) and, in all the proteins that they were able to identify, the sequences were cone-like rather than rod-like; those identified proteins comprised the α subunit of Gt (GNAT2), the catalytic and inhibitory subunits of the PDE6 (PDE6C and PDE6H), the α subunit of the cyclic nucleotide-gated channel (CNGA3), and arrestin (ARR3). Although these proteins were predominantly cone-like, a few residues were identified as being rod-like. On the other hand, in measuring expression levels and activities, they found that RGS9 was expressed at the low level expected for rods rather than the high level characteristic of cones, and the resulting GAP activity was correspondingly low; likewise, the low dark basal activity of the PDE was typical of rods rather than of cones.

Taken together, these results on the opsin and the cascade appear to indicate that the proteins of *Gekko gekko* photoreceptors are overwhelmingly cone-like, but that the expression levels and/or activities of at least two of the proteins that are important in generating slow responses (GAP activity and basal PDE activity) are instead rod-like.

Skate: Rods that can exhibit cone-like properties

Some deep-water species of skate have been shown to possess pure rod retinas, but their rods are able to function in a cone-like manner at intensities that would normally saturate rods (191). The outer segments of the rods in these species have all the morphological and other features of classical rods, in terms of large cylindrical outer segment, sealed-off discs, microspectrophotometric peak at 500 nm, and band-like incorporation of labeled amino acid. On the other hand, the ultrastructure of the synaptic terminal is intermediate between that of conventional rods and cones, with multiple synaptic ribbons and contacts at both invaginating and flat contacts (192).

The electrical responses of these cells were recorded by Dowling & Ripps (193) using the aspartate-isolated trans-retinal potential from the isolated retina, which reflects photoreceptor activity. Under dark-adapted conditions the electrical responses closely resembled those of conventional rods. Furthermore, application of steady background illumination led to saturation at relatively low intensities, as in other rods. However, when these backgrounds were left on for extended periods the rods slowly recovered and were able to respond to incremental stimuli. For backgrounds of moderate intensity, a steady state of adaptation was reached within 5-10 min, but for more intense backgrounds the rods took 20 min or more to recover from saturation and to reach a steady adaptational state. Those findings from trans-retinal recordings were subsequently confirmed by suction pipette recordings from skate rods, under dark-adapted conditions and at a single moderately bright background intensity (194). The suction pipette measurements showed that the acceleration of the flash response that occurs when the cell recovers from the initial saturation involves speeding-up of each of the shut-off reactions, in much the same way as occurs in a conventional rod exposed to steady backgrounds or to temperature changes.

These results are consistent with the notion that rods in the skate all-rod retina function as conventional rods under fully dark-adapted conditions and in dim illumination. However, upon exposure to brighter steady backgrounds, the skate rods initially saturate but then recover after tens of minutes and display adaptational properties that are reminiscent of those of cones. Hence it would appear that, in this retina that lacks cones, the rods have become modified in a way that permits them to slowly change their response properties from rod-like to somewhat more cone-like. At present, the cellular and molecular mechanisms that enable this transition are not known.

In a conventional 'duplex' retina, containing both rods and cones, there is no need for the rods to function at moderate to high background intensities. Indeed, there is a distinct advantage in the rods becoming saturated at the intensities at which cones operate, because this reduces the metabolic load on the outer retina and permits the oxygen tension to be maintained at a reasonable level for the cones. But in the all-rod skate retina, it seems that the rods have had to forgo this energy-saving trick in order to enable the animal to continue to see at intensities that would otherwise be blinding.

What is needed to make a 'true rod'?

In light of the results presented in Section 10 and up to here in Section 11, the following interpretations are drawn regarding the crucial features that are needed to make a 'true rod', defined as one that reliably signals the occurrence of individual photoisomerizations, as distinct from a photoreceptor with cone-like properties:

H-1) First, the photoreceptor needs to express an opsin with a peak spectral sensitivity shorter than about 520 nm, in order to achieve a sufficiently low rate of thermal isomerizations; hence, LWS opsins are effectively ruled out.

H-2) The amplification of the phototransduction cascade does not need to differ significantly from that in a conventional cone.

H-3) One essential change is that all of the shut-off reactions underlying recovery of the dim-flash response need to be slow enough that the response to a single photoisomerization can build up sufficiently to suppress at least 1% (and preferably more) of the circulating dark current.

H-4) In comparison with typical cone shut-off, the required slowing necessitates concerted changes that: (1) slow the shut-off of R*; (2) slow the shut-off of G*/E*; (3) slow the cGMP turnover time in darkness; and (4) slow the Ca^{2+}-mediated negative feedback loop so that the recovery of cGMP levels and the re-opening of ion channels are slowed. It is not crucial whether these changes are achieved by alteration in the activities of the proteins, or by altered expression levels.

H-5) The way that this slowing was actually achieved appears to have included: slowing the rate at which the GRK and arrestin could phosphorylate and bind to R*; slowing the GAP activity by lowering the concentration of the RGS9 complex; and slowing the cGMP turnover time in darkness by lowering the basal activity of the PDE6.

H-6) Secondly, the cytoplasmic messengers (cGMP and Ca^{2+}) need to be able to diffuse substantial distances axially along the outer segment, and this requires a significant change in outer segment morphology: the sac membranes need to be enclosed by the plasma membrane (in effect forming discs) in a manner that provides an enlarged conduit for axial movement. In addition, one or more longitudinal incisures in the outer segment can further assist in axial diffusion.

H-7) An additional change that will assist in rendering the (now) large single-photon response detectable above the background noise is a lowering of the intrinsic fluctuations in the phototransduction process through increased stability of the proteins of the cascade.

H-8) Through the combination of all the above changes, it should be possible to convert a cone photoreceptor that is specialized for high-performance rapid photopic vision into a rod photoreceptor that can reliably signal individual photoisomerizations under dark-adapted conditions. An inevitable consequence of the slowing of shut-off reactions, though, will be that this cell saturates at low to moderate background intensities.

Timing of the emergence of rods

In Section 10 it was shown that modern SWS2 'cone' opsins have an exceedingly low rate of thermal isomerization, making them exceptionally well adapted to act as the photopigment in the green rods of amphibia. We cannot be certain that the ancestral SWS2 opsin was equally as stable as this. But, even if its thermal stability had been several orders of magnitude poorer, then that would have been entirely adequate to support reliable single-photon detection if that opsin had been expressed in a 'rod'. We can conclude that cone opsins (at least of the SWS2 variety) already exhibited thermal stability sufficient to enable single-photon detection before rhodopsin evolved, and therefore presumably before rods evolved. Hence, it would appear that thermal stability of the opsin molecule was not the limiting factor in the evolution of rods (at least, when 'rods' are characterized by their ability to detect single photons).

It seems clear that photoreceptors with certain rod-like features had evolved prior to the divergence of cyclostomes from the lineage leading to jawed vertebrates. Thus, hagfish photoreceptors have been reported to have discs enclosed by plasma membrane, and their peak spectral sensitivity is at 500 nm (Section 3). Likewise, one class of lamprey photoreceptor has a number of rod-like features, including the expression of an opsin that appears homologous with Rh1, though the cell also retains other cone-like features, both anatomically and electrophysiologically (Section 3). Unfortunately, though, it has not yet been discovered whether these hagfish and lamprey photoreceptors are able to respond reliably to the absorption of individual photons of light - in other words whether they achieve the ultimate sensitivity that is the defining feature of the 'true rods' of jawed vertebrates. If future experiments were to show that both hagfish and lamprey photoreceptors indeed meet this criterion, then this would be evidence in support of the notion that their common ancestor likewise possessed true rods.

Until this issue can be resolved, it is not possible to confidently go further than to say, firstly, that it seems highly probable that the last common ancestor of hagfish and lampreys possessed a class of photoreceptor with a number of rod-like features and, secondly, that 'true rods' had definitely evolved by the time that the first jawed vertebrates appeared.

Scenario for the emergence of 'true rod photoreceptors'

The following steps are proposed as the likely means by which rod photoreceptors emerged from their cone photoreceptor forerunners:

I-1) Following the '2R' rounds of whole-genome duplication, the lateral retina of an early vertebrate possessed five classes of cone-like photoreceptor cell, each expressing one of the five opsin classes (LWS, SWS1, SWS2, Rh2, Rh1).

I-2) In the photoreceptor expressing the Rh1 opsin, a number of changes gradually occurred, that led to a slowing of the response and concomitantly to an increase in its sensitivity.

I-3) These changes in the photoreceptor expressing Rh1 included slowing of the three shut-off reactions and slowing of the negative feedback loop. Some of these changes involved specialization of the shut-off proteins expressed in that cell, some involved altered expression levels, and some involved changes in morphology.

I-4) R* shut-off became slower, in part because of the slower decay of metarhodopsin II due to the mutations at residues 122 and 189, and in part through changes in the kinase and arrestin (GRK1 and SAG).

I-5) G*/E* shut-off became slower primarily as a result of lowered levels of the RGS complex (RGS9-Gβ5-R9AP).

I-6) The turnover time for cGMP in darkness lengthened as a result of lowered resting phosphodiesterase activity (PDE6A, B).

I-7) The time constant for equilibration of cytoplasmic Ca^{2+} concentration increased in parallel, through a reduction in the number of $Na^+/Ca^{2+},K^+$ exchangers per unit volume of outer segment, in part as a result of lowered surface-to-volume ratio, and in part through an increase in cytoplasmic Ca^{2+}-buffering power.

I-8) Changes at the rim of the outer segment lamellae led to the plasma membrane enclosing groups of lamellae (which thereby became groups of discs), providing an enhanced cross-sectional area for axial diffusion in the cytoplasm.

I-9) With these changes occurring gradually, but in concert, the photoreceptor expressing the Rh1 opsin would, over time, have become steadily slower and more sensitive.

I-10) Eventually almost the entire outer segment became sealed over, providing extensive longitudinal spread, and the shut-off reactions became sufficiently slow that the response to a single photoisomerization became large enough to exceed the level of noise in the cell.

I-11) Any further slowing of the shut-off reactions would then have been disadvantageous.

I-12) The synapse of this cell had a less demanding role, because the signal-to-noise ratio was higher and the kinetics were slower, and hence the synapse was able to function satisfactorily with less expenditure on synaptic machinery (i.e. with less extensive ribbon and fewer vesicles).

I-13) The eventual outcome of these combined gradual changes was the emergence of a 'true rod' photoreceptor, that reliably signaled individual photoisomerizations.

12. Retinoid re-isomerization in darkness

As discussed in Section 5, a major difference between vertebrate retinal photopigments and those of invertebrates is that the vertebrate visual opsins release their all-*trans* retinoid following light activation. The vertebrate retina therefore requires a continual supply of 11-*cis* retinal, in order to silence the residual activity of the free opsin and at the same time regenerate native rhodopsin for further signaling by light. This is accomplished by two biochemical pathways that operate in darkness (Figure 27; reviewed in Lamb & Pugh, (160); Wang & Kefalov, (195); Saari, (196)). One is the classical 'retinoid cycle of vision' (Figure 27B), in which all-*trans* retinoid is transported to the RPE, isomerized to the 11-*cis* isomer, and then transported back to the retina. The second is a less well understood pathway, internal to the retina, involving Müller cells and cone inner segments, that is thought to contribute to the regeneration of cone visual pigment.

Intra-retina retinoid cycle

Although most work on retinoid recycling over the past four decades has concentrated on the RPE cycle, the fact that cone photoreceptors pre-date rod photoreceptors raises the distinct possibility that the ancestral retinoid cycle of the vertebrate eye may have been the intra-retina cycle involving the cones and Müller cells, with the RPE cycle having evolved subsequently. The intra-retina cycle appears simpler, in that it involves isomerization of all-*trans* retinol (vitamin A) directly to 11-*cis* retinol (bottom of Figure 27A), via what has been termed ‘isomerase 2’ in Müller cells, without requiring initial esterification followed by an isomerohydrolase reaction as in the RPE (see below). A very recent report has indicated that this second isomerase might be the desaturase, DEGS1 (197), but the identity of the other enzymes that contribute to this intra-retina cycle are only just beginning to emerge. Unfortunately, as this cycle has been less intensively studied, it has not yet proven possible to investigate its evolutionary roots.

RPE retinoid cycle

Two recent papers have made important advances in determining the origin of the classical RPE retinoid cycle. Albalat (198) and Poliakov et al (199) have shown that this cycle is present only in vertebrates, as

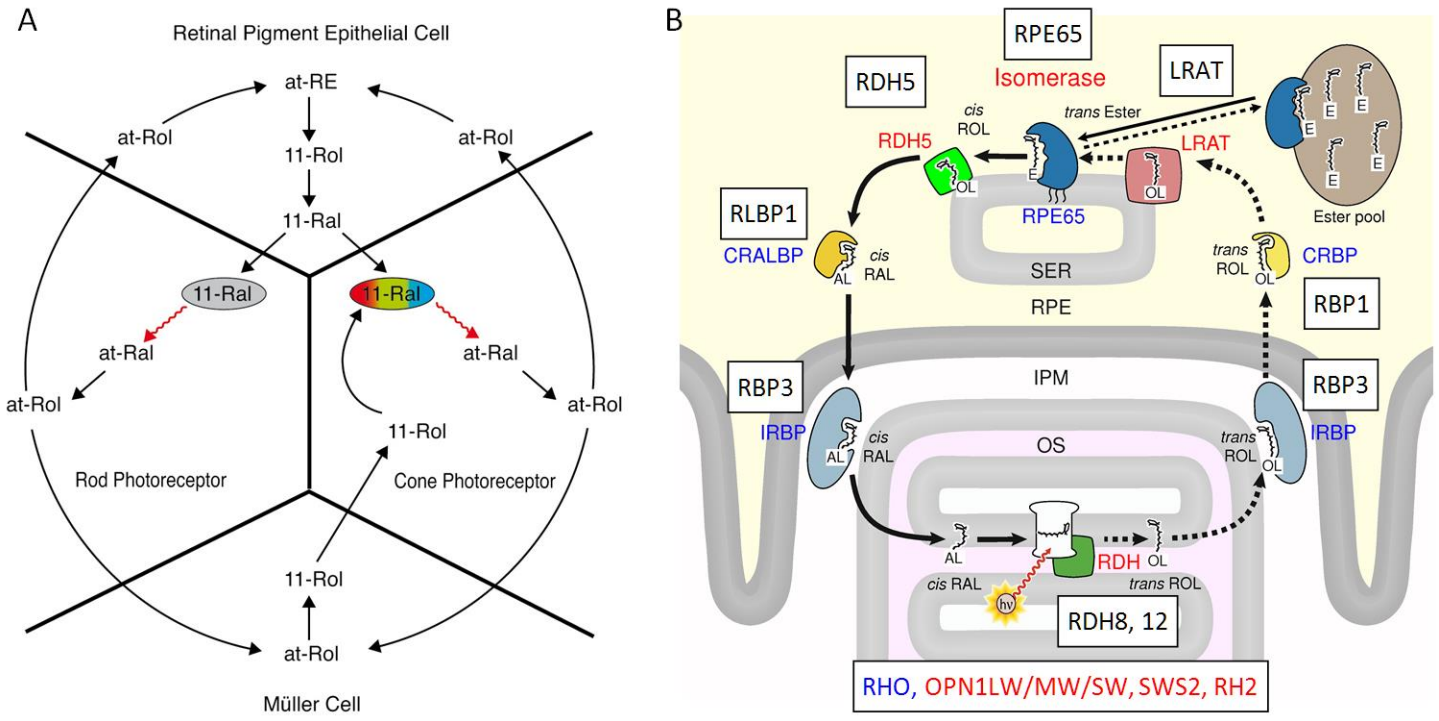

Figure 27. Retinoid cycles: Overview of the two cycles, and flow in the RPE cycle. A, Overview of the flow of retinoid in the two cycles. The areas separated by solid lines represent cellular compartments of a retinal pigment epithelial cell (top), a rod and a cone photoreceptor cell (middle), and a Müller cell (bottom). The ovals surrounding 11-Ral represent rhodopsin (gray) and cone opsins (tricolor). Photoisomerization reactions are shown in red. All other chemical reactions are catalyzed by enzymes. Retinoids are chaperoned by retinoid-binding proteins (not shown) during intercellular and intracellular movement. Abbreviations: at-RE, all-*trans* retinyl esters; at-Ral, all-*trans* retinal; at-Rol, all-*trans* retinol (= vitamin A); 11-Ral, 11-*cis* retinal; 11-Rol, 11-*cis* retinol. From Saari (196). B, Flow of retinoid in the RPE cycle. Delivery of 11-*cis* retinoid is shown by solid arrows, while removal of all-*trans* retinoid is shown by dashed arrows. Abbreviations: OS, outer segment; IPM, inter-photoreceptor matrix; RPE, retinal pigment epithelium; SER, smooth endoplasmic reticulum. RAL, retinaldehyde; ROL, retinol. For the chemical icons: AL, OL and E denote the aldehyde, alcohol, and ester groups attached to the retinoid hydrocarbon chain. Enzymes (in red): RDH, all-*trans* retinol dehydrogenase; LRAT; lecithin:retinol acyltransferase; RDH5, 11-*cis* retinol dehydrogenase. Chaperone proteins (in blue): IRBP, inter-photoreceptor retinol binding protein; CRBP, cellular retinol binding protein; RPE65, retinal pigment epithelium 65 kDa protein, now known to be the isomerohydrolase; CRALBP, cellular retinal binding protein. The ABCA4 transporter is not shown; this rescues the very small proportion of all-trans retinoid that inadvertently reaches the luminal leaflet of the disc membrane, and it has only a minor role in total retinoid cycling. From Lamb & Pugh (139). Gene names are given in boxes; see also Item D.

cephalochordates and tunicates do not possess the required enzymes, implying that the cycle evolved during the 100 million year interval from #4 to #5 in Figure 1.

Two crucial enzymes in the retinoid cycle are LRAT (lecithin:retinol acyltransferase) and RPE65. LRAT esterifies vitamin A (all-*trans* retinol) to all-*trans* retinyl ester, which is the substrate for RPE65, which actually performs the isomerization while at the same time cleaving the ester bond, in a so-called 'isomerohydrolase' reaction. This step generates 11-*cis* retinol which is subsequently oxidized to the aldehyde, 11-*cis* retinal, and then transported to the retina.

Albalat (198) undertook an *in silico* search for the genetic machinery of retinoid processing amongst invertebrates, and he analyzed the likely function of the components that he found. He concluded that "genome surveys, phylogenetic reconstructions and structural analyses of invertebrate components similar to those of the vertebrate retinoid cycle - that is, Rdh8, Rdh12, Lrat, Rpe65, Rdh5, Rlbp1, and Rbp3 - did not provide any evolutionary or functional support for the existence of the genetic machinery of the retinoid cycle outside vertebrates".

Poliakov et al (199) extended that approach, by experimentally determining the functional activity of the key enzymes LRAT and RPE65 (and similar molecules) in lamprey and in tunicate. In lamprey (*Petromyzon marinus*), they showed that LRAT and RPE65 are both present and functional, and further that the key sites for RPE65's ability to act an isomerohydrolase are remarkably similar to those of jawed vertebrates. On the other hand, their phylogenetic analyses confirmed that neither RPE65 nor LRAT have orthologs in the cephalochordate (amphioxus) or the tunicate (*Ciona intestinalis*). They showed that an enzyme previously proposed (and named) as a *Ciona* ortholog of RPE65 by Takimoto et al (200) has no isomerohydrolase activity, confirming the report of Kusakabe et al (9), and they showed that it functions instead as a BCMO (β-carotene mono-oxygenase).

Taken together, these results show that both the crucial transition from a BCMO to a true RPE65 isomerohydrolase, and also the origin of LRAT, occurred only in the lineage leading to vertebrates (jawless and jawed), after the divergence of tunicates. Hence, the RPE retinoid cycle evolved only in vertebrates.

In a number of invertebrate species, it has been known for many years that rhodopsin can be regenerated in darkness (201), but there is scant evidence as to how this occurs. In *Drosophila*, evidence has recently been obtained for the likely existence of a retinoid cycle, though rather different from that in the RPE (202).

Scenario of the origin of retinoid recycling in the vertebrate retina/RPE

From our current knowledge of the intra-retinal and RPE retinoid cycles, it is possible to hypothesize the following scenario for the evolution of retinoid processing in the vertebrate eye:

J-1) At around the time that chordate ciliary opsins lost their bistable (photoreversible) properties and instead released their all-*trans* retinoid, an intra-retinal retinoid processing cycle arose, that utilized an isomerase (currently termed isomerase 2) in the Müller cells to isomerize retinol from its all-*trans* to its 11-*cis* form.

J-2) Subsequently, around the time that the RPE became specialized as a monolayer apposed to the retina, the two crucial enzymes LRAT and RPE65 evolved, and the RPE was able to adopt an additional role in retinoid re-isomerization.

13. Development of the retina at a macroscopic level

Clues to the evolution of the vertebrate eye can be obtained by studying its embryonic development, though caution is required. Nearly 200 years ago, Karl Ernst von Baer (203) observed that organisms with widely different adult forms have embryos that resemble each other closely, and he suggested that the developmental stages through which the embryo passes might to some extent reflect the evolutionary history of the organism; for a recent evaluation of von Baer's ideas, see Brauckmann (204).

This concept was extended by Ernst Haeckel (205) to the extreme view that 'ontogeny recapitulates phylogeny'; i.e. that each step in development reflects a corresponding step in the evolutionary sequence. The problem with this strict relationship is that it implies that evolution can work only by altering or adding to the final stage of embryogenesis, and this is clearly not correct. Nevertheless, despite the fact that all stages of development are subject to evolution, there is a marked tendency for more ancient steps to be preserved, so that the fundamental body plan that was established early in evolution appears seldom to be altered in a major way during embryogenesis, and instead there appears to be a tendency for newly-evolved features to be 'tacked-on' to later stages of embryogenesis.

Because of the likelihood that events that occurred in the distant past during eye *evolution* have left remnant traces in the process of eye *development,* we shall now examine several aspects of eye embryology: firstly, the overall sequence of eye development across jawed vertebrates, lampreys and hagfish; secondly, the sequential differentiation of cell classes in the vertebrate retina; and thirdly, the maturation of photoreceptors and the

formation of their neural connections. Inevitably, this leads on to the nature and origin of retinal bipolar cells. Analysis of each of these topics provides important clues to the evolution of the retina.

Development of diencephalic light-sensitive organs in jawed vertebrates

During vertebrate embryonic development, a small region of the anterior neural plate (the eye fields) contains cells that will give rise to several distinct light-sensitive organs: the paired lateral eyes, the pineal organ, and the parapineal organ or the parietal eye, though not all are present in all vertebrate species (Figure 28; (206, 207)). Each of these organs arises as an evagination from the developing diencephalon; the dorsal evagination begins as a single bulge, but then becomes constricted, dividing into paired evaginations that take up rostral and caudal positions, with the caudal vesicle becoming the pineal organ and the rostral vesicle becoming either the parapineal organ or parietal eye (206). These organs share close homologies with each other, and the evolutionary significance of these parallels have been highlighted in a number of studies, including Reichenbach and Robinson (208), Vigh et al (207, 209), Ekström & Meissl (210), Klein (211), Mano & Fukada (212).

Polarity of the developing diencephalic vesicles. The developing light-sensitive outgrowths from the diencephalon (retina, pineal, parapineal, parietal) become rather flattened – compare Figure 10A for the lamprey pineal with Figure 29F for the lateral retina and RPE. One significant difference between the organs concerns the side of the vesicle that develops as the retina (or its homolog). In the pineal and parapineal organs, and in the parietal eye, it is primarily the proximal side of the vesicle (nearest the brain) that develops as a 2-layered retina, so that the photoreceptor outer segments (which project into the lumen) point out towards the external world. As the projection neurons are on the outer surface, their axons have no need to penetrate the organ, and are able to run directly to the CNS. The distal side of the organ (facing the external world) develops differently, in some cases as non-photoreceptive tissue; e.g. in the parietal eye as a so-called 'lens', and in the pineal as a thinner layer either containing either occasional photoreceptors or sometimes UV-sensitive photoreceptors (71). In comparison with these dorsal organs, the polarity is reversed in the lateral eyes, with the proximal side developing as a monolayer of RPE cells, and with the distal side differentiating as the multi-layered retina. It will be suggested below that the signal for this inverted polarity came from an ancestral placode in the stem vertebrate, that subsequently evolved to become the lens placode.

In the parietal eye, and also in the pineal organ of non-mammalian vertebrates, the glial cells (amongst which the photoreceptors are embedded) are pigmented; in the parietal eye, these glia contain black pigment granules (213), whereas in the pineal organ they contain reflective organelles that give a slate gray appearance.

Lateral eye development at a macroscopic level. The paired lateral evaginations of the developing diencephalon give rise to the eyes, in a sequence (Figure 29 and the animation below) that was described nicely by Walls (184) and that has been reviewed recently in Martinez-Morales & Wittbrodt (214). On each side of the rostral neural plate a depression forms, termed the optic groove (Figure. 29B). As the neural plate folds upwards and inwards (Figure 29B, Figure 29C), meeting and closing over to form the neural tube, these growing regions bulge outwards (Figure 29D) and are now termed optic vesicles. However, it appears that the luminal space is minimal, so that the interior surfaces of the vesicle remain effectively in contact with each other, somewhat like a deflated balloon. Contact between the expanding optic vesicle and the surface ectoderm (Figure 29E), at a region termed the lens placode, induces changes in both, with the ectoderm thickening progressively and eventually forming the lens (Figure 29G). Although it has sometimes been suggested that invagination of the optic cup is a physical result of growth of the lens, this cannot be the case, because a normal eye-cup and retina can develop in the absence of a lens, as in human congenital primary aphakia (215). Remarkably, such development can also occur in cell culture, in the absence of ectoderm or lens tissue (216), see below).

Lamb et al (3) Supplementary Animation S1

Specification of retina and RPE. The initial polarization of the lateral eye vesicles into RPE and retina is under the control of a number of extracellular signaling molecules, including FGFs released from the surface ectoderm, but also involving Bmp, Activin and Wnt. Very recently, evidence has been found for a positive feedback circuit involving Pax6 whereby, once the initial specification of RPE and retina has begun, the signals within the retina/RPE become self-reinforcing (217). These authors propose that, when expressed in conjunction with Mitf or Tfec, Pax6 acts as a pro-RPE (i.e. anti-retina) factor, whereas in conjunction with other retinogenic genes it acts as a pro-retina factor. Thus, once there is a bias towards an initial retina/RPE polarity, this bias becomes self-reinforcing by signaling events that are internal to the developing retina/RPE.

A further exciting and intriguing recent finding is that when aggregates of mouse embryonic stem cells are grown entirely in vitro, as vesicles in 3D culture, they are capable of autonomously organizing themselves into eye-cups with appropriately oriented retina and RPE (216), as illustrated in the movie linked below. This observation is again consistent with the notion of a signaling system internal to the retina/RPE that can regulate its development in the absence of external signals.

Coordinated migration of cells. The early steps in formation of the zebrafish eye vesicle have been monitored in several studies that have used time-lapse video imaging (218-220), so that individual cells could be visualized and their migration tracked. The movies (linked below) from each of these studies provide impressive visualizations of the coordinated cell migrations that occur in zebrafish. Thus, the macroscopic development (indicated, for example, in Figure 29) can be visualized as the coordinated migration of individual cells, firstly as primarily outward migrations, and then through a combination of inward migration of those cells near the locus of contact with the placode, together with continued outward migration of new cells into the eye vesicle (see movies).

Scenario for the evolution of chordate diencephalic light-sensitive structures

It seems reasonable to think that the events in vertebrate embryonic development described above may represent a shadow of the sequence of steps that occurred during chordate evolution, in the interval between the divergence of tunicates and the emergence of vertebrates (i.e. between #4 and #5 in Figure 1). Accordingly, the following steps (also explained in the schematic in Figure 30) are suggested to have occurred:

K-1) The anterior neural tube of an early chordate contained a light-sensitive region that sent axons to relevant parts of the nervous system (e.g. to the forerunner of the hypothalamus).

K-2) The inner surface (in contact with the CSF) contained ciliary photoreceptors, while microvillar photoreceptors (that later simply became projection neurons) were located on the outer side (Figure 30A). Pigment-containing cells were also present.

K-3) This light-sensitive region expanded, possibly initially simply as a means of increasing the number of photoreceptors and thereby increasing the organism's ability to catch light. In doing so, it bulged outwards in different directions, dorsally and laterally (Figure 30B).

K-4) As these regions expanded, the somata of the ciliary photoreceptors and the microvillar photoreceptors (i.e. projection neurons) remained in close proximity to each other, while the axons of the projection neurons

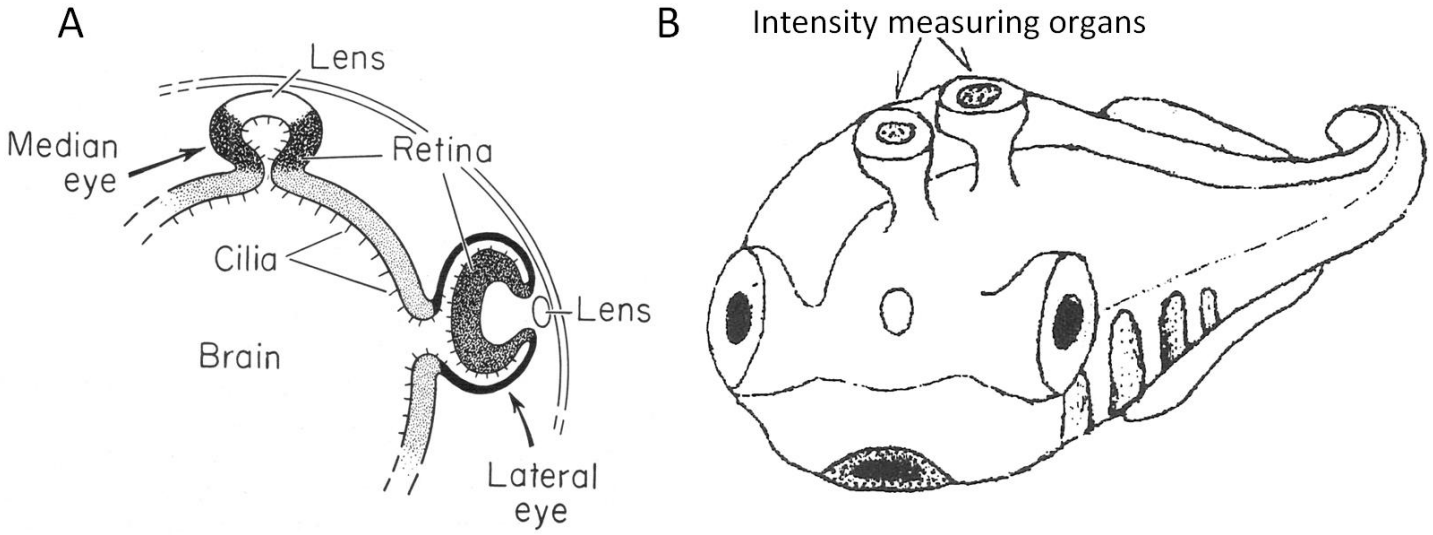

Figure 28. Light-sensitive organs that evaginate from the diencephalon. A, Schematic of the light-sensitive organs that evaginate from the developing diencephalon. The median (or parietal) eye is often found in reptiles and amphibia. During development an initially single dorsal evagination then divides into two roughly bilaterally symmetric organs that rotate their location to become a caudal pineal organ and a rostral median eye or parapineal organ. The developing vesicles of the paired visual eyes evaginate laterally to form eye-cups; they retain very little luminal space and thereby appear invaginated. From Eakin (206). B, Schematic of the possible arrangement of light-sensitive organs in a proto-vertebrate. In addition to the paired lateral eyes, there were two dorsal organs that measured light intensity. From Vigh et al (207).

lengthened so that they continued to reach their targets in the CNS; thus the cell bodies remained close together but the axons of the projection neurons 'stretched'.

K-5) The interior of each bulge (the luminal space, containing CSF) remained relatively small, so that the inner surface of the epithelium (with ciliary photoreceptors and pigment cells) became folded in upon itself, resembling a deflated balloon rather than an inflated one.

K-6) Initially, this double layer of epithelial tissue was probably spatially uniform, with ciliary photoreceptors, pigment cells and projection neurons distributed across the entire surface of the organ (not shown in Figure 30).

K-7) In due course each of the organs (dorsal and lateral) tended to develop a polarity, with one side remaining predominantly light-sensitive and with the other side adopting a different role (e.g. as a lens in the parietal eye).

K-8) In the lateral bulges, but not in the dorsal bulges, the orientation of this polarization was such that only the distal (outer) side remained light sensitive, and only the proximal side (closer to the brain) made pigment cells (see Figure 30B). In this way, ciliary photoreceptors occupied the entire cross-sectional area struck by incident light, and the pigmented cells were behind the photoreceptors yet still in close contact with them.

K-9) In these lateral organs, the axons continued to run across the outer surface, which now comprised the vitreal surface of the retina. As they headed centrally they converged as a bundle running along a groove under the optic stalk (Figure 30C). With continued lateral and downward expansion of the retina/RPE, the narrowing gap around the optic stalk became the optic fissure. At some (possibly later) stage in evolution this fissure sealed over, so that the optic nerve penetrated the lateral eyecup.

Eye development in lampreys and hagfish

Lamprey eye development. Lampreys have a larval form (the ammocoete, Figure 13A) that develops slowly over a period of 5 years or more, before metamorphosing into the adult (see for example Dickson & Collard (84)). The ammocoete is effectively blind, and its eyes resemble those of the hagfish, in being small and buried beneath

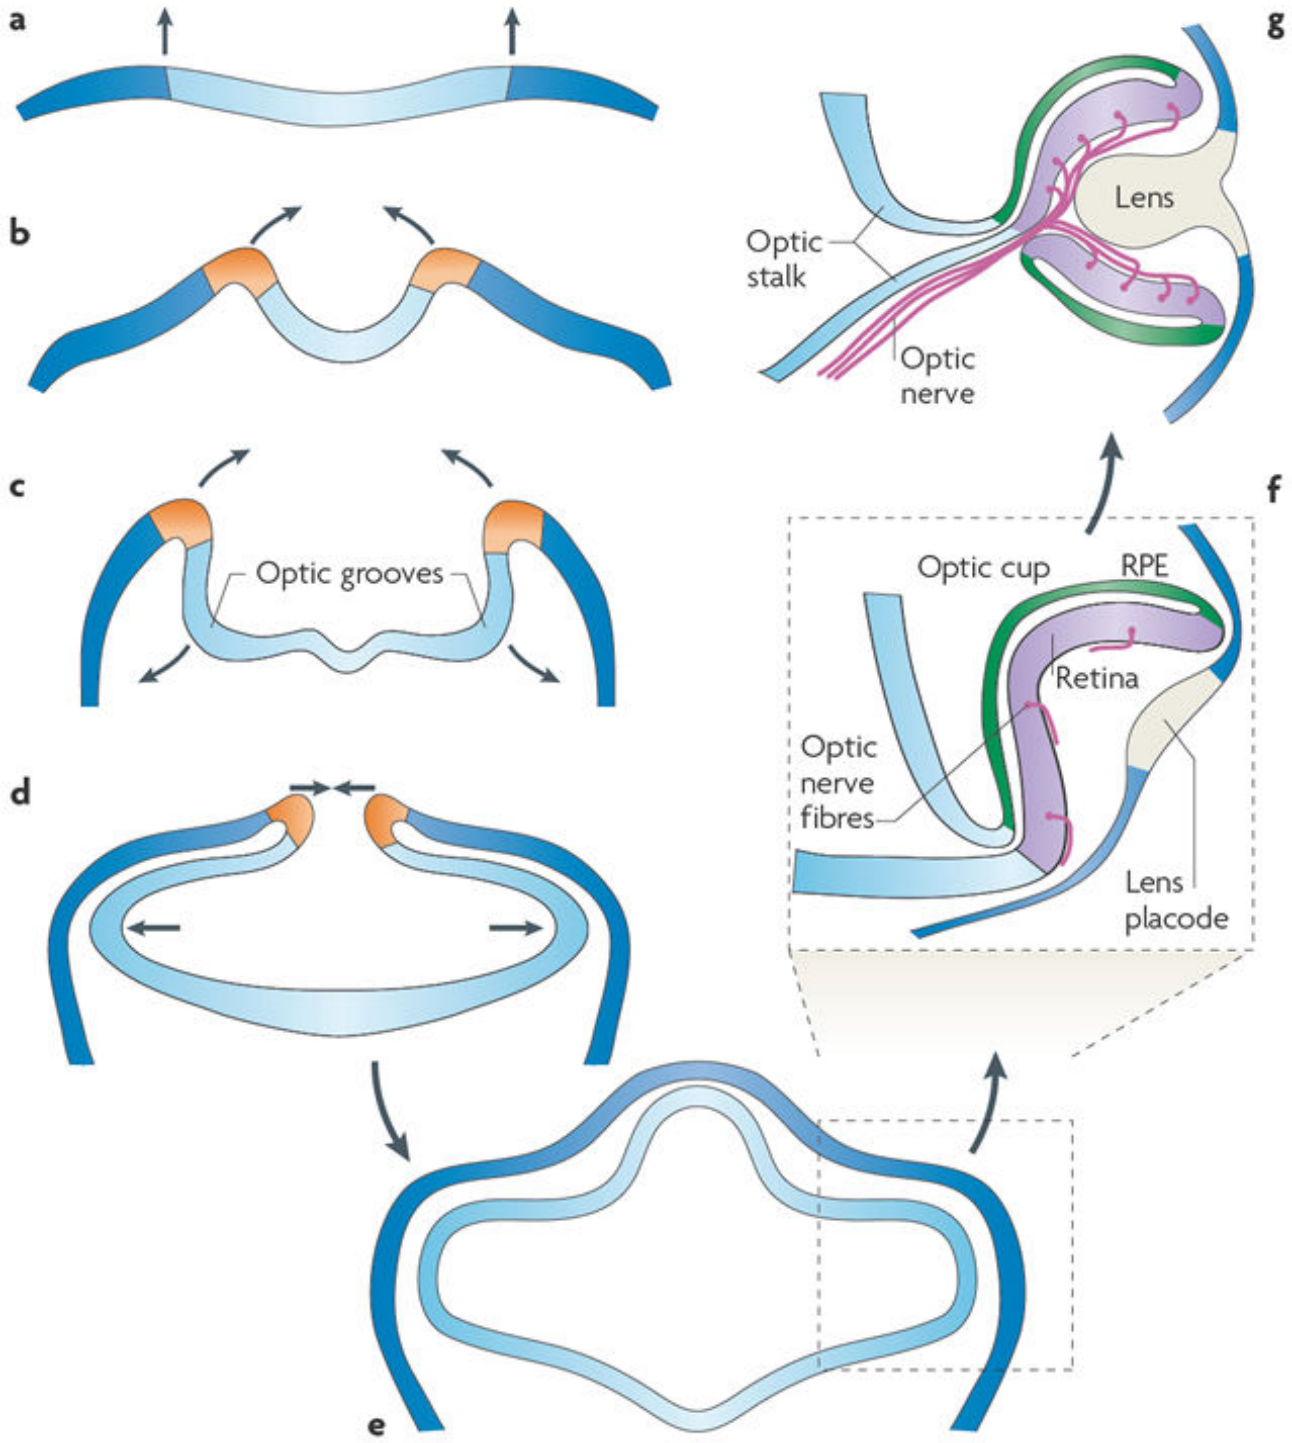

Figure 29. Development of the vertebrate eye cup. (a) The neural plate is the starting point for development of the neural tube. (b) The neural plate folds upwards and inwards. (c) The optic grooves form, and begin to evaginate. (d) The lips of the neural folds approach each other, and the optic vesicles bulge outwards. (e) After the lips have sealed, the neural tube is pinched off. At this stage the forebrain grows upwards and the optic vesicles continue to grow outwards. One aspect of this diagram that is not accurate is that the expanding optic vesicles actually have very little luminal/ventricular space; i.e. the wall thickness is much greater than shown here. (f) The expanding optic vesicles contact the surface ectoderm at the lens placode, inducing changes in both tissues. The optic vesicle now appears invaginated, and with the future retina closely apposed to the future RPE; what little ventricular space had been present between them disappears. Developing retinal ganglion cells send axons out across the retinal surface. The surface ectoderm at the lens placode thickens, forming the lens pit. The section in (f) is midline in the right eye, through the choroid fissure, so that only the upper region of retina/RPE is visible. (g) The eyecup continues to grow, through a combination of new material expanding outwards and continued warping of the eye cup. This expansion eventually causes the choroid fissure to seal over, thereby enclosing the axons of the optic nerve (as well as the hyaloid/retinal vessels; not shown). The ectodermal tissue continues to differentiate, eventually forming the lens. From Lamb et al (3). The text provides a link to an animation of this developmental progression.

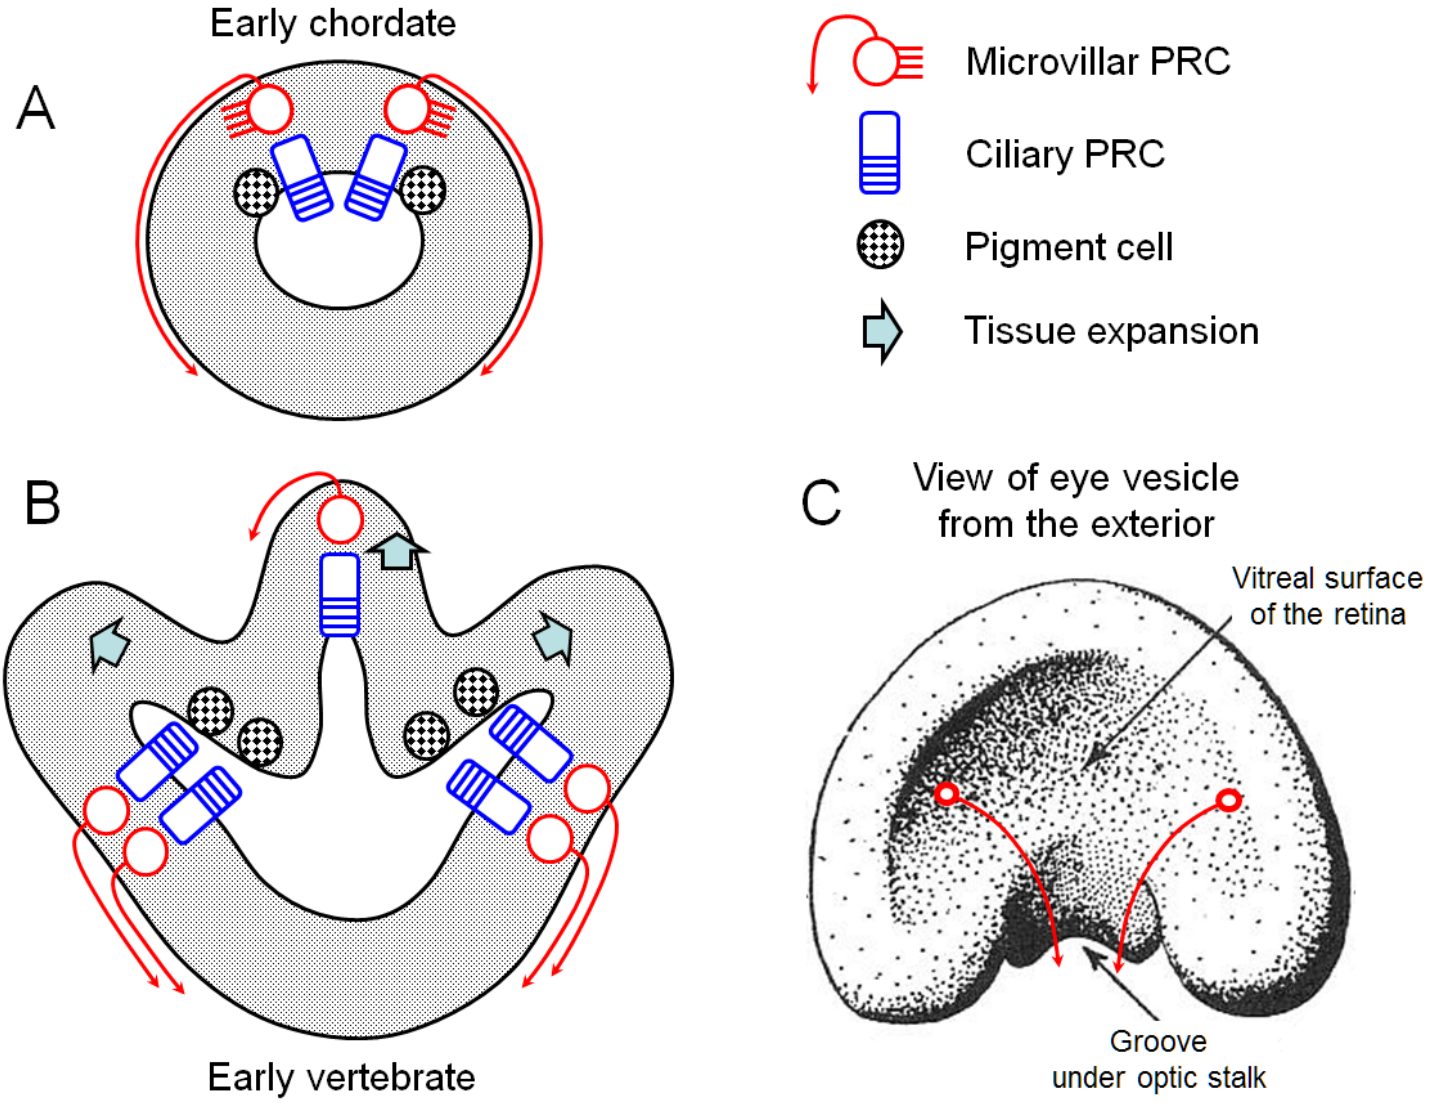

Figure 30. Schematic for evolution of chordate diencephalic light-sensitive structures A, B, Schematic sections through rostral neural tube, at stages corresponding to an early chordate and an early vertebrate. The key at the upper right identifies the icons; PRC, photoreceptor cell. A, In the early chordate (i.e. around the time that tunicates diverged), a region of the rostral neural tube was light-sensitive. On its inner surface, in contact with the CSF, there were ciliary photoreceptors (blue), and on its outer surface there were microvillar photoreceptors (red) that sent axons out to other regions of the nervous system (e.g. to the forerunner of the hypothalamus). Pigment cells (stippled black) were also present. It seems likely that each of these cell types (as well as glial cells) was descended from a single multifunctional type of ancestral cell. B, Later in chordate evolution, around the time that the earliest vertebrates appeared, the light-sensitive region of the rostral neural tube had expanded, bulging outwards (gray arrows), both dorsally and laterally. In each of these regions the ciliary photoreceptors retained their positions at the inner surface, while the microvillar photoreceptors remained near the external surface; by this stage most of the microvillar cells had lost their microvilli and their R-opsin, and had become projection neurons. In the lateral bulges (the eye vesicles), signals from the surface ectoderm (not shown) initiated polarization of the vesicles, so that only the outward-facing surface made photoreceptors and projection neurons, and only the rear surface made pigment cells. C, A view of (either) lateral eye vesicle from the exterior. Projection neurons from all across the retinal surface sent their axons across the surface and out along a groove, under what by that stage had become the optic stalk, eventually to reach their targets, probably in the hypothalamus. Diagram in C modified from Walls (184).

skin. The initial stages of eye development occur at an early age in the ammocoete, and appear comparable to the initial stages of eye development in jawed vertebrates. However, eye development then becomes arrested; for the remainder of the ammocoete phase (i.e. perhaps 5 years) the main change to the eye is that it (and its lens) slowly grows in size as the animal grows.

The bulk of the ammocoete retina is undifferentiated, with a thick neuroblastic layer, though a narrow central region (~50 μm wide, adjacent to the optic nerve) is differentiated (84, 221-223). Although it has been reported that all the conventional layers of the vertebrate retina are present, re-examination of those micrographs suggests that bipolar cells may not in fact be present in the ammocoete retina. A slow process of neural differentiation occurs, over a period of years, and this accelerates as metamorphosis approaches. The area of differentiated cells spreads outward, and the cells differentiate in the following sequence: ganglion cells, amacrine and horizontal cells, photoreceptors, and finally bipolar cells (221, 222); i.e. in broadly the same order as occurs much more rapidly during embryogenesis in jawed vertebrates (see Section 14).

Then, at metamorphosis, development of the lamprey's eye resumes, apace. The eye and lens grow rapidly in size, differentiation of the retina reaches completion, the cornea splits into scleral and dermal layers (allowing the eye to move with respect to the epidermis, as in jawed fish; (224)), extraocular muscles develop, and the eye erupts at the surface, as a vertebrate-style visual organ (Figure 13B).

Hagfish eye development. The development of hagfish embryos was first studied by Price (225), and comprehensive accounts were given by Dean (226, 227) and von Kupffer (228), though there was only limited data on the eye in any of these. The embryonic development of hagfish eyes was investigated by Allen (65) and Stockard (229), with particular reference to the origin (or the absence) of a lens. The combined results of those early studies are consistent with the following description.

The developing eye is always very small in comparison with the size of the embryo. At a very early stage the optic vesicle contacts the surface ectoderm and a definite 'lens placode' is seen, though even at its thickest (in a 15 mm embryo) this placode is only a few cells deep (229); thereafter the lens placode thins and disappears. Allen (65) concluded by suggesting that, if the thickening of the lens placode represented a rudimentary lens, then "we should have a clear case of arrested development resulting in the continuance of an embryonic condition into adult life. This view is strongly supported by the condition of the retina with its space of separation between the inner and outer layers of the optic-cup, by the rudimentary iris, and by the often persistent choroid fissure".

Following those studies, it did not prove possible to obtain viable fertilized hagfish eggs for about 100 years; it would be exciting to continue those earlier studies using the procedures recently developed in Shigeru Kuratani's laboratory (230).

Implications of cyclostome eye development for vertebrate eye evolution

In view of the comparative aspects of cyclostome and jawed vertebrate eye development described above, the following implications for evolution of the vertebrate eye are hypothesized (3):

L-1) The 'arrested development' of the hagfish eye (65) may reflect a failure of hagfish eye development to proceed beyond a point corresponding to an earlier stage in vertebrate eye evolution. Hagfish do not undergo metamorphosis, and in the absence of the developmental changes that occur at metamorphosis, perhaps the hagfish eye has been 'frozen' in its earlier evolutionary state. In other words, eye development (and perhaps all development) in hagfish might correspond to a kind of neoteny.

L-2) If this is correct, then the hagfish eye and retina provide an invaluable window into an important stage of vertebrate eye evolution, with the following additional implications.

L-3) The retina of the stem vertebrate would, at some stage of evolution, have resembled that of the hagfish, with photoreceptors directly contacting projection neurons (ganglion cells). Further evidence relating to this notion will be presented in Section 14 on maturation of retinal connectivity.

L-4) The failure of the hagfish 'lens' placode to develop into a lens would suggest that the ancestral function of this placode may have been to influence the orientation of polarization of the retina/RPE (see above), rather

than to form a lens. On this basis, the evolution of the lens would have occurred subsequent to the evolution of the paired lateral 'eye-cups' that comprised infolded, two-layered retinas.

L-5) Likewise, the extraocular muscles would not have evolved until after the lateral eye-cups were already present.

L-6) Taken together, these interpretations further suggest that the ancestral function of the paired lateral retinas was not for image-forming vision, because the evidence suggests that these retinas were present before the evolution of a lens, of extraocular muscles, or of anything more than the most basic computational power in the retina. Instead, these lateral counterparts of the pineal organ may have subserved a function in circadian and/or seasonal timekeeping, or perhaps in shadow detection, or even in control of axial orientation (i.e. roll).

L-7) Hence, it is suggested that at an early stage in vertebrate evolution, *after* the '2R' genome duplications but before the divergence of cyclostomes from the jawed lineage, a pair of primitive lateral retinas with RPE had evolved in the stem vertebrate. These retinas possessed early forms of the five 'visual' ciliary opsins, expressed in cones and in a rod-like photoreceptor. Bipolar cells had not evolved, nor had a lens or extraocular muscles. It is suggested that the ancestral function of the 'lens placode' was to specify the polarity of the lateral eyecup, possibly by releasing molecules like fibroblast growth factors (FGFs).

L-8) It is suggested that a state resembling this is retained in the eyes of living hagfish, possibly as a result of neoteny. In lampreys (and in their ancestors) the subsequent stages of eye development occur (and may have occurred) slowly, predominantly during metamorphosis. But in living jawed vertebrates those subsequent stages of eye development occur rapidly, and inseparably from the earlier stages.

14. Molecular signatures and cell differentiation in the vertebrate retina

Molecular signatures of neurons in the developing vertebrate retina

In the developing nervous systems of both protostomes and deuterostomes the specification of neuronal cell fate appears to be determined by the combinatorial code of transcription factors (mainly of the bHLH and homeodomain superfamilies) that are expressed. In the differentiating cell, the particular combination of transcription factors regulates the programs controlling cellular morphology, outgrowth of axons, and the expression of effector molecules (such as members of transduction cascades, neurotransmitter-synthesizing enzymes, ion channels, etc.). For a review of the deployment of transcription factors in eye development across phyla, see Vopalensky & Kozmik (6).

A comparison of the molecular factors that underlie the differentiation of cell types has been applied to the retina, both within an organism and between organisms, by Detlev Arendt and his colleagues, in order to gain insight into the evolutionary history of the component cells (231). Arendt refers to the approach as 'comparative molecular cell biology'.

Sister and homologous cell types. Arendt (231) defined 'sister' and 'homologous' cell types as follows. Within an organism, 'sister cell types' are those that have evolved from one common precursor, by diversification of cell type. And across the evolutionary tree, 'homologous cell types' are those that have evolved from the same type of precursor cell in the last common ancestor of the groups being compared. Using these definitions he argued that, within any vertebrate species, the horizontal cells, amacrine cells, and ganglion cells are 'sister' cell types, having descended from a single ancestral cell type. And across phyla, he argued that rhabdomeric photoreceptors and vertebrate retinal ganglion cells are 'homologous' cell types, having descended from a microvillar photoreceptor in the last common (bilaterian) ancestor.

The evidence supporting the former assertion is illustrated in Figure 31 which compares the transcription factors and effector genes expressed in the different cell types of the vertebrate retina. Cone and rod photoreceptors are clearly sister cell types, having descended from a common ancestral ciliary photoreceptor (see Section 11). Although Arendt was equivocal about the origin of retinal bipolar cells, it will be argued subsequently (Section 16) that the bipolar cells are also sister cells of ciliary photoreceptors.

The lower part of Figure 31 shows that the transcription factors and effector genes expressed in horizontal, amacrine, and ganglion cells are closely similar (for detailed comparisons, see Arendt (231)). Furthermore, most notably in the case of ganglion cells, these factors are fundamentally the same as the factors that underlie differentiation and that specify phototransduction in the rhabdomeric photoreceptors of *Drosophila*. By Arendt's analysis, horizontal, amacrine, and ganglion cells appear to have descended from an ancestral microvillar photoreceptor, so not only are they 'sister' cell types (to each other) but they are also each 'homologous' cell types to protostome rhabdomeric photoreceptors.

Complications. Two observations that complicate this relatively simple account have been pointed out by Davies et al (94). Firstly, despite their postulated common origin as microvillar photoreceptors, some horizontal cells and some ganglion cells express a C-opsin (VA/VAL). Secondly, it appears that this C-opsin VA/VAL is frequently co-expressed with the R-opsin melanopsin. What might lead to expression or co-expression of a C-opsin in a cell that has descended from an ancestral microvillar photoreceptor? In addition to this complication with the opsins, it is now known that the set of transcription factors is more extensive than shown in Figure 31, and as a result the grouping of cell types is less distinct.

Solution? One possible solution to this conundrum (as well as to other issues) would be to take the view that all vertebrate retinal and RPE cells are descended from a single pre-bilaterian cell type that combined the features of a photoreceptor cell, a pigment cell, and a glial cell; i.e. from an ancestral cell of the kind envisaged in the 'division of labor' model proposed by Arendt et al (5). Such a view seems consistent with knowledge of cell differentiation in the vertebrate retina (see next sub-Section), where it has been shown that progenitor cells are initially unrestricted in their cell fate, and are potentially able to form any type of retinal cell. By taking this viewpoint, one would not need to apply the restriction that all vertebrate retinal/RPE cell types had proceeded through antecedents that were either strictly 'ciliary photoreceptor type' or strictly 'microvillar photoreceptor type' before reaching their current forms. Instead, some cell types (such as horizontal cells) might be descended from intermediate cell type(s) that had not committed to either a ciliary or a microvillar form of photoreceptor. If this were the case, then modern cells in the retina and RPE might share certain features with one more of the ancestral ciliary, microvillar, pigment, or glial categories, in what might resemble a mix-and-match fashion.

This concept will be followed up after a brief description of cell differentiation in the vertebrate retina.

Cell differentiation in the vertebrate retina

For reviews of cell differentiation and neuronal development in the retina, the reader is referred to Webvison "Retinal neurogenesis" as well as to the chapters in Sernagor et al (232), and to Agathocleous & Harris (233), Swaroop et al (234), Reese (235) and Chen et al (21). Here the briefest of summaries is given.

Cells in the neuroepithelium of the optic vesicle, that will generate the retina, proceed through the standard cycle of cell replication in much the same way as in other regions of the brain. The soma of a progenitor cell migrates vertically within the neuroepithelium, between the outer (ventricular) and inner (vitread) surfaces, in a characteristic pattern, and when a daughter cell exits the cell cycle its soma then migrates towards its final position within the retinal layer. Differentiation begins in the central retina and proceeds outwards to the periphery.

Fate, competence, and birth order. Initially, progenitor cells are unrestricted in fate, with the capacity to form any class of retinal cell. Nevertheless, the order in which different classes of retinal cell are 'born' (i.e. exit the cell

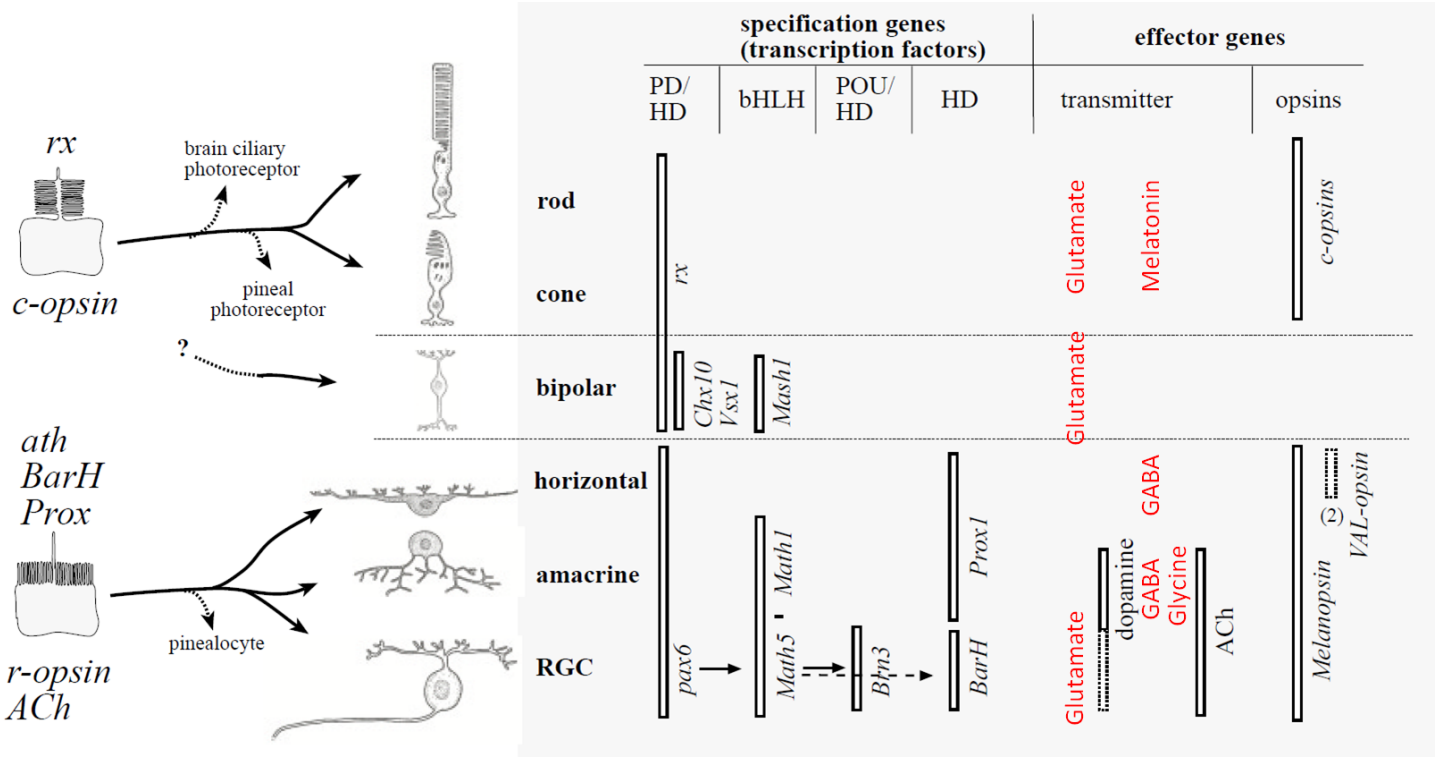

Figure 31. Molecular signatures and possible origins of vertebrate retinal neurons. Diversification of cell types in the vertebrate retina, as proposed by Arendt (231). Comparative molecular cell biological analysis indicates (Top) that cones and rods have evolved from a common ciliary photoreceptor precursor, and also suggests (Bottom) that retinal ganglion, amacrine and horizontals may have evolved from a common ancestral microvillar photoreceptor precursor. Black arrows represent cell type evolution. The evolutionary origin of bipolar cells was unclear from this kind of analysis. The right-hand side of the diagram shows the transcription factors and also the genes for neurotransmitters and opsins that have been identified in these cell classes. Additional neurotransmitters not indicated in the original diagram are shown in red. From Arendt (231).

cycle) is well defined within a species, as illustrated in Figure 32 and well conserved across vertebrate species. In particular, most cone photoreceptors are born before most rod photoreceptors, and most bipolar cells are born very late, though there is temporal overlap in the generation of different classes (236, 237).

A number of models have been put forward to explain the experimental results that have been amassed on the determination of retinal cell fate, and three are illustrated schematically in Figure 33. One model, termed serial competence (Figure 33A(a)), proposes that at any time a given progenitor has competence to produce cells of only one or a few types, and that the progenitors proceed through multiple states of this kind. Another model, progressive restriction (Figure 33A(b)), proposes that early progenitors have competence to produce all cell fates and that this competence is steadily lost (restricted) over time.

An explicit scheme under the latter model is shown in Figure 33B, from Reese (235). This scheme is based on the results of Wong & Rapaport (238), which suggested that restriction of competence represents a unidirectional sequence through which progenitors progress. The diagram illustrates the (unusual) case in which a single progenitor cell generates the entire set of retinal cell classes. As we shall see below, though, not every division produces one post-mitotic daughter cell plus one continuing progenitor cell; some divisions can produce a pair of post-mitotic daughter cells (e.g. a ganglion cell and a cone, or a pair of horizontal cells), while some can produce a Müller cell and a progenitor, or a pair of progenitors. Importantly, though, in the scheme of Wong & Rapaport (238), at every division the competence of the progenitor is progressively restricted, so that cells corresponding to an 'earlier' stage can no longer be created. In Figure 33B, the presumed influence of signaling

molecules is indicated by the broader shaded arrows: diagonal colored arrows indicate signals from the different classes of newly-born cells, while vertical gray arrows indicate Notch-Delta mediated lateral inhibition.

Alternative stochastic scheme. Recently, Gomes et al (239)proposed an alternative stochastic model (Figure 33C) in which the sequential order of cell birth in the overall population results from random choices of cell fate at each cell division, and both they and He et al (240) have obtained evidence in support of this stochastic model. Intuitively, it may be difficult to envisage how it could be possible for random divisions to lead to a deterministic make-up of cell classes, but He et al (240) provide numerical simulations that support their contention.

Three modes of cell division are possible (Figure 33C). In the first mode, termed 'PP', the progenitor cell gives rise to a pair of progenitors, resulting in an expansion of the progenitor population. In the second mode, 'PD', it gives rise to one continuing progenitor and one daughter cell that exits the cell cycle. In the third mode, it gives rise to two daughter cells, 'DD', thereby terminating the lineage. The analysis of He et al (240) showed that as the progenitors proceeded through multiple mitoses, they exhibited a shift from the initially preferred PP mode to the PD mode and finally to the DD mode. Furthermore, the types of daughter cell appeared to be correlated with the PD and DD division modes. In particular, most RGCs arose from PD mode divisions; amacrine cells arose from either PD or DD modes; but horizontal cells, photoreceptors, and bipolar cells mostly arose from DD divisions. They also showed that Ath5 was required both for the specification of RGCs and also for the PD mode of division, explaining why RGC differentiation is always earlier than that of other cell types.

Through the combination of these (and probably additional) factors influencing the probabilities of individual stochastic divisions, the overall effect at a macroscopic level is that the cells of the retina are born (on average) in a well-defined sequence, and also that the final composition of retinal cell types is determined appropriately.

Horizontal cells. In spite of the general understanding that retinal precursors undergo mitosis at the outer (ventricular) surface, and that the daughter cells migrate vertically to their final position in the retina, an exception applies to horizontal cells (at least in the zebrafish retina). In the case of zebrafish horizontal cells, the great majority of precursor cells (90% of the final population) undergo a symmetrical 'DD' mode of mitosis at the laminar position of the mature horizontal cells, giving rise to a pair of horizontal cell daughters (241). This mode of division at the final laminar position may assist in the formation of the layer of horizontal cells, and in achieving lateral connectivity between these cells.

Photoreceptors. The birth and differentiation of photoreceptors is influenced by a plethora of transcription factors and other messengers, as reviewed in Swaroop et al (234). Interestingly, the default situation for a newly-born mammalian photoreceptor cell is that, in the absence of other influences, it will become an S-cone (expressing the SWS1 opsin). In the absence of exposure to the factors NRL/NR2E3 the generic photoreceptor will become a cone, and in the absence of the factor TRβ2 it will become an S-cone. Exposure of the cone to TRβ2 will cause it to express an LWS opsin, with the choice (in human) between L- and M- (via the tandem OPN1LW and OPN1MW genes) being under control of an upstream locus control region. Exposure of the generic photoreceptor to NRL/NR2E3 will commit the cell to becoming a rod.

The default condition, of producing an S-cone, makes sense if one assumes that the ancestral cone type was the SWS variety. At the stage in chordate evolution, prior to '2R', when this ancestral cone and its opsin duplicated, an additional signal would have been needed to specify the alternative LWS fate. Likewise, at the later stage of vertebrate evolution when rods emerged, an appropriate signal would have been needed to specify that fate.

Hypotheses for the evolutionary origin of cells in the vertebrate retina/RPE

On the basis of the observations in the preceding sections, the following hypotheses are advanced for the evolutionary origin of cells in the vertebrate retina/RPE:

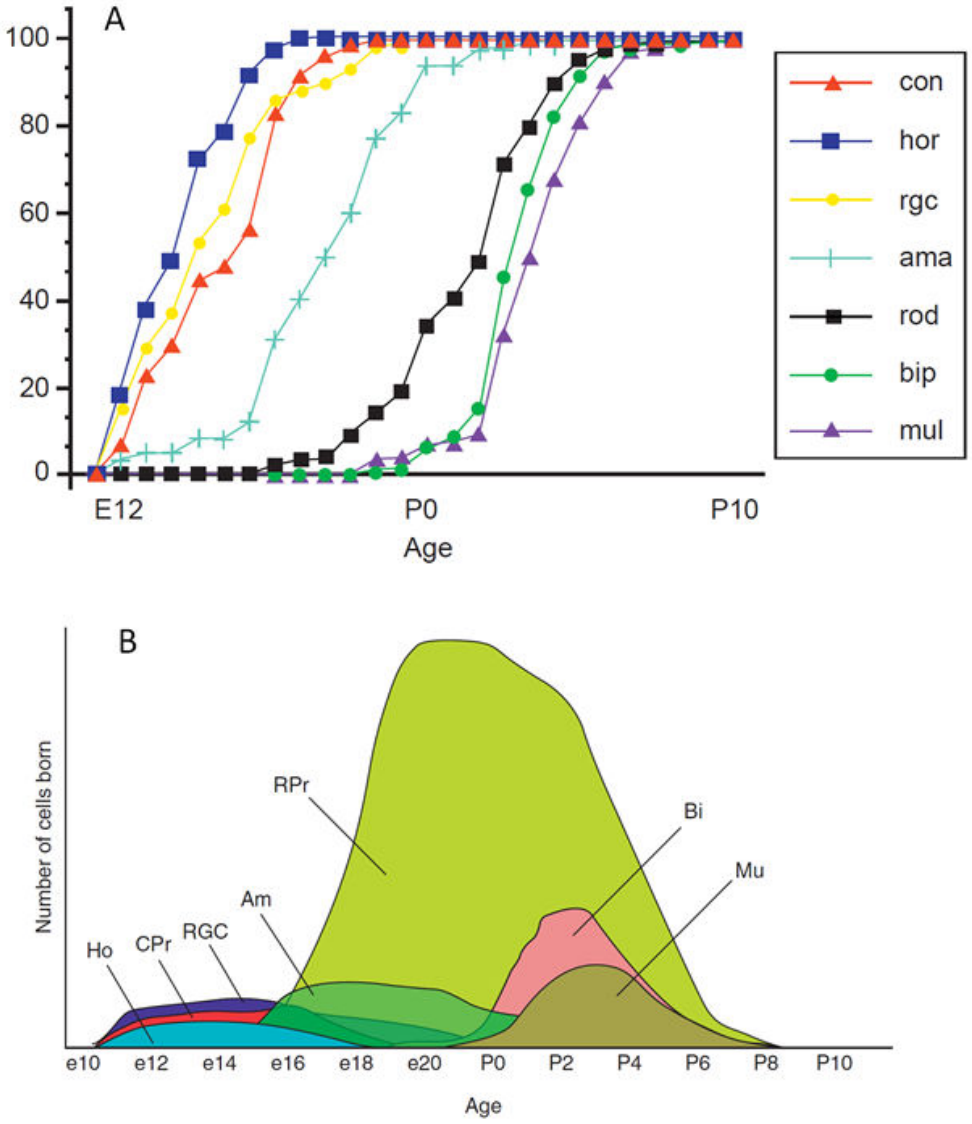

Figure 32. Sequential generation of classes of retinal neuron in the mammalian retina. Two representations of data obtained by Rapaport et al (237) for the rat retina. A, Cumulative percentage of cells in each class, as a function of age. From Brzezinski & Reh (271). B, Rate at which cells in each class were born, in absolute numbers, as a function of age. From (272). Abbreviations in the two panels are as follows. Horizontal cells: hor, Ho. Retinal ganglion cells: rgc, RGC. Cone photoreceptors: con, CPr. Amacrine cells: ama, Am. Rod photoreceptors: rod, RPr. Bipolar cells: bip, Bi. Müller cells: mul, Mu.

M-1) All the cell types in the vertebrate retina/RPE are descended from a single ancestral type of multifunctional cell, that existed in a pre-bilaterian organism, and that functioned as a photoreceptor and that also contained shielding pigment.

M-2) That cell expressed the ancestral opsin and activated a G-protein cascade, and it probably employed cyclic nucleotide-gated channels to generate its electrical response; it might also have had additional (e.g. motile) functions.

M-3) During evolution, subsequent duplications and division of labor gave rise to separate ciliary and microvillar photoreceptors, as well as (in some cases) to separate pigment cells and separate glial cells, in bilaterian organisms.

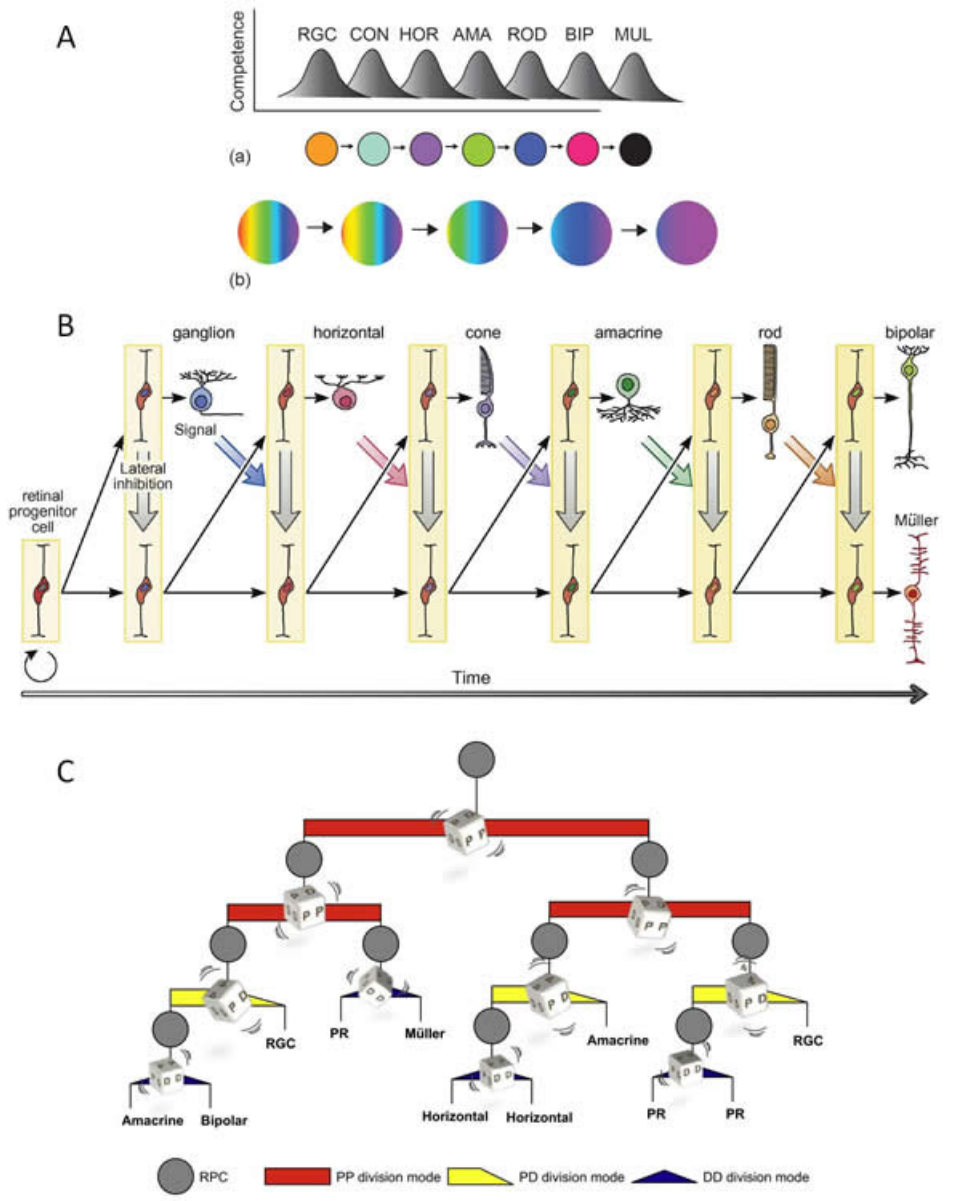

Figure 33. Models for the generation of retinal cell classes. A, Models of serial competence (a) and progressive fate restriction (b). From Brzezinski & Reh (271). B, Sequence of retinal cell classes that would be produced in the special case of a progenitor cell that gave rise to all the possible classes. From Reese (235). C, Stochastic model proposed by Gomes et al (239) and He et al (240). From Chen et al (273). See text for further details.

M-4) Since ancient times, development of the light-sensitive region has involved divisions of a multipotent progenitor cell. In early bilaterians, that progenitor might have given rise only to ciliary photoreceptors, microvillar photoreceptors, pigment cells, and glial cells.

M-5) In the vertebrate lineage, probably after the time of the '2R' duplications but before the divergence of the jawed and jawless lineages, other cell types emerged, as variants of the pre-existing cells (including the microvillar and ciliary photoreceptors). In due course these new cells became horizontal cells, amacrine cells, rod photoreceptors, and bipolar cells.

M-6) In the expanding vertebrate lateral vesicles, a polarity arose, possibly triggered by a signal from the ancestral 'lens placode', causing the outer layer to generate only epithelial cells (RPE), and causing the inner layer to generate all the other classes of cells (the retina). In the dorsal vesicles (pineal, parapineal and parietal) that

lacked the placode signal, the same polarization did not occur, leading to a somewhat different distribution of cell classes.

In considering the data on the order of cell birth in the retina, Dowling (242) has suggested that the early birth of ganglion cells, cones, and horizontal cells may indicate that these were the original classes of cells in the ancestral retina. He notes that horizontal cells share many properties with glial cells, and suggests that the original glia took on neuronal properties and thereby became horizontal cells, with a new class of glia (the Müller cells) emerging; thereafter amacrine cells, rods, and bipolar cells were added. Dowling's scheme represents an explicit proposal for the origin of horizontal cells in step M-5) above.

Uncoupling of differentiation and lateral expansion. As a final point, it is interesting to note that the differentiation of retinal neurons is not obligatorily coupled to the lateral expansion of the eye vesicles. Thus, Manns & Fritzsch (243)showed that application of retinoic acid to *Xenopus* embryos could prevent the formation of eye vesicles, yet in this case an apparently normal set of retinal and RPE cells could differentiate in the dorsal region of the forebrain, with the photoreceptors protruding into the third ventricle.

15. Synaptic transmission from photoreceptors to ganglion cells

Development of photoreceptor connectivity in the mammalian retina

The process of development of photoreceptor neural connectivity is intriguing, and may represent an informative relic of retinal evolution. The process is probably common across mammalian species, though it has been studied most comprehensively (244, 245) in the ferret, which has proved convenient as the young are born at a relatively immature stage of retinal development, and eye-opening does not occur for a further 2 weeks. The process is illustrated by the micrographs and the schematized sequence in Figure 34.

Initially (during the first post-natal week in the ferret) the photoreceptors have a simple bipolar form, making it almost impossible to identify them on purely morphological grounds. But even these very young cells express markers specific for photoreceptors (e.g. recoverin, vGluT1, rhodopsin), and they do so long before they exhibit the characteristic morphology of mature photoreceptors. In the immunofluorescence image of Figure 34A, the young rods are labeled green as a result of reactivity for rhodopsin, which is found to be distributed throughout the entire cytoplasm of the rods before the outer segments have differentiated.

Transient contacts at the inner plexiform layer. At very early times each immature cone or rod photoreceptor sends a process directly to the inner plexiform layer (schematic in Figure 34C). Over the course of the first two post-natal weeks, more and more photoreceptors form, and their processes continue to penetrate the location of the nascent outer plexiform layer, even though the horizontal cells with which they will eventually connect are already in their final positions and have begun to extend their processes laterally (schematic in Figure 34D). Within the IPL, the processes of the young photoreceptors terminate in two discrete sub-layers, coincident with the stratifying processes of cholinergic amacrine cells (micrographs of Figure 34A,Figure 34B and schematic in Figure 34E). The photoreceptor terminals express the synaptic proteins synaptophysin and synaptotagmin, and have the morphological appearance of functional synapses (245). However, it has not been established whether the post-synaptic processes that they contact are amacrine or ganglion cells.

Mature contacts at the outer plexiform layer. Subsequently (around post-natal day 14 in the ferret), these transient processes retract from the IPL, and the photoreceptors instead make synaptic contacts within the developing OPL (schematic in Figure 34F). This phase of retraction coincides in time with maturation of the bipolar cells and with continued maturation of horizontal cells and the OPL. At the developing OPL, each photoreceptor terminal develops a ribbon synapse which first forms a dyad contact with a pair of horizontal cell processes, and is thereafter contacted by a bipolar cell process, giving rise to the adult triad arrangement of the ON pathway. At

around the same time, the distal process of each photoreceptor penetrates the outer limiting membrane, and begins to form an inner segment and an outer segment.

The above developmental sequence, whereby the route for signal transmission from the photoreceptor initially occurs via direct synaptic contact onto the output layer, but is subsequently transformed by the insertion of a bipolar cell into the afferent pathway, is consistent with the notion that a comparable transformation occurred during the evolution of the retina.

Photoreceptor connectivity in organs other than gnathostome retina

Pineal organ: Photoreceptor connectivity to ganglion cells. In non-mammalian vertebrates, pineal photoreceptor cells make direct synaptic contact via ribbon synapses onto projection neurons ('ganglion cells'), as indicated previously in Figure 10A,Figure 10D and reviewed in Dodt (246) and Ekström & Meissl (247). It is generally thought that the pineal organ contains only photoreceptors, ganglion cells, and glial cells, and that it completely lacks the other classes of neuron that characterize the lateral retinas; however, Ekström & Meissl (247) reported the occurrence of a single case of a presumed interneuron that exhibited electrical response properties closely similar to those of the photoreceptors.

Pineal ganglion cell responses are predominantly 'luminosity OFF' units, showing sustained firing in darkness and a graded inhibition of firing during illumination at any wavelength (69, 74, 246, 248). Typical responses for a pineal photoreceptor and a standard 'luminosity OFF' pineal ganglion cell to moderately bright illumination were indicated schematically in Figure 12. For sub-saturating intensities the form of the graded response in the ganglion cell closely resembles that in the photoreceptor. For maintained exposures, the firing rate is reduced in proportion to the logarithm of the intensity, over a range as great as 8 log units (74).

In addition, some luminosity cells are transient, showing little spike activity in darkness but giving a burst of firing at the cessation of a light stimulus. Occasionally, chromatic responses are seen, that involve antagonism between UV-sensitive photoreceptors on the distal side of the organ and the main rhodopsin-containing photoreceptors.

The interpretation of these results is as follows. In the light-sensitive pineal organ of non-mammalian vertebrates, the photoreceptor cells make direct synaptic contact onto ganglion cells via ribbon synapse junctions. The high rate of release of glutamate in darkness leads to a sustained depolarization and steady firing in the ganglion cells. In response to light, the photoreceptors hyperpolarize, reducing their release of glutamate, and eliciting graded responses of similar form in the ganglion cells. The resulting sign-preserving responses in the ganglion cells are accordingly of 'OFF' polarity; they are maintained during steady illumination and show a logarithmic relation to intensity. There is no 'ON' pathway, and no evidence for the involvement of cells other than the photoreceptors and ganglion cells. Given that the pineal organ may well have antedated the lateral retinas of vertebrates, these results suggest that the ancestral pathway for signal flow in the vertebrate retina could conceivably have been directly from cones to OFF retinal ganglion cells.

Hagfish 'eye': Photoreceptor connectivity to ganglion cells. In the hagfish eye, the only known classes of neuron are ciliary photoreceptors and projection neurons. The synaptic terminals of the photoreceptor cells have been shown to form dyad contacts with post-synaptic elements, though to date the identity of those post-synaptic processes has not been determined; nevertheless, it is presumed that they are the projection neurons. Hence the presumption is that the ciliary photoreceptors make direct synaptic contact onto the projection neurons in hagfish.

Contact between ciliary and microvillar cells in amphioxus? The kind of molecular homologies discovered by Arendt and his colleagues, between the vertebrate and *Drosophila* retinas, have recently been extended to the frontal eye of amphioxus. As presented in Section 3, Vopalensky et al (47) have shown a close homology between ciliary photoreceptors in Row 1 of the amphioxus frontal eye and the cone and rod photoreceptors of the

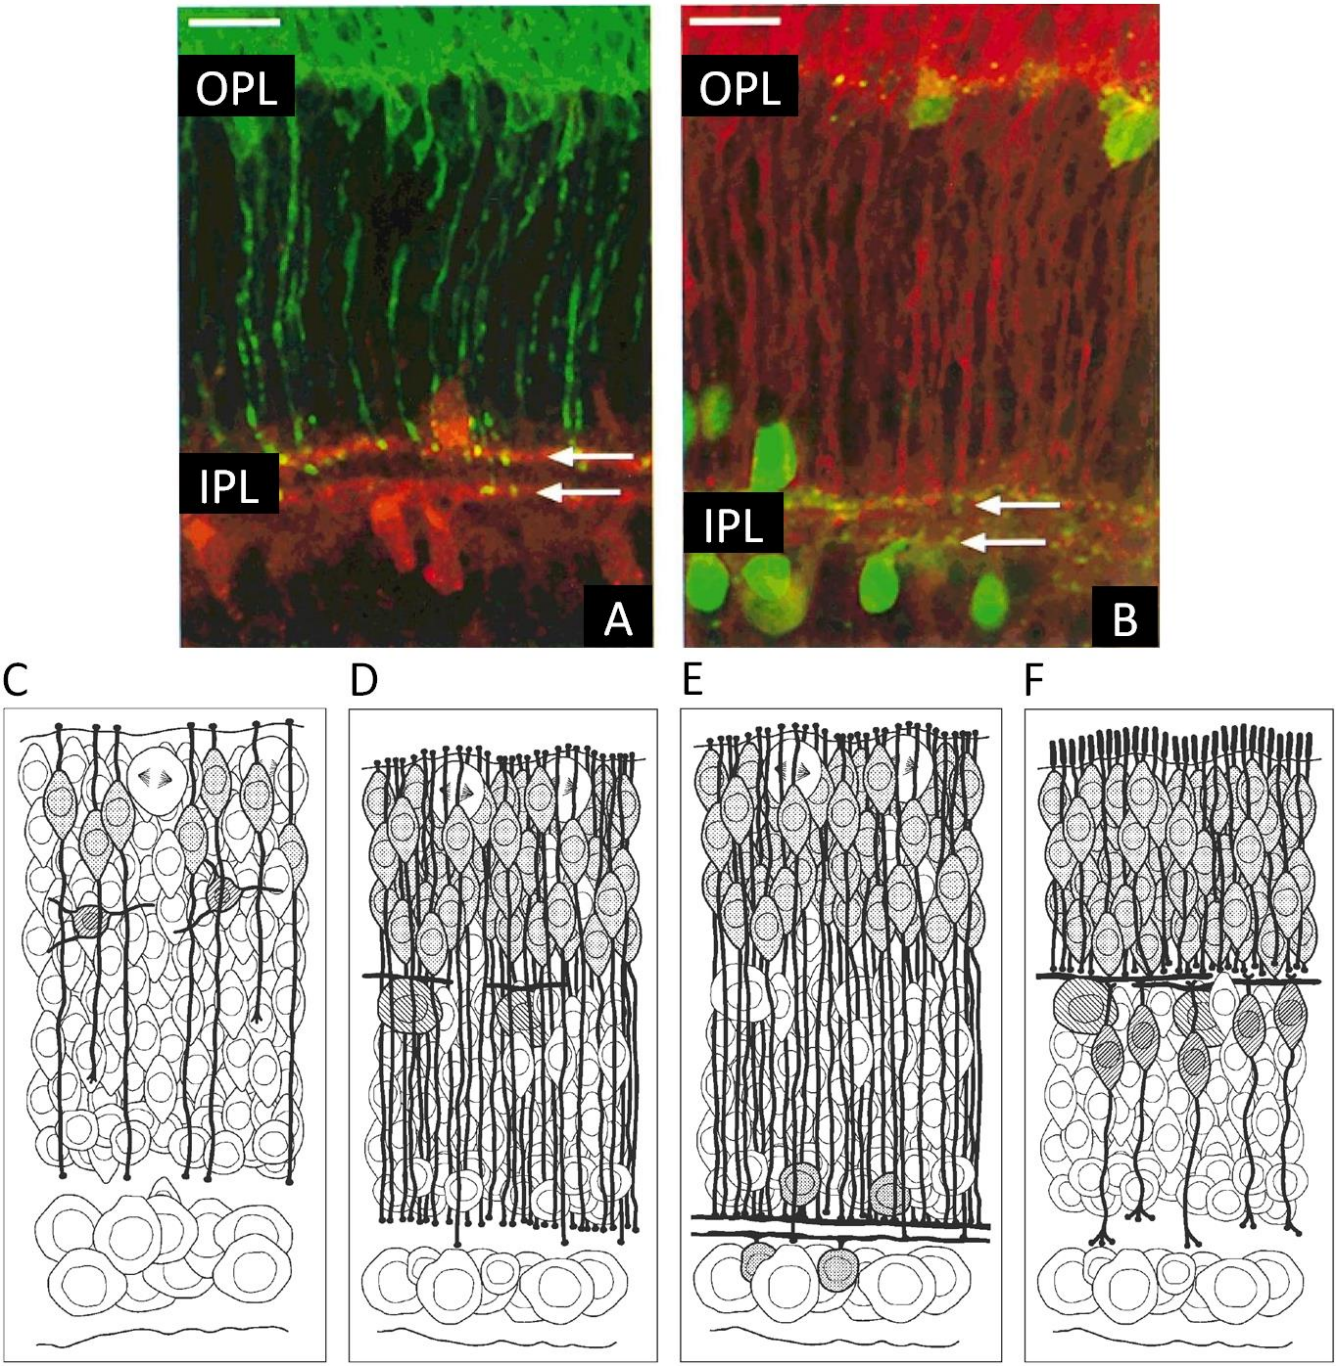

Figure 34. Photoreceptor transient contacts at IPL and final contacts at OPL. Top row: Immunolabeling of ferret retina at P15 (post-natal day 15), the day on which the density of rods projecting to the IPL is highest. Scale bars 10 μm. Modified from Johnson et al (245). A, Rod photoreceptors (green, rhodopsin labeled) send processes to the IPL, where their terminals overlap with the two strata (arrowed) of dendrites from cholinergic and displaced amacrine cells (red, ChAT labeled). B, Cone photoreceptors (red, recoverin labeled) send processes to the IPL, where their terminals overlap with the two strata (arrowed) of dendrites from amacrine and ganglion cells (green, parvalbumin labeled). Bottom row: Schematic representation of the development of photoreceptor and bipolar cell connectivity, in the course of the first (C), second (D, E) and third (F) post-natal weeks. From Reese (274). C, First week. Photoreceptors (pale stippling) extend processes through the neuroblast and amacrine cell layers to the IPL. Horizontal cells (diagonal shading) have migrated into the neuroblast layer, to the site of the future OPL, yet despite their presence the photoreceptors extend beyond them. D, Second week, showing horizontal cells. Horizontal cells (diagonal shading) begin elaborating their horizontally oriented dendrites, giving rise to the OPL. E, Second week, showing cholinergic amacrine cells. Photoreceptor cell processes terminate at two levels within the IPL, coincident with the stratifying processes of the cholinergic amacrine cells (dark stippled cells at the bottom). F, Third week. Horizontal cells, and then bipolar cells (diagonal shading), continue to mature, giving rise to a continuous plexus of processes within the OPL. The photoreceptors retract their terminals from the IPL and form synapses within the OPL. Outer segments begin forming.

vertebrate retina; in addition, it is possible that the Row 2 cells might be homologous to retinal ganglion cells. Elsewhere in the brain of amphioxus, microvillar photoreceptors (Joseph cells) are immediately adjacent to the cells of the lamellar organ, with the Joseph cells 'capping' the lamellate cells (37, 249, 250). Although there is no evidence that the lamellate cells are actually photoreceptors, these reports at least show that during evolution microvillar photoreceptors have come into very close apposition with lamellate ciliary cells.

Scenario for origin of synaptic transmission from photoreceptors to ganglion cells

In light of these observations, the following scenario is proposed for the origin of synaptic transmission from ciliary photoreceptors onto projection neurons in a proto-vertebrate retina (see Figure 35):

N-1) At an early stage in chordate evolution, ciliary photoreceptors and microvillar photoreceptors (that had descended from a common ancestral cell) lay adjacent to each other. They responded to light with hyperpolarizing and depolarizing responses, respectively. These photoreceptor cells were embedded amongst pigmented cells, and possibly separate glial cells, that had likewise descended from the common ancestral cell.

N-2) At this stage, the ciliary photoreceptors conveyed their output via a 'local circuit' or paracrine mechanism, probably releasing melatonin, and possibly also glutamate. This paracrine release may well have had a circadian or seasonal time-keeping function.

N-3) The microvillar photoreceptors signaled their output to other regions of the CNS via axon terminals that released glutamate as synaptic transmitter.

N-4) Over time, the microvillar photoreceptors additionally came to express glutamate receptors and thus were able to respond to signals from the ciliary photoreceptor, and in due course full-blown synaptic contacts evolved. At this stage, the microvillar photoreceptors acted as projection neurons and could transmit the responses of the ciliary photoreceptors rapidly, via their axons and synaptic outputs.

N-5) At some stage (probably coinciding with the improvements in C-opsin performance and the invention of retinoid re-isomerization in darkness), the signals from the ciliary photoreceptors provided virtually all the information that was needed by the organism, and the phototransduction machinery in most of the projection neurons became redundant and withered away.

N-6) The region in which these cells were located was the forerunner of the 'eye fields' that in the future would give rise to the several diencephalic light-sensitive organs. Its expansion occurred as described above in Section 13.

16. Retinal processing: Bipolar cells and the photopic and scotopic pathways

The nature and origin of retinal bipolar cells

Retinal bipolar cells share a large repertoire of features with cone and rod photoreceptors. Structurally, retinal bipolar cells have the same 'bipolar' shape as is initially exhibited by developing photoreceptors, prior to the differentiation of their inner and outer segments.

Landolt's club. Some bipolar cells possess an appendage, the Landolt's club (Figure 36) that bears a striking similarity to the inner segment of the photoreceptor (251-253). This organelle has microtubules organized in the 9+0 pattern characteristic of non-motile cilia, and is located at the outer limiting membrane, though it differs from the inner segment in not giving rise to an outer segment. In the chick retina, Quesada & Genis-Galvez

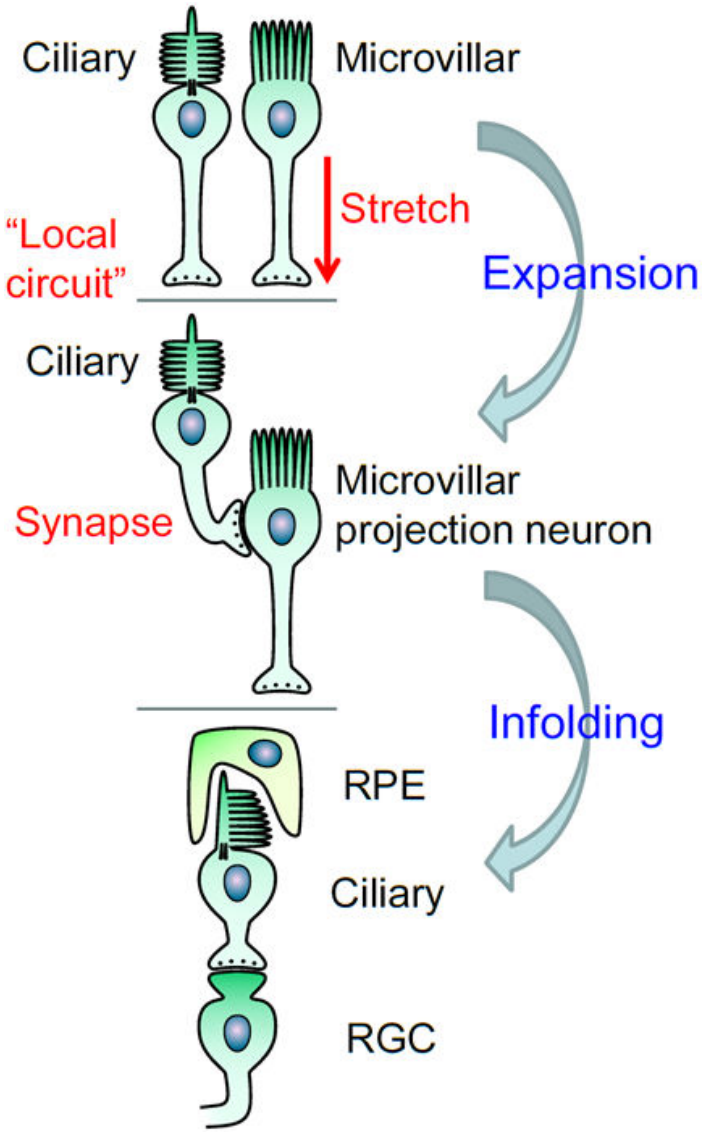

Figure 35. Ciliary photoreceptors make synaptic contact onto ganglion cells. Hypothesized sequence of steps for the formation of the photoreceptor to retinal ganglion cell pathway from ciliary and microvillar photoreceptors. Top: At some stage, ciliary and microvillar photoreceptors co-existed in close proximity to each other; pigmented glial cells were also present but are not shown. The ciliary photoreceptor is envisaged to have had a 'local circuit' or paracrine role, in releasing one or more chemical messengers (perhaps melatonin and glutamate), whereas the microvillar photoreceptor made synaptic contacts onto target cells (not shown). Middle: As this light-sensitive region of the diencephalon expanded, the ciliary and microvillar photoreceptors maintained their respective 'local circuit' and synaptic transmission modes, with the axons of the microvillar cells elongating to reach their targets, and with the paracrine release from the ciliary cells developing into synaptic transmission with the expression of glutamate receptors on the microvillar cells. At this stage it is envisaged that both sets of cells would have responded to light, though with opposite polarity, and the axons of the microvillar cells provided the neural output for both sets of photoreceptors. Bottom: With the in-folding of the eye-cup, the outer segments of the ciliary photoreceptors came into close apposition with the monolayer of retinal pigment epithelial cells, and at this stage the pigment cells that had previously been present in the retina were able to be dispensed with. At some stage, most of the formerly microvillar cells lost their microvillar membrane and their phototransduction cascade, though a subset retained vestiges, as intrinsically photosensitive retinal ganglion cells. Modified from Lamb, Pugh & Collin (275).

(254) have reported that in early embryonic stages all of the bipolar cells are connected to the outer limiting membrane by a Landolt's club, and that during development many of these processes retract.

Transduction. In terms of transduction mechanisms, the G-protein cascade of the ON bipolar cells bears a remarkable similarity to the phototransduction cascade in vertebrate photoreceptors. In addition, the output

synapse of the bipolar cell is very similar to that of the photoreceptor, employing synaptic ribbon structures that are not found in any other types of retinal neuron. Finally, many proteins expressed in retinal bipolar cells are either identical to, or else represent isoforms of, proteins found in cone and rod photoreceptors; for example, recoverin, potassium channels, and the molecular machinery of ribbon synapses.

In view of these close similarities, as well as the order of differentiation of retinal cells (Figure 33) it is possible to view retinal bipolar cells as probable 'descendants' of retinal ciliary photoreceptors, in the sense that they appear to have evolved as a kind of variant of the established ciliary photoreceptor theme and have thereby inherited a great many of the properties of those photoreceptors. If this is indeed the case then one might anticipate that cone ON bipolar cells would have descended from cones, and that rod bipolar cells might have descended from rods rather than from cone bipolar cells.

An alternative (though perhaps less likely) possibility that might account for these observations is that photoreceptors and bipolar cells are independent descendants of the 'proto-neuron' that has been hypothesized to have been the most ancient type of vertebrate nerve cell (208, 209, 255). However, this hypothesis would not seem to sit well with the evidence that cone and rod photoreceptors are descended from an ancestral ciliary photoreceptor. An extant representative of the presumed ancestral proto-neuron has been suggested to be the sensory 'cerebrospinal fluid (CSF)-contacting neuron' present in the CNS of amphioxus, hagfish (256) and lampreys (257), as well as jawed vertebrates.

Scenario for evolution of the photopic signaling pathway via bipolar cells

From the observations in Section 14 on the development of photoreceptor contacts in the embryonic retina, and the observations above on the nature of bipolar cells, as well as the findings in Section 14 on the timing of retinal development, the following is proposed as the likely sequence of events that occurred during evolution of the afferent pathway in the vertebrate retina:

O-1) At the stage of eye evolution where the eye vesicles had bulged laterally to form the ancestral retina/RPE, the photoreceptors already made synaptic contacts directly onto ganglion cells, which projected axons to the CNS.

O-2) Horizontal cells evolved, and made synaptic contacts with photoreceptors at ribbon synapses in a dyad structure; they provided spatial integration of light signals, and fed this spatially-averaged signal back (inverted) onto the photoreceptor terminals thereby generating an element of spatial contrast.

O-3) Subsequently, a modified class of 'pseudo photoreceptor' cell evolved, that had lost the capability of expressing visual pigment and an outer segment, but that expressed metabotropic glutamate receptors.

O-4) During retinal development, this new class of cell, the retinal ON bipolar cell, inserted its dendritic terminals into photoreceptor dyads, to form triads, while its afferent process made the same journey to the IPL that its predecessor (the photoreceptor) had made.

O-5) A variant of this cell expressed ionotropic glutamate receptors and became the OFF bipolar cell.

O-6) Overall, a new twin-set of neural elements had been incorporated into the ancestral two-layered retina, greatly expanding the retina's capacity to perform spatiotemporal processing computations.

Dedicated scotopic pathway for rod signals

The existence of unexpected retinal circuitry in the rod pathway of mammals was first described by Kolb & Famiglietti (258), Nelson (259) and Kolb and Nelson (260); see chapters in webvision on "Circuitry for rod signals", "AII amacrine cells" and "Bipolar cell pathways". The details of this circuitry were expanded upon by Strettoi et al (261) and Vaney et al (262), and shortly afterwards Strettoi et al (263) set out the concept that the

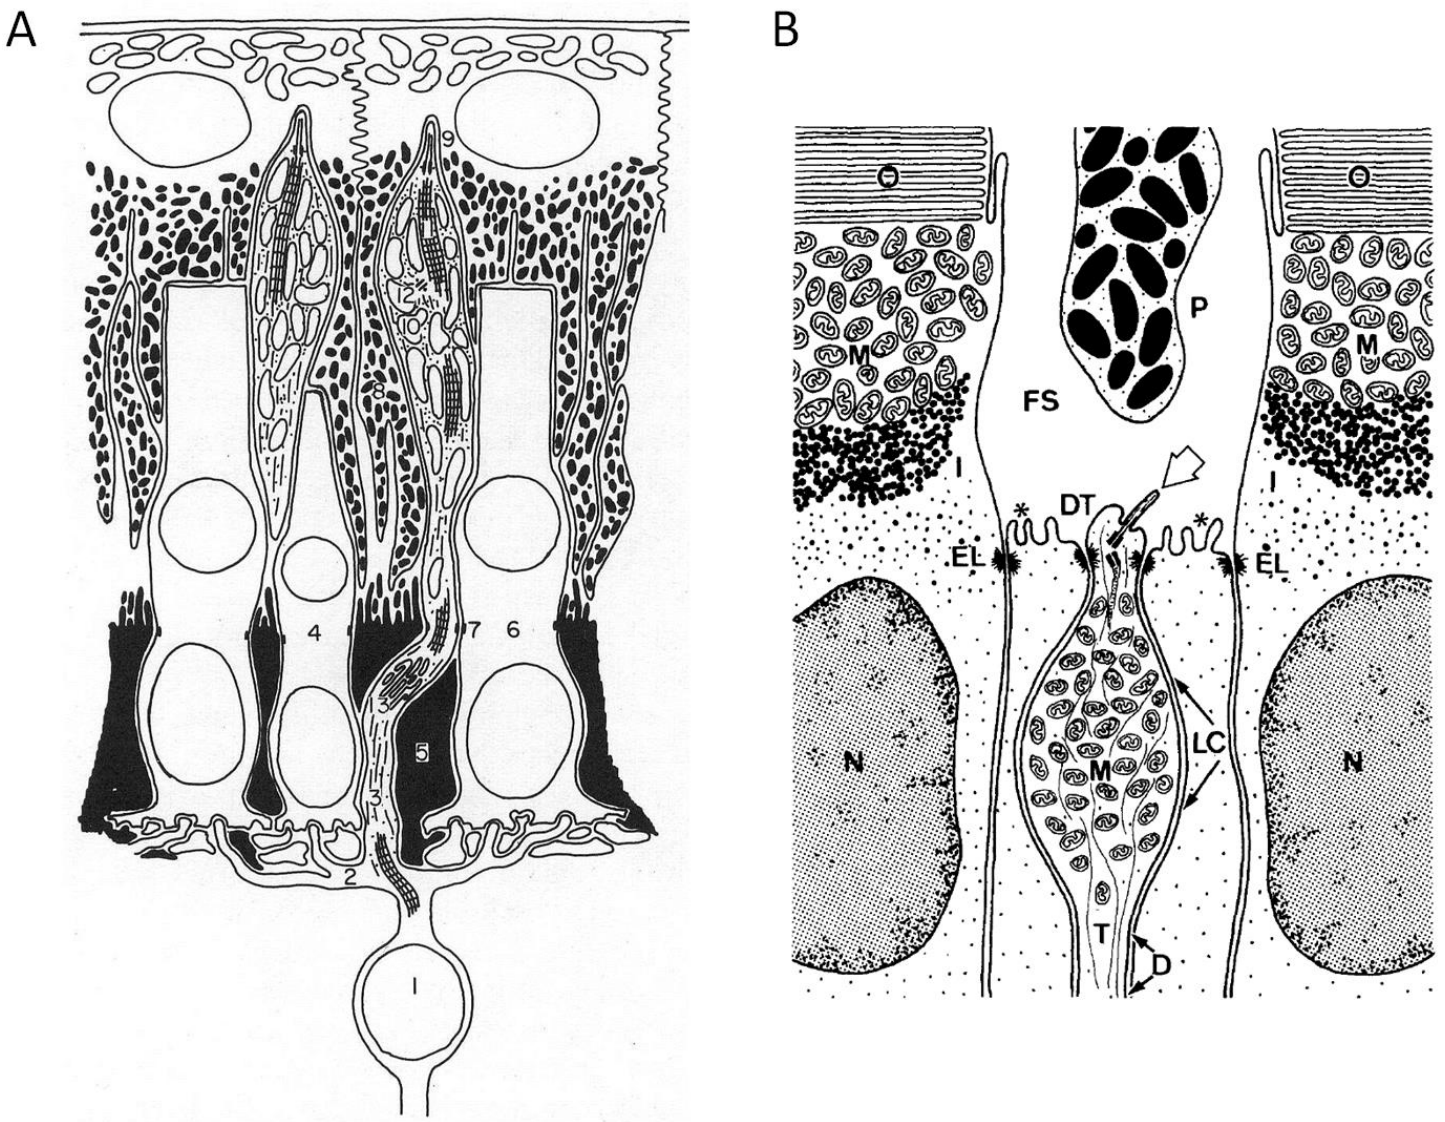

Figure 36. Landolt's club. Two schematic representations of Landolt's clubs in the retinas of different species, showing several points of resemblance to photoreceptor inner and outer segments. A, Schematic of bipolar cell and Landolt's club in lungfish retina. The bipolar cell of origin (1) gives rise to a tuft of dendrites (2) from which the stalk (3) of Landolt's club arises. Beyond the outer limiting membrane (7), the club expands and is closely apposed to the cone and rod inner and outer segments and to the processes (8) of RPE cells. The club terminates in a 9+0 cilium (9) that inserts into the RPE cell. The expanded region of the club is packed with mitochondria (10) and contains the ciliary rootlets (11). Cone (4); rod (6). From Locket (252). B, Schematic of Landolt's club for a generalized vertebrate retina. The club (LC) expands from a bipolar cell dendrite (D) and is packed with mitochondria (M); it is shown enwrapped by a Müller cell. Its dendritic terminal (DT) and 9+0 cilium (broad arrow) penetrate the outer limiting membrane (EL), and enter the sub-retinal space (FS). I, O, inner and outer segments of photoreceptors. From Vigh et al (253).

mammalian scotopic (rod-driven) retinal pathway 'piggybacks' on a pre-existing photopic (cone-driven) pathway. Coincidentally, this was the same year that Okano et al (115) discovered that rod opsins had evolved from cone opsins.

In functional terms, the main advantage of this piggyback arrangement is that the duplex cone-plus-rod system does not require duplicate pathways for neural processing in the retina, and nor does it require a duplicate set of nerve fibers to the brain. Instead, the rod signals enter the pre-existing sophisticated cone neural processing circuitry, where they can be seamlessly integrated. For visual perception, this means that it is almost impossible for one to distinguish whether it is one's scotopic or photopic system that is being utilized.

The manner in which the rod signals are injected into the mammalian cone system looks complicated (Figure 37), but it cleverly avoids introducing major compromises, especially by avoiding the generation of additional noise. From mesopic (twilight) light levels down to high scotopic (moonlight) levels, the rod signals pass via gap junctions onto cones (denoted ON2 and OFF2 in Figure 37) thereby employing the photopic pathway in its entirety. But at very low scotopic (starlight) levels, a separate dedicated system comes into operation, utilizing the rod bipolar cell and the AII amacrine cell.

For the ON system, illustrated on the left side of Figure 37, the photopic pathway uses a sign-inverting synapse (red arrow) from cone photoreceptor to cone ON bipolar cell (via a metabotropic glutamate receptor mechanism), followed by a sign-preserving synapse (green) from cone ON bipolar cell to ON ganglion cell. Thus, at low light levels, when the cones are contributing little in the way of signals, the ON bipolar cell is hyperpolarized and the synapse from ON bipolar cell to ganglion cell is quiescent. At low scotopic levels (indicated ON1), rod activity is signaled via a sign-inverting synapse onto the rod bipolar cell, and thence via a sign-preserving synapse to the AII amacrine cell, so that dim scotopic illumination causes depolarization of the AII amacrine cells (i.e. the same polarity as any light-stimulated activity in the cone ON bipolar cells). The scotopic signals are then coupled into the cone pathway, with no additional noise contribution, via gap junction electrical connections from the AII amacrine cells onto the cone ON bipolar cells (indicated in orange). In bright light, when the rods are saturated, and the rod bipolar cells and AII amacrine cells are strongly depolarized, it is possible that the gap junctions close, to prevent the intrusion of unwanted signals. If instead the rod bipolar cells had connected directly onto the ON ganglion cells synaptically (as for cone bipolar cells), a major disadvantage would have been the injection of large levels of synaptic noise into the photopic system when the rods were saturated.

For the OFF system, illustrated on the right of Figure 37, the photopic pathway uses a sign-preserving synapse (green arrow) from cone to OFF bipolar cell (via an ionotropic glutamate receptor mechanism), followed by a second sign-preserving synapse (green) from cone OFF bipolar cell to OFF ganglion cell. As a result, in the quiescent dark state, the cone OFF bipolar cell is depolarized and is continually releasing synaptic transmitter (glutamate) onto the OFF ganglion cell at a high rate. How, then, could activity from the scotopic system be injected into the cone OFF pathway, in the presence of this continual synaptic input? The answer that has been adopted is to employ a sign-inverting synaptic input from the AII amacrine cell onto the pre-synaptic terminal of the cone OFF bipolar cell (indicated OFF1). In this way, dim scotopic light leads to hyperpolarization of the cone OFF bipolar cell's synaptic terminal, thereby suppressing its on-going high rate of release of synaptic transmitter, just as occurs for signals that come from the cones.

This analysis shows that, by the time that mammals appeared, evolution had found a means by which to superimpose the single-photon detection capabilities of the more recently evolved rods onto a pre-existing cone neural processing pathway, in a seamless manner, with minimal additional wiring, and in a way that introduced minimal additional noise and that minimally perturbed the sophisticated signal processing functions of the cone circuitry. However, it is not yet clear whether this was the first solution that had been adopted in the early vertebrate retina.

Thus, it will be important to discover whether similar AII amacrine cell circuitry is employed in the retinas of vertebrates other than mammals, but so far a definitive answer to this question does not appear to have been established. In non-mammalian vertebrate retinas, it is clear that scotopic signals are processed via bipolar cells that are highly sensitive and that display response properties very similar to those of mammalian rod bipolar cells; e.g. Ashmore & Falk (264) in dogfish. Likewise, ERG recordings in lamprey retina have show a sensitive *b*-wave signal at very low light intensities However, the circuitry by which rod and cone signals are combined is not entirely clear. One possibility is that in non-mammalian retinas rod and cone signals are merged solely at the level of the outer plexiform layer, via gap junctions between rods and cones, and possibly via synaptic input from both rods and cones onto a single class of bipolar cell. In this case the bipolar cells would be of the mixed rod-

cone type, and thereafter the signals would be processed by the conventional cone pathway, comprising bipolar cell to ganglion cell. Alternatively, it is possible that circuitry analogous to that of the AII amacrine cell exists in the inner retina. Until the details of the scotopic circuitry of non-mammalian vertebrate species have been elucidated, it may not be possible to ascertain the extent to which the ancestral vertebrate retina employed the outer versus the inner plexiform layer to inject its rod-derived signals into the cone pathway. But in either case it is clear that, as a minimum, the output (ganglion cell) stage of the pre-existing cone system was utilized.

At this stage, there is insufficient information available to justify the proposal of explicit steps in the evolution of the dedicated scotopic pathway.

17. When did spatial (imaging) vision arise in the chordate lineage?

It was argued above, in Section 13, that the retina of the vertebrate lateral eyes evolved first as a non-imaging light-sensitive organ, with many similarities to the two-layered retina in the dorsal organs (pineal, parapineal, and parietal eye) of extant non-mammalian vertebrates. But when did that two-layered retina first emerge? And when, and by what means, did that pair of 'lateral pineal-like organs' evolve to become imaging organs for a visual system?

There is no evidence to suggest that the last common ancestor that we share with tunicates (at point #4 in Figure 1) could have possessed anything resembling a retina. On the other hand, our last common ancestor with lampreys (at point #5 in Figure 1) seems almost certain to have possessed a fully-fledged vertebrate-style eye, with three-layered retina, lens, extraocular muscles, and so on. Unfortunately, none of the numerous organisms that diverged from our own lineage (represented by the red curve in Figure 1) between those times has survived to the present day. Several extinct species that diverged during that interval are known from the fossil record. Although these fossil species have been reported to have possessed 'eyes', the preservation of their soft tissues is so imperfect that it is not even known whether those organs contained a lens. It seems that the fossilized lateral impressions described as 'eyes' tend to be black, or at least dark, which might be consistent with their having contained pigment.

Accordingly, it does not currently seem possible to be more specific than to say that the lateral two-layered retina arose some time after point #4 in Figure 1 and that the full-blown lateral eyes arose subsequently, at some time prior to point #5 in Figure 1. On the basis of the dates put forward by Erwin et al (20), these divergences occurred 600 Mya and 500 Mya, respectively. So, unfortunately, we do not appear to be in a position to tie down the relevant times of evolution of these important features any more precisely than within that interval of 100 million years.

If it were possible to date with any precision the timing of the occurrences of the '2R' pair of whole genome duplications, then it might be possible to narrow down the timing of the events of interest in eye evolution. Thus, the ciliary opsin quadruplication did not appear until after '2R', and hence the present five classes of ciliary opsin could not have appeared before that time, so that (for example) rods could not have appeared before that time.

A calculation has been made by Nilsson & Pelger (265) of the time required for a lens to evolve. This calculation assumed that a fully functional retina was already present, and that it was already connected appropriately to the brain, but the calculation did not take account of other changes that might be required, such as the emergence of a system of muscles to orient the eye. Hence, the time that they calculated, of approaching 1 million years, would appear to enormously underestimate the time required to transform a handful of photoreceptors into a functional eye.

Instead, we can expect that the transitions described above might have taken far longer, because each must have involved a long sequence of changes. To transform a handful of ciliary and microvillar photoreceptors into a

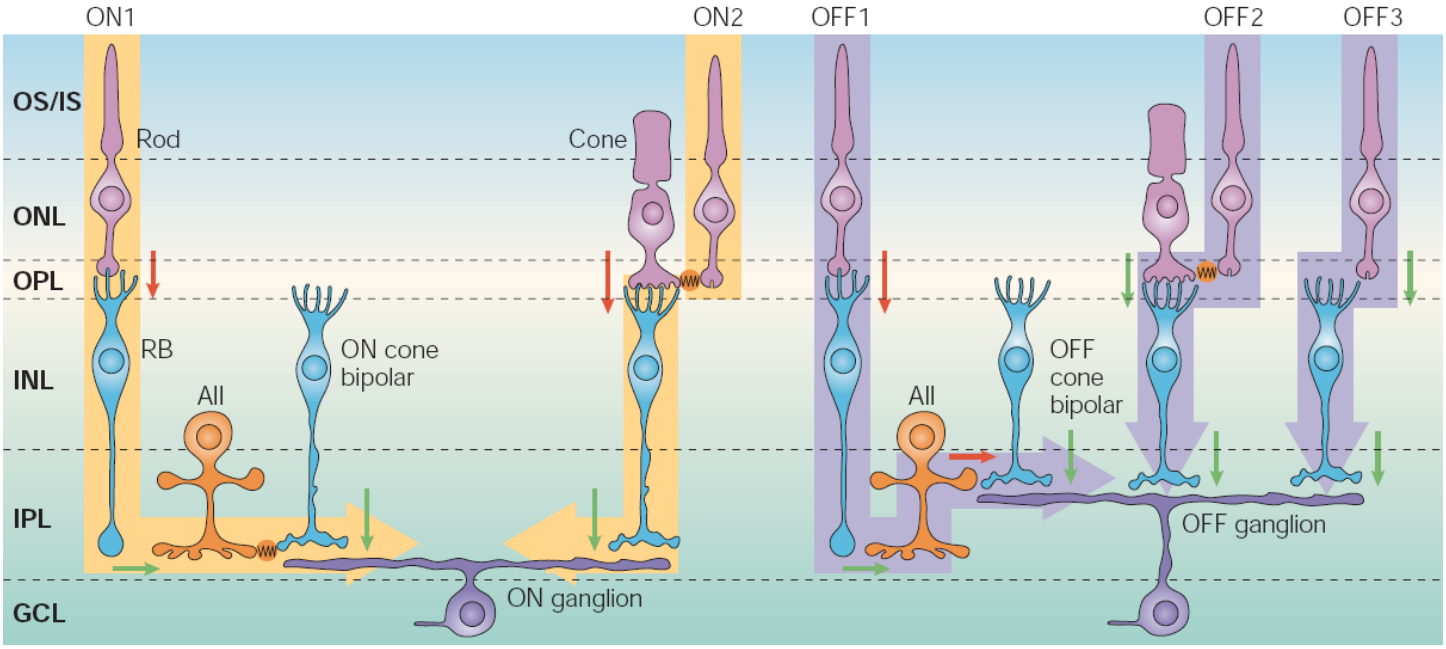

Figure 37. Cone and rod afferent pathways through the mammalian retina. Schematic wiring diagram of the mammalian retina, emphasizing the rod (scotopic) pathways. Left, ON pathways. Right, OFF pathways. Cone circuitry is indicated using just two cone photoreceptors; that in the left half is shown connecting via an ON cone bipolar cell to an ON ganglion cell; that in the right half is shown connecting via an OFF cone bipolar cell to an OFF ganglion cell. The rod pathways are described in the text. From Wässle (276).

pineal-like retina would have required numerous steps. Thereafter, to add bipolar cells, to add a lens and cornea, to add extraocular muscles, and (possibly most demandingly) to create a processing center in the brain that could deal with this spatial information, would have required enormous numbers of parallel steps. It does not seem unreasonable to contemplate that the time taken to implement the combination of these major transformations (first to non-imaging retinas, and then to imaging eyes) might have occupied a very substantial proportion of the 100 million year interval that is currently thought to have been available.

18. Conclusions: Scenario for the evolution of photoreceptors and the vertebrate retina

The following sub-sections set out a proposed scenario for the sequence of the more important of the numerous steps that were involved in the evolution of photoreceptors cells and of the vertebrate retina, using the epoch numbering scheme from Figure 1.

Early metazoans: Prior to point #1 (>700 Mya)

Sensory cell. The sensory cell from which all animal photoreceptors evolved employed a G-protein coupled receptor (GPCR), which triggered a G-protein cascade that is likely to have employed cyclic nucleotide gated channels (CNGCs).

Opsins. The original opsin arose during the relatively short interval (of ~10 million years), just prior to 700 Mya (see Figure 2), between the divergence first of placozoans and then of cnidarians from our own lineage. Prior to this, mutations in a GPCR had changed its binding specificity so that the ligand that activated it became retinaldehyde, and this modified GPCR thereby became a retinaldehyde receptor; as in other GPCRs the ligand bound non-covalently. (One of the close relatives of this GPCR appears to have given rise to the melatonin receptors of vertebrates.) After placozoans had diverged, mutation of this retinaldehyde receptor gave it a lysine

residue in its seventh transmembrane helix (corresponding to K296), so that the retinaldehyde ligand could now bind covalently via a Schiff base bond. A further mutation added a negatively charged residue nearby (corresponding to E181) that acted as a counterion, enabling the Schiff base to be protonated. This molecule thus became the ancestral opsin. It would have absorbed at the short-wavelength end of the spectrum, though we cannot be sure whether its peak would have been in what we call the 'visible' part of the spectrum or in the UV. Subsequently, this ancestral opsin duplicated twice, prior to the divergence of cnidaria, giving rise to three major branches of opsins, namely C-, R-, and RGR/Go-opsins.

Photoreceptor cells and phototransduction cascades. Once that ancestral opsin appeared, the ancestral photoreceptor had been born. It seems likely that this original photoreceptor cell resembled the ciliary category, with the opsin expressed in the membrane of the cilium and coupling via a Gi and/or Gs cascade to modulate cyclic nucleotide levels and CNGC activity. It is possible that this ancestral photoreceptor cell possessed the components of more than one G-protein signaling cascade, but at present there is too little information available to be sure about its transduction cascade(s). In the short time before cnidaria diverged, it is possible that two classes of opsin-containing cell had come into existence, with one expressing the ancestral C-opsin in its ciliary surface membrane and the other expressing the RGR/Go-opsin in the membrane of intracellular organelles. One likely function of the ancestral RGR/Go-opsin was as a retinoid photoisomerase that used light to convert the all-*trans* isomer to the 11-*cis* isomer. While it is possible that separate microvillar photoreceptors using the R-opsin had also emerged, and that they later disappeared in cnidaria, it is suggested that the microvillar class of photoreceptor arose only in bilaterians.

Other components of the ancestral light-sensitive cells. It is likely that the ancestral light-sensitive cells in those early metazoa were multifunctional, additionally expressing pigment that could act as a light shield, and it is also possible that these cells had motile functions (79). The animals possessing these cells would have been very small and would not have had a recognizable nervous system. Their cells would have been able to signal to each other by means of diffusible chemical messengers; i.e. by paracrine release. A chemical messaging system to control the basic features of differentiation in these cells would need to have been laid down by this time. Thus, the ancestral system of transcription factors specific to light-sensitive tissue was probably already in place.

Division of labor. As proposed by Arendt et al (5), it seems likely that processes of gene duplication and evolution led to the emergence of more specialized daughter cells, that shared out between them roles that had originally been performed by a single cell. If, as is suggested above, an ancient multifunctional photoreceptor cell had expressed more than one class of opsin and transduction cascade, and also functioned as a pigment cell and had a motile role, then over time these functions may have been delegated to separate specialized cells that inherited only the components relevant to a subset of the original functions. Thus, motile cells and pigment cells became separate from those that performed phototransduction; likewise, the 'photoisomerase' opsins could have been relegated to separate cells (for example, to the pigment cells). Similarly, the different opsins and their transduction cascades became separated into distinct cell types.

Bilaterians, protostomes, and early deuterostomes

Early bilaterians. In the bilaterian lineage (i.e. after the divergence of cnidaria), at least two variants of photoreceptor cell were present: a ciliary photoreceptor class expressing a C-opsin, and a microvillar photoreceptor class expressing an R-opsin. It seems likely that these two classes of cell came to be utilized for different functions. One possibility is that the ciliary photoreceptors adopted a role in diurnal and seasonal time-keeping functions, whereas microvillar photoreceptors adopted a role in phototactic behavior, providing the signal for the organism to move either towards or away from light (e.g. up or down in the water column).

Protostomes. Following the split between protostomes and deuterostomes (at point #2, Figure 1), it would appear that some protostomes evolved a lens in front of a handful of microvillar photoreceptors, in what would have become an ocellus or a single ommatidium. Perhaps signals evolved that led to the duplication/multiplication of

a number of such adjacent ommatidia, leading to the formation of compound eyes. At some later stage, the microvillar photoreceptors in some protostome lineages developed a highly organized sub-cellular structure (the rhabdomere) and a highly-specialized version of the transduction cascade, and gave rise to rhabdomeric photoreceptors. Until the advent of full-blown rhabdomeric photoreceptors in those particular lineages, it is entirely plausible that microvillar photoreceptors may not have been very sensitive. In the chordate lineage, for example, microvillar photoreceptors in amphioxus have much lower sensitivity than their protostome counterparts that evolved rhabdomeric structure (46).

Early deuterostomes. No such developments (in the form of either a lens or a rhabdomere structure) appear to have occurred in the deuterostome lineage. Thus, although microvillar photoreceptors persisted in deuterostomes, they remained as relatively simple cells, sparsely distributed, sometimes in association with pigmented cells. Likewise, relatively little seems to have occurred in the way of changes to the ciliary photoreceptors in the early deuterostome lineage.

Chordates - Early events: From point #3 onwards (Since ~650 Mya)

Refinement of C-opsins. The transformation of an ancestral C-opsin into vertebrate visual opsins appears to have involved a prolonged sequence. One of the most important changes was the re-location of the counterion site (from 181 to 113), as this allowed the meta II state to be modified in a way that achieved a higher rate of activation of the G-protein and it also allowed the meta II state to decay fairly rapidly, releasing all-*trans* retinal.

In the phylogenetic tree of C-opsins (Figure 19), there are several extant opsins that clade between the most basal C-opsin and the cone opsins, and these include Opn3, parietopsin, parapinopsin, VA/VAL-opsin, and possibly pinopsin. The functional properties of these opsins also tend to follow a sequence (Section 5), and it seems clear that the performance of C-opsins was steadily enhanced during chordate evolution, reaching a high level by the time that the first cone opsin emerged (Section 5) Thereafter this ancestral cone opsin duplicated to form both an SWS and an LWS opsin. The tunicate *Ciona intestinalis*, which diverged at point #4 (Figure 1), possesses a single C-opsin, Ci-Opsin1, that clades close to VA/VAL (though this is not shown explicitly in Figure 19. Accordingly it seems plausible that the refinement of chordate C-opsins that ultimately gave rise to cone opsins was only partway through by the time that tunicates diverged, and perhaps that the entire process of refinement may have stretched out over much of the 150 million year period from #3 to #5 in Figure 1.

Refinement of the phototransduction cascade. Over the course of chordate evolution, it appears that refinements also occurred in the phototransduction cascade. These changes include: the emergence of a Gt variant of the G-protein alpha subunit (i.e. transducin), apparently through duplication of a common Gαi / Gαt ancestor; the emergence of PDE6 specific for cGMP; the emergence of its regulatory PDEγ subunits; and so on. While the exact sequence of these developments remains obscure, and the chain of events was no doubt prolonged, it seems clear that, prior to the '2R' whole-genome duplications, the phototransduction cascade in the ancestral cone photoreceptor had already reached a state that would have been fundamentally similar to that in modern vertebrate cones.

Synaptic contact from ciliary photoreceptors onto microvillar photoreceptors. There are few landmarks to indicate when it was that synaptic contact became established between ciliary photoreceptors and their microvillar counterparts (most of which subsequently lost their light sensitivity). Amphioxus possesses microvillar photoreceptors (Joseph cells) that are immediately adjacent to cells of the lamellar organ, with the microvillar cells 'capping' the lamellate cells (Section 15) although these lamellate cells have generally been presumed to be ciliary photoreceptors, this has not been confirmed through electrophysiological recording and nor has an opsin yet been identified in them. In the 'frontal eye' of amphioxus, it has recently been shown that ciliary photoreceptors (Row 1 cells) are positioned immediately adjacent to projection neurons (Row 2 cells) that may conceivably be homologous to retinal ganglion cells (6). Hence it is possible that the last common ancestor we

share with amphioxus already had ciliary photoreceptors making synaptic contact onto microvillar photoreceptors.

Chordate to vertebrate transition: Interval #4 - #5 (~600 - 500 Mya)

In the chordate lineage, it would seem that most of the transformations that distinguish an 'eyespot' from an 'eye' are likely to have occurred during the 100 million year interval from #4 to #5 (Figure 1), around 600-500 Mya. In the light-sensitive tissue itself, these transformations included: massive enlargement of the tissue to form a retina; the invention of a means of re-isomerization of retinoid in darkness; the elaboration of retinal processing power, including the invention of bipolar cells; and the transformation of one class of cone into more rod-like cells. Outside the retina, the transformations included: the formation of accessory structures, including the lens, the cornea, the iris, and intra- and extra-ocular muscles, as well as the formation of brain regions to process the visual information and to control the motor system.

Expansion of diencephalic light-sensitive region. The region comprising the light-sensitive tissue expanded, both dorsally and laterally, at some stage during chordate evolution; most of this expansion appears to have occurred after the divergence of tunicates. The initial driving force for expansion may simply have been the need to achieve greater sensitivity, and that may have led to the deployment of a larger area for absorption of incident light. One factor favoring expansion in the lateral direction may have been the shielding of down-welling light that accompanied the expansion of the primitive brain and the formation of a cartilaginous cranium. The advantages to the organism would have been not only increased light sensitivity, but the potential for shadow detection and a crude comparison of the direction of incident illumination.

In the tissue expansion that occurred, it seems that only the microvillar photoreceptor cells extended axons to their pre-existing targets in more central brain regions, and that the ciliary photoreceptor cells continued to signal in a purely local manner. At some stage, their signaling mechanism became synaptic, rather than paracrine, though the ciliary photoreceptors have retained to this day the capacity to release melatonin.

The region that bulged appears to have had minimal luminal space, so that its apposing luminal (interior) surfaces were in contact with each other; the innermost surface of each side contained ciliary photoreceptors embedded amongst pigment cells and glial cells. This expanding vesicle developed a 'polarity', that rendered the two sides different, and that in due course gave rise to a complete distinction between 'retina' on one side and 'RPE' on the other; the signal for this development of polarity may have been generated by the ancestral placode that subsequently evolved into the lens placode. As a result of the polarization, pigment cells no longer formed on the side facing the external world, while neural elements formed only on that side. This afforded a major advantage to the organism, in terms of increased light sensitivity, because the entire cross-sectional area of the organ was now tiled with photoreceptors, whereas previously a substantial proportion of that area had been occupied by pigment cells; instead, the pigment cells were now effectively placed behind the photoreceptors (in terms of the incident light path) but nevertheless still in physical contact with them.

This expansion and bulging, combined with the retention of minimal luminal volume and the development of a polarity to the organ, is what gave rise to the 'inside-out' vertebrate retina.

At this stage of chordate evolution, it is suggested that the rudimentary 'eye' had not yet evolved optical components (lens, etc.), or sophisticated neural processing power (bipolar cells, etc.), or a motor system for orienting it, and that instead it probably bore a close resemblance to the 'eye' of extant hagfish.

Dark re-isomerization of retinoid. Concomitant with the improvement in efficacy of G-protein activation that evolved in chordate C-opsins was the loss of ability of the active metarhodopsin to undergo photoreversal to the 11-*cis* isomeric form (Section 5). This necessitated release of the all-*trans* retinoid and its re-isomerization via some other route. Potentially, that could have utilized a separate photoisomerase, along the lines of the retinochrome that is used in the squid eye - and possibly such an isomerase was at some stage used, given the

presence in the RPE of RGR-opsin that is capable of such *trans*-to-*cis* photoisomerization. However, it appears that what was of greater importance in the chordate lineage was a chemical route for isomerization in darkness (Section 12). In living vertebrate species there is clear evidence for the existence of an intra-retina retinoid cycle, available to cones, though the details are obscure and the origins unknown - but it is entirely possible that this intra-retina cycle might represent the ancestral pathway for isomerization of the all-*trans* form to the 11-*cis* isomer in darkness. The better known pathway, involving retinoid transport to the RPE and back, evolved after the divergence of tunicates, judging from the absence of a true RPE65 or LRAT in *Ciona*.

Triumph of ciliary photoreceptors. The advent of a chemical route for re-isomerization in darkness is likely to have invested chordate ciliary photoreceptors with a major advantage over microvillar photoreceptors that utilized bistable photopigments. Whenever the animal moved from a brightly-lit environment to a dimly-lit one, the microvillar photoreceptors would have been burdened by a large complement of stable metarhodopsin, with no way to rapidly convert it back to rhodopsin; hence the content of useful rhodopsin would have remained low, and these photoreceptors would have exhibited a prolonged reduction in sensitivity. In contrast, the ciliary photoreceptors would have been able to 'dark adapt' through release of all-*trans* retinoid and re-binding of 11-*cis* retinal to form rhodopsin; to maintain this ability in the long-term, the released all-*trans* retinoid needed to be chemically isomerized back to the 11-*cis* form in darkness. As a result, pre-vertebrate chordates are likely to have had a distinct advantage over organisms with stable photopigments, when they entered dim environments during the daytime, as well as at the fading of sunlight. Likewise, the ciliary photoreceptors may have enjoyed a sufficiently large advantage over their microvillar companions within the same retina, in terms of higher sensitivity and the ability to dark adapt, that there was little to be gained in retaining both sets of photoreceptor. Instead, the microvillar cells for the most part lost their photoreceptive properties and instead became specialized as projection neurons, though some retained a role in signaling light for circadian entrainment and other 'non-visual' purposes.

Multiple classes of retinal opsin and photoreceptors. Prior to the '2R' rounds of whole-genome duplication, there appear to have been just two types of cone opsin (SWS and LWS) that were expressed in two classes of cone. Then, as a result of the '2R' duplications, the SWS opsin quadruplicated into SWS1, SWS2, Rh2 and Rh1 opsins, expressed in what originally would have been four classes of short-to-mid-wave-sensitive cone photoreceptors. However, the pressure for high sensitivity at low light levels would have made it advantageous for the meta II lifetime to have lengthened in (at least) one of these opsins, so that the light response could be integrated for longer. This appears to have led to mutations at sites 122 and 189 in the Rh1 opsin, that lengthened the meta II lifetime by partly shielding the retinoid binding site from access by water. The same pressure additionally led to the slowing of other recovery steps in the cells expressing the Rh1 opsin, so that modified versions of the GRK, arrestin and PDE6 arose. Although the LWS opsin is likewise assumed to have quadruplicated, only a single copy has survived.

Even by the stage at which lampreys diverged from our own lineage (i.e. #5 in Figure 1), it seems unlikely that 'true rods' had evolved; thus, although the short photoreceptors of northern hemisphere lampreys express an Rh1 opsin and are quite sensitive, they exhibit a number of cone-like properties and it remains to be determined whether they are capable of reliably signaling individual photon hits. True rods, of the kind we recognize in jawed vertebrates, may not have been perfected until after that divergence.

Evolution of retinal bipolar cells. In vertebrate light-sensitive regions other than the lateral retinas (i.e. in the pineal organ, the parapineal organ, and the parietal eye), and also in the retina of the hagfish eye, the ciliary photoreceptors make synaptic contact directly onto projection neurons which, as argued above, are likely to represent descendants of microvillar photoreceptors. In contrast, the cone and rod photoreceptors of the vertebrate retina communicate with their projection neurons via an intervening bipolar cell. Examination of retinal development shows that these bipolar cells differentiate later than all other retinal neurons, and

furthermore that the developing bipolar cells become interposed into a circuit that initially comprises direct contact from photoreceptors onto ganglion cells.

These findings are consistent with the notion that retinal bipolar cells evolved late, after a two-layered retina had already been established (comprising ciliary photoreceptors connected to projection neurons) and that these newer cells became inserted into the pre-existing neural pathway. That new arrangement provided an enormous increase in computational power in the retina, allowing the pooling of photoreceptor signals, as well as comparisons of different signals, as in center-surround processing and spectral (color) comparisons.

Accessory structures (lens, cornea, muscle). The accessory structures that enable a retina to function as the 'sensor' in a camera-style eye include the lens, the cornea and sclera, the iris, and the intra- and extra-ocular muscles. In addition, and arguably most importantly, there needs to be a neural processing center in the brain to interpret the information and act on it, as well as to control the movement of the eyes. Although it is clear that these structures must have evolved in parallel with the evolution of the retina, unfortunately any account of their evolution is beyond the scope of this article.

Jawed vertebrates: After point #5 (Since 500 Mya)

After the divergence of cyclostomes, the fundamental bauplan of the eyes of jawed vertebrates did not change substantially. Nevertheless, numerous refinements occurred, many of which relate to the optics of the eye, and especially to the optics required with an air interface once tetrapods emerged. Those changes will not be discussed here.

One major change that evolved within the jawed vertebrate retina involved scotopic pathways. As far as we know, neither lampreys nor hagfish possess a 'duplex' retina of the kind that evolved in jawed vertebrates, with true rods capable of reliably detecting single photon hits and with a dedicated scotopic visual system. Instead, lamprey photoreceptors that express the rod-like Rh1/RhA opsin retain a variety of cone-like features. On current evidence I suggest that the ultimate scotopic sensitivity exhibited by modern vertebrates, that is made possible by the retina's ability to 'count' individual photons hitting 'true rods', did not evolve until after our ancestors had diverged from the ancestors of lampreys and hagfish. It will be important to test this assertion through future research.

19. Summary

The following is an abbreviated summary of the main events hypothesized to have contributed to the evolution of vertebrate cone and rod photoreceptors and their transduction cascades, and to the evolution of the vertebrate retina:

1. An ancestral cyclic nucleotide version of a G-protein cascade arose very early in metazoan evolution. In that cascade a (non-light-sensitive) GPCR activated a G-protein that coupled to an effector enzyme that modulated cyclic nucleotide levels, thereby modulating the opening of CNGCs.
2. One type of GPCR evolved the ability to bind retinaldehyde non-covalently, as its ligand, and hence effectively became a retinaldehyde receptor. This occurred prior to the divergence of placozoans. Subsequently, the lysine 296 residue evolved, so that the binding of retinoid became covalent, via a Schiff base bond. A counterion site (e.g. E181) also evolved, enabling the Schiff base bond to be protonated, and generating the ancestral opsin that would have had its peak absorption near the shortwave end of the spectrum.
3. The cell that expressed this first opsin thereby became the ancestral metazoan photoreceptor cell. It employed a G-protein cascade broadly comparable to that of modern ciliary photoreceptors, and in particular it used a cyclic nucleotide as cytoplasmic messenger to modulate the opening of cyclic nucleotide-gated ion channels.

4. The organism in which this photoreceptor cell evolved was very small, and did not yet possess what could be described as a nervous system. The cell signaled its response to other cells by the local release of one of more chemical messengers, probably melatonin and glutamate.
5. This cell probably did not require a source of 11-*cis* retinal, because the opsin apoprotein could bind all-*trans* retinal, and because the resulting visual pigment could undergo photoreversal from the active metarhodopsin state to the ground state rhodopsin (as can most opsins, with the exception of vertebrate cone and rod opsins).
6. Variants of this cell arose, through a number of duplications, leading to different cell types that expressed a C-opsin, an R-opsin, or an RGR-opsin.
7. In the cell expressing the ancestral C-opsin, the opsin trafficked to the plasma membrane of the cilium. In time, mechanisms evolved for the massive expansion of this ciliary membrane. At first, these expansions were poorly organized; often they tended to align parallel to the axis of the cilium (longitudinally).
8. In the deuterostome/chordate lineage, these expansions of the ciliary membrane progressively evolved greater degrees of organization, becoming flattened (lamellar) by the time that cephalochordates diverged, and as rather bud-like lamellar petals by the time that ascidia diverged, and then subsequently being splayed-out at right angles to the ciliary axis by the time that vertebrates appeared.
9. During early chordate evolution there was probably just a single type of C-opsin, probably of the Opn3 family, that in many respects did not differ greatly from R-opsins. But during early vertebrate evolution a number of variants of this C-opsin arose, of which residual members in living vertebrates include parietopsin, parapinopsin, VA opsin, and pinopsin.
10. During this progression, the counterion for the Schiff base migrated from site 181 to site 113, and this re-location turns out to have been important in at least three ways. First, it permitted release of all-*trans* retinal and hence the rapid regeneration of visual pigment in darkness (from a store of 11-*cis* retinal); secondly, it improved the time resolution of the cone by shortening the lifetime of active meta II; and thirdly, it paved the way for the achievement of a higher efficacy of G-protein activation by enabling further intra-molecular rearrangements that led to a large tilt in helix 6 in the meta II state. That last improvement prevented photoreversal of meta II, and made the release of all-*trans* retinal essential.
11. Hence the ancestral cone photoreceptor utilized an opsin (the ancestral cone opsin) that was expressed in lamellar sac membranes that radiated laterally from the cilium. It required a source of 11-*cis* retinoid, which (by analogy with modern cones) was probably provided by the Müller cells.
12. The primary proteins involved in activation of the cascade had evolved to become: (*i*) the ancestral transducin, with its Gt alpha subunit duplicated and modified from an earlier Gi, and with a ubiquitous beta and unique gamma subunit; (*ii*) the ancestral PDE6 cyclic GMP phosphodiesterase, comprising a pair of identical catalytic subunits and a pair of regulatory (gamma) subunits; and (*iii*) a tetrameric cyclic nucleotide-gated channel composed of two classes of subunit, alpha and beta.
13. The primary proteins involved in response recovery and regulation had evolved to become the ancestral 'cone' components: GRK7, ARR3, RGS9, GUCY2D, GUCA1C, SLC24A1, RCVRN.
14. Duplication of the first cone opsin gave rise to a pair of retinal cone opsins: an SWS opsin with the standard E181 residue, and an LWS opsin with the H181/K184 combination that provided a chloride-binding site and a substantially red-shifted absorption. These two opsins were expressed in separate, but closely similar, cone photoreceptors. Their outputs provided signals that could have been utilized to provide dichromatic processing.
15. Also present nearby were microvillar photoreceptors that had descended from a common ancestral photoreceptor. The paracrine release mechanism of the ciliary photoreceptors evolved into synaptic contacts onto the neighboring microvillar photoreceptors. At some stage, the performance of the ciliary photoreceptors (as transmitted to the cells of microvillar origin) became sufficient to signal all the features of illumination that were important to the organism, and thereafter the majority of the

microvillar photoreceptors dispensed with their opsin and phototransduction cascade, and specialized as projection neurons.

16. All the above events took place prior to the '2R' two rounds of whole-genome duplication that occurred at the base of the vertebrate lineage.
17. As a result of the two genome duplications, the quadruplication of the SWS opsin gave rise to the vertebrate SWS1, SWS2, Rh2, and Rh1 opsin classes. Only a single copy of the LWS quadruplication survived. These five opsins were expressed in five classes of cones.
18. The genome duplications additionally gave rise to the cone versus rod differences in isoforms of many of the components of the phototransduction cascade.
19. In the cone photoreceptor that expressed the Rh1 opsin, the confluence of a number of changes led to a slowing of response shut-off, which elicited a larger response per photoisomerization. One of these changes was an increase in lifetime of meta II that occurred as a result of mutations at sites 122 and 189. This also reduced the rate at which rhodopsin could be regenerated, and probably explains the resistance of rhodopsin to hydroxylamine.
20. Ultrastructural changes in the outer segment of this cell, including the enclosure of lamellae within the plasma membrane, permitted more extensive longitudinal spread of messengers.
21. In due course, the combination of these changes gave rise to a photoreceptor that was capable of reliably signaling individual photoisomerizations, and that thereby deserved the title of 'first true rod'. Whether this stage was reached before or after the divergence of cyclostomes is not yet certain, but it seems likely to have been after.
22. At around the time that chordate C-opsins lost their ability to undergo photoreversal, one or more mechanisms arose for the re-isomerization of retinoid in darkness. It is possible that the first of these mechanisms was the intra-retina cycle that modern cones have access to. The other cycle, involving transport of retinoid to and from the RPE, had not arisen by the time that tunicates diverged, and hence (among extant species) is a purely vertebrate phenomenon.
23. The light-sensitive region in the anterior neural tube of an ancestral chordate expanded dorsally and laterally. The ciliary photoreceptors and the projection neurons remained in close proximity to each other, and what 'stretched' was the axon of the projection neuron that conveyed information to other areas of the brain.
24. The lateral vesicles developed a sidedness, such that the side facing outwards made only the cells of the neural retina whereas the proximal side made only the epithelial cells that provided supportive, nutritional, and retinoid processing functions, as well as pigment to absorb unwanted light. At that stage of evolution the lateral retinas broadly resembled the retinas of modern hagfish.
25. As a consequence of the genome duplications, two new classes of retinal cells appeared. These horizontal cells and amacrine cells made synaptic connections with ciliary photoreceptors and ganglion cells, respectively, in a manner that mediated lateral interactions between cells and possibly mediated extraction of simple spatial contrast.
26. Also as a consequence of the genome duplications, another new class of cell, the retinal bipolar cell, evolved. It closely resembled the ciliary photoreceptor cells in many ways, though instead of making an outer segment it expressed glutamate receptors. This new cell became incorporated into the neural pathway from ciliary photoreceptors to ganglion cells, and thereby permitted a great increase in the computational ability of the retina.
27. Relics of the evolution of retinal cells and the evolution of retinal wiring are retained in various features of retinal cell differentiation and the early connectivity of retinal cells.
28. Spatial vision in chordates arose gradually, through parallel changes not just in the photoreceptors and the retina, but also through the formation of an imaging element (the lens) and other ancillary structures such as the cornea/sclera, the iris, and intra- and extra-ocular muscles, as well as through elaboration of brain structures that could make use of spatial information.

29. The advent of spatial vision provided immense survival value to the organism, but the process occurred slowly, over countless steps, with the transition from a simple eye spot in an early chordate to the vertebrate-style camera eye possibly taking as long as 100 million years.

I should emphasize that the brief summary painted above represents my best guess at the events underlying the evolution of vertebrate photoreceptors and retina, distilled from a large body of experimental data in the literature. The purpose of presenting an explicit proposal for events that occurred over 500 million years ago is to stimulate further experiment, in order to test and thereby refine or reject specific proposals. I look forward to updating the ideas that I have presented above, in the light of the results of future experiments.

Acknowledgements

I am extremely grateful to Helga Kolb for stimulating me to undertake this project, to Nansi Colley, Tom Cronin, John Dowling, Martin Heck, Dan Larhammar, Robert Marc, Ralph Nelson and Yoshinori Shichida for helpful comments on a draft of this article, and to Shaun Collin for the use of images. Supported by grants CE0561903 and DP110103294 from the Australian Research Council.

About the Author

Trevor D. Lamb received a degree in Electronic Engineering from Melbourne University in 1971 and then moved to Cambridge, UK, to do his graduate studies under the guidance of Sir Alan Hodgkin, working with Denis Baylor on retinal horizontal cells and photoreceptors. He received his PhD in 1975. Then as a post-doc at Stanford, USA, Denis Baylor, King-Wai Yau and Trevor developed the suction pipette technique for recording from photoreceptors. For the following 25 years he again worked in Cambridge, UK, on phototransduction and light- and dark-adaptation. He was elected a Fellow of the Royal Society in 1993. With Ed Pugh in the USA he developed a mathematical description of the molecular reactions underlying the photoreceptor light response, as well as a model of dark adaptation and the retinoid cycle. In 2003, Trevor returned to Australia, as a Federation Fellow at the Australian National University (ANU), in Canberra. Since 2011 he has been an Emeritus Professor at ANU, where he pursues his current interest in the evolutionary origin of photoreceptors and the retina. e-mail Trevor at *Trevor.Lamb@anu.edu.au*

Neural Basis of Color Perception

Color Vision

Peter Gouras

Created: May 1, 2005; Updated: July 1, 2009.

Introduction

Color vision is an illusion created by the interactions of billions of neurons in our brain. There is no color in the external world; it is created by neural programs and projected onto the outer world we see. It is intimately linked to the perception of form where color facilitates detecting borders of objects (Fig. 1).

Color is created by utilizing two properties of light, energy and frequency of vibration or wavelength. How our brain separates these two properties of light, energy and wavelength, and then recombines them into color perception is a mystery that has intrigued scientists through the ages. We know much about the nature of light and the subjective impressions of color, definable by physical standards (1) but ultimately color should be explained at the level of single cells in our brain. Examination of the responses of single neurons or arrays of such neurons provides the best insights into the physiology of color vision. Ultimately our understanding of this process will allow us to model the neural circuits that underlie the perception of color and form. Although still beyond reach, progress is being made in deciphering these clever circuits that create our perception of the external world.

We start by describing the nature of the photoreceptors that convert light energy into neural signals. Then we consider the parallel channels leading from the retina to the thalamus carrying information into visual cortex, where color is ultimately determined. Lastly we use our current understanding to speculate on how visual cortex uses neural circuits to create the perception of color and form.

The Photoreceptors

Photoreceptors are neurons specialized to detect light. The detection occurs in an organelle called the outer segment, a membranous structure where light absorbing proteins, opsins, are embedded. There are two major types of photoreceptors in most vertebrate eyes, rods and cones. Rods are very sensitive but slow and their response saturates at light levels where cones function optimally. Rods are not used much in modern society where artificial illumination adequate for cone vision is ubiquitous. Cones are less sensitive but are fast and can adapt to the brightest lights, being almost impossible to saturate. Cones evolved before rods undoubtedly in areas of strong sunlight where vision was a great advantage. In broad sunlight, shadows are strong and more important to detect than increments of light in the struggle for survival. Shadows depolarize cones leading to a release of a transmitter that influences second order retinal neurons. The appearance of light hyperpolarizes cones leading to a curtailing of this transmitter.

A cone responds only to the energy it absorbs (2). All wavelength of light can produce identical responses from a cone if the energy absorbed by the cone is the same for these wavelengths (Fig. 2). Cones are therefore color blind producing a univariant response reflecting only the amount of energy they absorb. Detecting objects by the energy reflected from their surfaces, however, can fail when objects reflect a similar amount of energy as their background. Here is where color vision becomes important. Wavelength contrast can detect objects when energy contrast is absent or minimal. An object can reflect the same energy but seldom reflects the same wavelength composition as its background. Color vision combines both energy and wavelength contrasts to detect objects and this advantage must have evolved early in the evolution of vision.

In order to detect objects by differences in spectral reflectance, two or more different types of cones are needed. This is an important concept for understanding color vision. For divariant color vision, two cone types must exist and be sensitive to different parts of the visible spectrum, preferably as different as possible. The range of the visible spectrum depends on the ability of light to penetrate the eye and be absorbed by the photoreceptors.

Figure 1. A floral scene with and without color.

Ultra-violet light is absorbed by the anterior segment of our eyes and seldom reaches the photoreceptors. Infra-red light penetrates our eye readily but its quantal energy may be too small to activate opsins. Therefore early in the evolution of color vision, opsins sensitive to the middle of our visible spectrum evolved, near spectral yellow, and a short wavelength opsin evolved in a second type of cone, near spectral blue (Fig. 3). These have been called L (long wavelength sensitive) and S (short wavelength sensitive) cones, respectively, and this was a first step in the evolution of color vision.

In animals with large eyes, an interesting strategy evolved. L-cones were used to detect both energy and wavelength contrast but S-cones were used only for wavelength contrast. This was due to chromatic aberration. Short wavelength images are out of focus when longer wavelength images are in focus on the photoreceptor mosaic. Chromatic aberration increases greatly at short wavelengths, which led to the L cone system dominating energy contrast. As a result there are many more L than S cones in many mammals in order to gain spatial resolution by achromatic contrast detectable by L cones.

In animals with small eyes, like mice and rats, ultra-violet light can reach the photoreceptor mosaic and in this case ultra-violet sensitive cone opsins have evolved to widen the spectral range of vision and if combined with L cones could allow color vision (3-5). Chromatic aberration is reduced in these small, highly spherical eyes which have outer segments as long as animals with large eyes. This increases their depth of focus minimizing chromatic aberration, an advantage of being small. Their retinal images are less magnified, however, than those in large eyes.

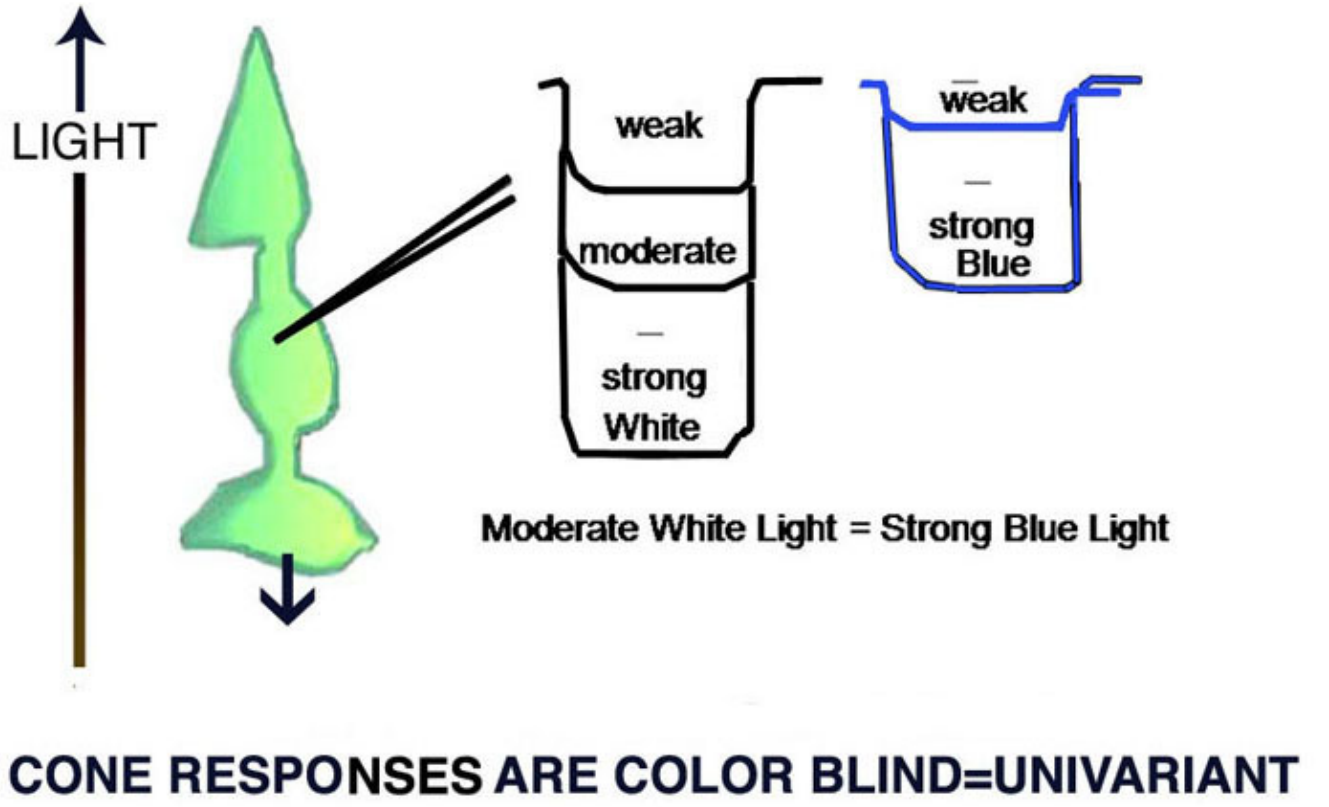

Figure 2. Different wavelengths (colors) producing identical responses from cones.

Chromatic and Achromatic Contrast

In order to establish chromatic contrast it is necessary to compare the responses of a group of cones of one type with the responses of a group of cones of another type within the same area of visual space. One cannot compare only two neighboring cones such as the S and the L cone in Fig. 4A.

If an image of gray and yellow were to cover these two cones in an inappropriate way as done in Fig. 4A the brain would reach an erroneous conclusion about this border because the S cone would not be affected by the yellow side and the L cone would be strongly affected by the gray side. The brain might consider this to be a black/yellow border rather than a yellow/gray border. Even if a slit of light imaged on only the more numerous L cones (Fig. 4B), there would be ambiguity about the colors of adjacent images. If only L cones are affected by both yellow and gray light, the brain would not see any border here. Only when a larger image covers a number of S and L cones (Fig. 4C) can an unequivocal decision be made about the color of these bordering images. In this case the left side, which is yellow, would strongly affect L but not S cones and therefore be judged to be yellow. The right side of this border, which is gray, would strongly affect both L and S cones and therefore would appear white or gray. For achromatic contrast, smaller images can be analyzed for border contrasts and in most cases only two neighboring cones would be sufficient to distinguish a light/dark border. This is why a unit area of achromatic space is smaller than a unit area of chromatic space.

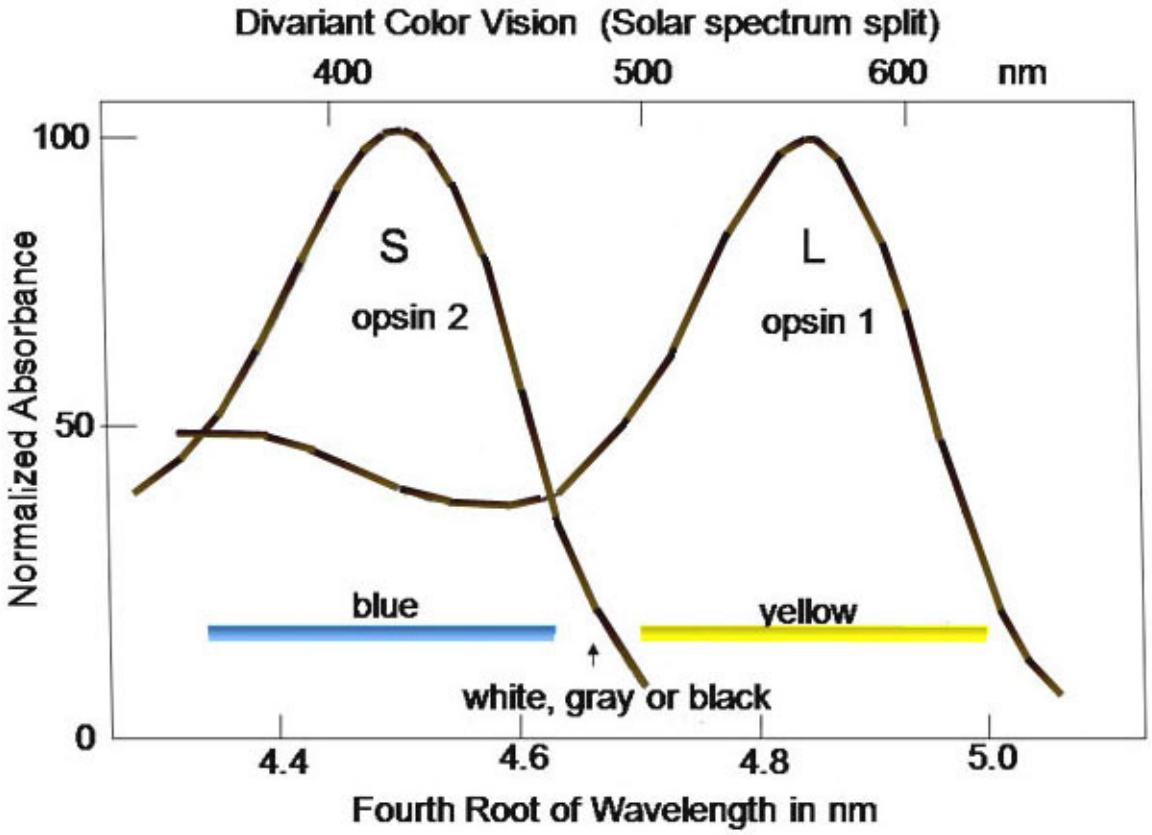

Figure 3. The normalized absorption spectra of the S and L cone opsins mediating divariant color vision. Strong absorption by the S cone opsin alone induces "blue"; strong absorption by L cone opsin induces "yellow" and absorption by both induces "white or gray" depending on achromatic contrast of light and dark. The 4th root makes the curves identical in shape.

Horizontal Cells

Cones receive an antagonistic input from horizontal cells, whose cell bodies reside in the outer nuclear layer and whose processes contact the spherules of rods and the pedicles of cones (6). There are at least two varieties of cone horizontal cells (Fig. 5).

One variety (H1) only contacts L cones; the other variety contacts both S and L cones (H2). Cone horizontal cells receive an excitatory input from cones and send back an inhibitory input to cones. This is a type of negative feedback. When a cone is hyperpolarized by an increment or depolarized by a decrement of light, it receives an opposing input from horizontal cells after a brief synaptic delay. This dampens the response and can also reduce the effects of scattered light by minimizing cone responses outside of the focal image on the retina. In color vision the horizontal feedback also acts to narrow the action spectrum of cone bipolar cells. In divariant color vision this can narrow the action spectrum of S cone bipolar cells. This occurs because the processes of the H2 horizontal cell that reach L cones are only post-synaptic to S cones. Therefore L cones can send an antagonistic signal to S cones which can reduce the effectiveness of wavelengths, absorbed by both L and S cones and this narrows the action spectrum of the S cone channels (7).

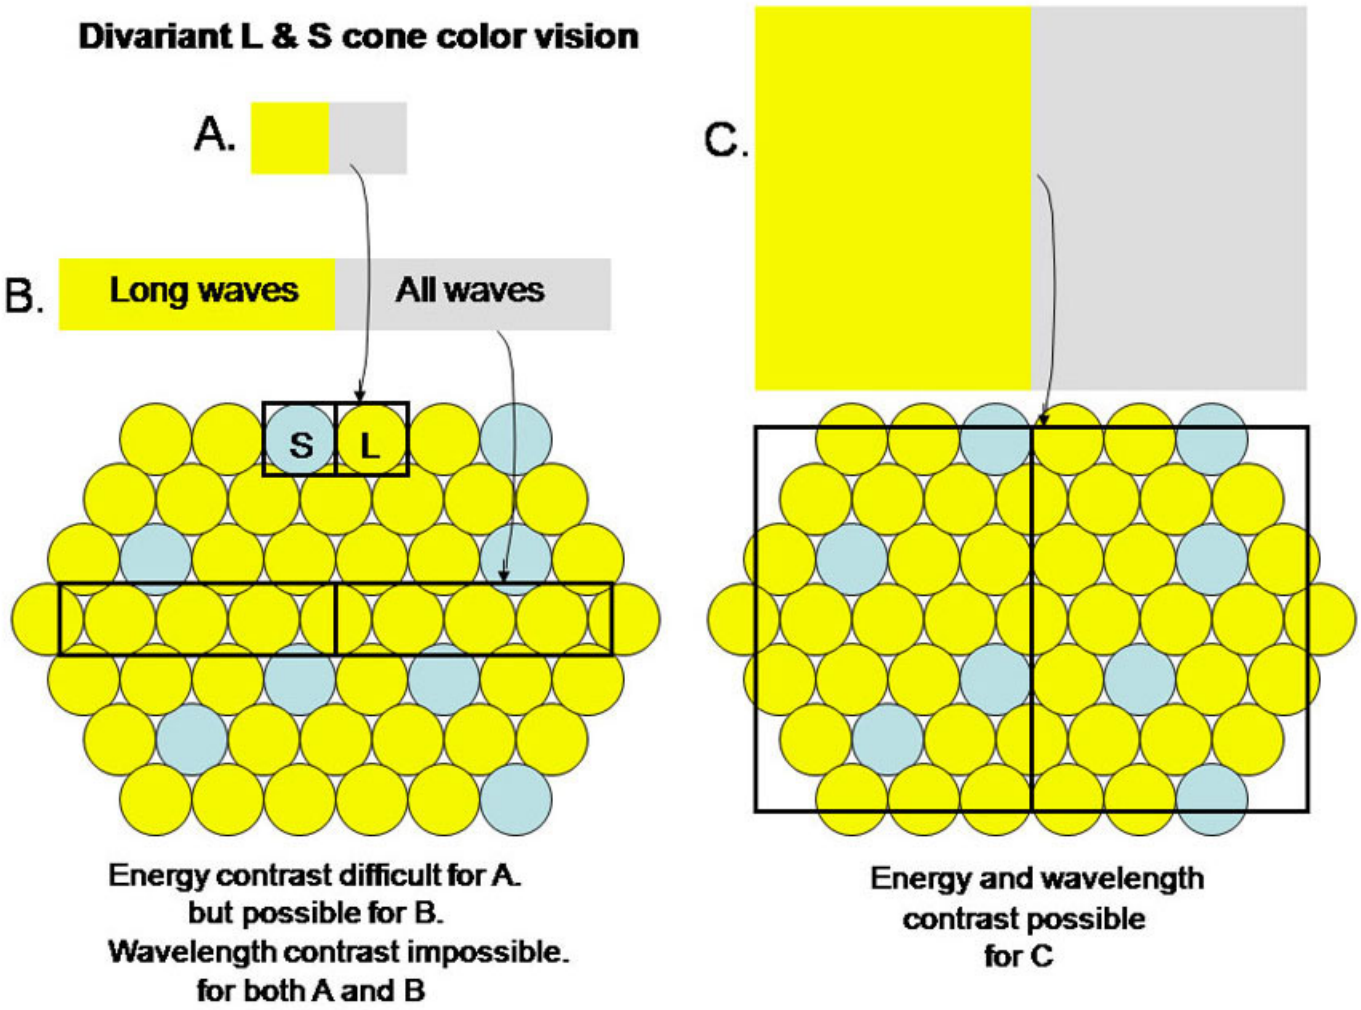

Figure 4. The difficulty determining the color of small objects.

Bipolar and Ganglion Cells

The retina is composed of three layers of neurons, the outermost being the photoreceptors, rods and cones, which for divariant color vision are L and S cones. A second layer of bipolar cells transmits the signals of the photoreceptors to a third layer of neurons, the ganglion cells whose axons form the optic nerve. The ganglion cells serving the two photoreceptor systems are quite different. The L cones synapse with unique bipolar cells, called "midget" bipolar. These single cone detectors were discovered by Stephan Polyak (8) in monkey retina using the Golgi method of silver impregnation. Because of their small size they were called "midget" bipolar cells. This provides the brain with the ultimate in spatial resolution, a single cone, and in addition isolates the signals of L cones which can be used for color vision. A feature of this L cone bipolar system is the presence of two types of cells (Fig. 6). One type of L cone bipolars depolarizes whenever the cone or cones they synapse with hyperpolarize; this set is called on-bipolars because they are excited (turned on) by light. The other set is depolarized whenever the cones they synapse with detect decrements of light; this set is called off-bipolars because they are excited by darkness and inhibited (turned off) by light. These two sets of cone bipolar cells synapse with separate sets of on and off ganglion cells at two levels in the inner plexiform layer of the retina, a more external off-lamina and a more internal on-lamina (9).

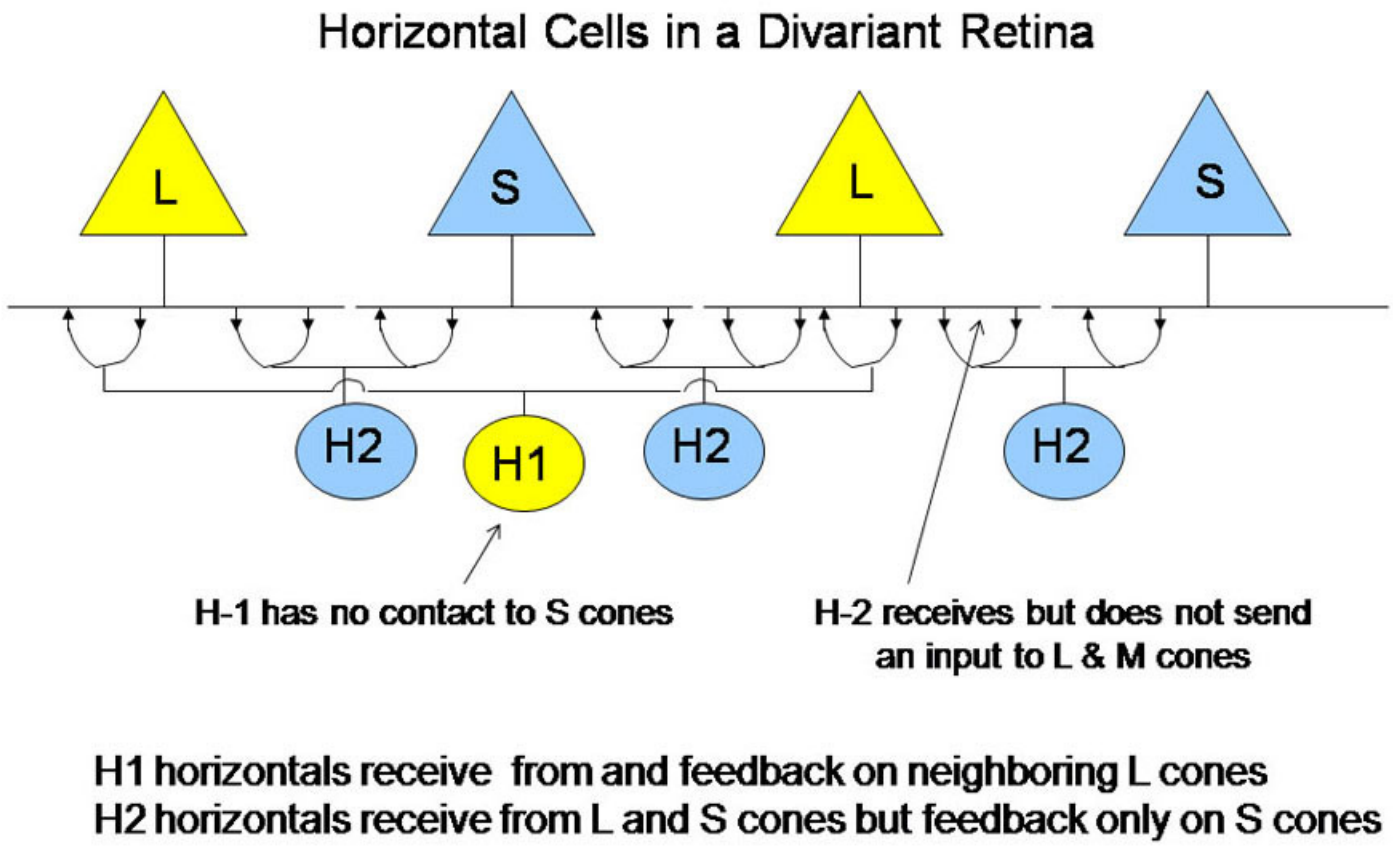

Figure 5. Two varieties of horizontal cells and their relation to L and S cones in a divariant retina.

These parallel channels, transmitting lightness and darkness from local retinal areas, are maintained throughout the visual pathway to visual cortex. This "push-pull" system of neurons is thought to increase the dynamic range for detecting decrements and increments of light in local areas of the retinal image. Only L cones seem to be connected to both on and off bipolar cells while S cones are connected to only on-bipolar cells. The reason for this may be that the latter are only involved in chromatic vision while the former are involved in both chromatic and achromatic vision. Achromatic vision involves the detection of lightness and darkness while chromatic vision involves the detection of color. Not only do S cones lack an off-bipolar system but they have a much different route to the ganglion cell output layer. The S cone on bipolar excite the internal arbor of a bistratified ganglion cell while a wide-field L cone off bipolar excites the external arbor of this same ganglion cell (10). This S cone system is absent in the very center of the fovea where achromatic contrast is mediated by the L cone midget system. Away from the fovea the L cone midget system begins to contact more than one cone and therefore loses spatial resolution.

There is a second ganglion cell system that plays no role in color vision but is also connected to only L cones. These are parasol ganglion cells. They are larger cells with faster conduction velocities and they target the magno-cellular layers of the lateral geniculate nucleus (LGN). They appear to play a role in the detection of movement and possibly slow tracking movements. There is some evidence that they might receive an input from S cones but I have never been able to detect such an input. Barry Lee's group considers these cells play a role in the detection of luminance (11).

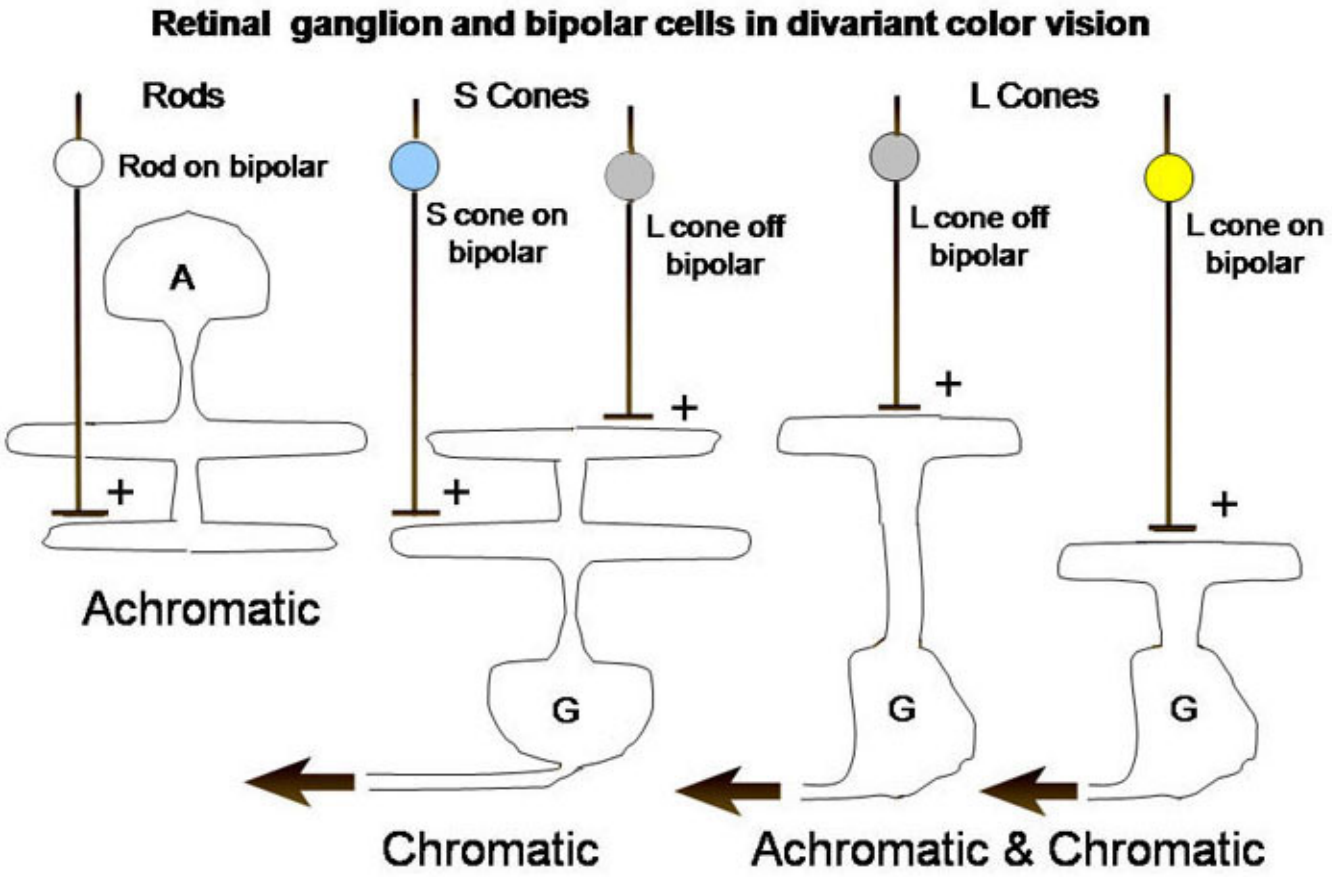

Figure 6. The currently understood retinal ganglion cells responsible for rod (achromatic) and cone achromatic and chromatic signals being sent to the lateral geniculate nucleus. We assume that the L cone off bipolar signals darkness but it could also be blue.

Divariant Blue/Yellow Color Vision

The ganglion cells in Fig. 6 are thought by most to be the essential channels for divariant color vision. The bistratifid S cone on-cells and the L cone midget cells monitor the light absorption of S and L cones respectively. The signals from these two channels must be compared in the same areas of visual space for color vision. The cone bipolar cells driving the bistratified S cone on-ganglion cells have co-extensive fields (Fig. 7), which is ideal for comparing differences between two cone mechanisms in the same area of visual space.

These two different bipolar inputs to the bistratified ganglion cell do not appear to oppose each other because these cells are excited by white light. Another more indirect input to these cells comes from the H2 horizontal cell which transmits antagonistic signals from L to S cones. This input provides spectral antagonism to the bistratified ganglion cell because light activation of L cones will produce a depolarizing signal in S cones that counteracts the hyperpolarization produced by short wavelength light. The strong response to white light, however, implies that this H2 mediated antagonism is relatively weak.

The channel transmitting L cone signals for spectral contrast in visual cortex has been considered to be the midget system, at least in primates. These midget ganglion cells are considered to receive no input from S cones, either synergistic or antagonistic, although there are connections to S cones through H2 horizontal cells. In trivariant monkey retina there is no evidence of S cone input to either the midget or the parasol ganglion cell

systems which implies that H2 horizontal cells are only post- and not pre- synaptic to L cones. The H1 horizontal cell only contacts L cones and therefore provides only spatial antagonism to neighboring L cones and does not produce spectral antagonism.

This previous picture is not accepted by everyone. There is evidence that a L cone on/S cone off ganglion cell exists to provide an opponent L cone on input to visual cortex (12-15). It has been difficult to find such a ganglion cell in primate retina but they they have been reported in the koniocellular layers of the primate lateral geniculate nucleus. These geniculate cells have been traced back to their retinal ganglion cell inputs, which have their dendritic arbors in the on-lamina of the inner plexiform layer, quite different than the bistratified arbors of S on/ L off ganglion cells. This produces a curious difference in the blue/yellow channels of color vision in primates. In small animals, ground squirrels, guinea pigs and mice, there appears to be a more symmetrical system of S cone on/Lcone off and M cone on/S cone off opponent ganglion cells, both of which send their dendrites to the on-lamina of the inner plexiform layer. This implies that the horizontal cells and/or intervening amacrine cells are involved in their unique opponent organization, perhaps more similar to the rod system. The existence of this retinal L cone on/S cone off channel would preclude the midget cells depicted in Fig. 7 from contributing to color vision in animals with divariant color vision.

A more iconoclastic hypothesis recently proposed by the Neitz group (13) considers the bistratified S cone on/L cone off retinal ganglion cell to play no role in color vision proposing that its signals go to the brain stem where they mediate unconscious visual functions together with light sensitive retinal melanopsin ganglion cells. They propose that surround antagonism from the H2 horizontal cell turns L cone off-center midget bipolar cells into S cone-on/L cone-off cells and L cone-on/S cone-off cells. This hypothesis brings S cone signals into the midget ganglion cell system designed for high spatial resolution. Evidence that the bistratified S cone on-cell does affect conscious vision comes from an observation of W.S. Stiles (16) that his S cone mechanism, isolated psychophysically, affects conscious experience because it exhibits a curious behavior; its sensitivity declines when a long wavelength adapting light, which has no effect on S cones, is turned off. The bistratified S-cone ganglion cell exhibits this same behavior implying that its signals do reach visual cortex and consciousness. It is also possible, however, that the unusual midget cells proposed by the Neitz team (13) also exhibit this phenomenon, which has been labeled "transient tritanopia".

Regardless of which of these three hypotheses is correct, there must be a way for the visual cortex to compare L with S cone activity in the same area of visual space in order to produce color vision. In Fig. 8 we use two of the ideas that are demonstrated in Fig. 7 to illustrate how striate cortex uses these retino-geniculate inputs to construct cells that are more responsive to color.

Fig. 9 shows a logical way to extract the signals from the cone mosaic into parallel channels mediating achromatic contrast with high spatial resolution and chromatic contrast with lower spatial resolution from the same mosaic.

The perception of color mixes both achromatic with chromatic signals to create the combined experience of color. In this arrangement the S cone system only plays a role in chromatic vision while the L cone system contributes to both chromatic and achromatic vision. The repertoire of colors that are produced and their relationship to the activity of the two cone mechanisms involved are shown in Fig. 10; these colors are shown at borders of minimum achromatic contrast where chromatic contrast becomes most important.

Color Constancy and Double Opponency

The schemes of the previous figures neglect a problem called "ch22color constancy". We see colors as unchanged even when there are large changes in the spectral properties of an illuminant. The colors in a scene illuminated by fluorescent lights, which generate much short wavelength energy or by tungsten filament lights, which generate much long wavelength energy are not significantly altered by such changes. In other words we should

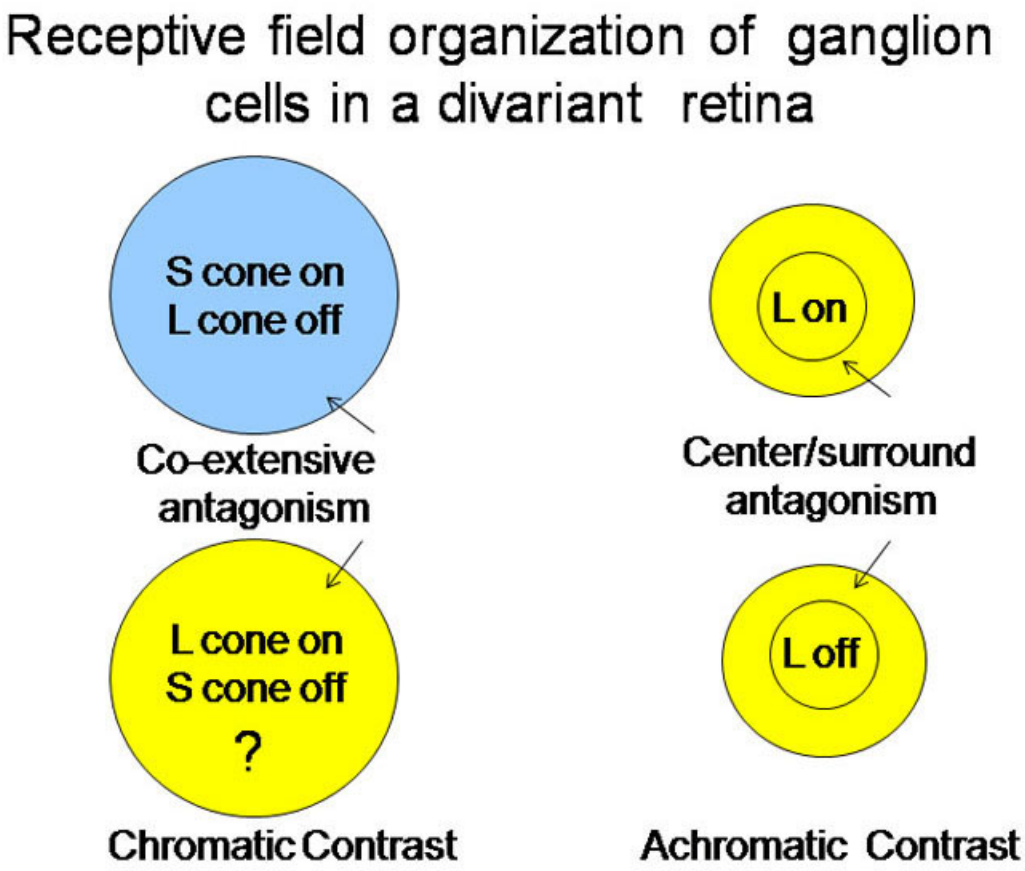

Figure 7. Two options being considered for the ganglion cell system providing chromatic and achromatic information to the lateral geniculate nucleus for divariant color vision.

see things "bluer" in fluorescent light and redder in tungsten light but we don't. This constancy of colors despite changes in illumination intrigued Edwin Land, the founder of the Polaroid Corporation, who spent years investigating this phenomenon and demonstrating significant global aspects of color vision (17). Local objects can reflect identical spectral components from their surfaces but will appear of different color because of the influence of the entire scene. He proposed a model in which the signals from each cone mechanism are normalized over the entire visual scene before being compared with each other locally to generate the perception of the color of an object scene. Fig. 11 illustrates why this idea is reasonable. Here two lights beams, one white, the other yellow illuminate a screen.

An arrow blocks a portion of the yellow beam and this produces a shadow that appears "blue". If one determines the light energy being absorbed by the L and S cones from the screen, it is apparent that there is more light affecting the L than the S cones coming from the shadow, which would suggest that the shadow should look yellow and not blue. But if one normalizes the light coming from the entire screen to 100%, then the relative effect on the S cones becomes greater than that on the L cones and the shadow appears "blue". This supports the idea that responses from each cone mechanism across the entire visual scene are first normalized before being compared with each other locally to produce the perception of color from specific objects in the scene. Such normalization could occur if S cone and L cone transmitting neurons were to inhibit each other following the rules outlined in Fig. 12. This could reduce the responses to global illumination that affected one cone mechanism more strongly than the other and support color constancy. If, in addition, the excitation of these cone specific channels were organized so that each local area of color space would be enhanced by neighboring spectral contrast between cone mechanisms it would lead to simultaneous color contrast.

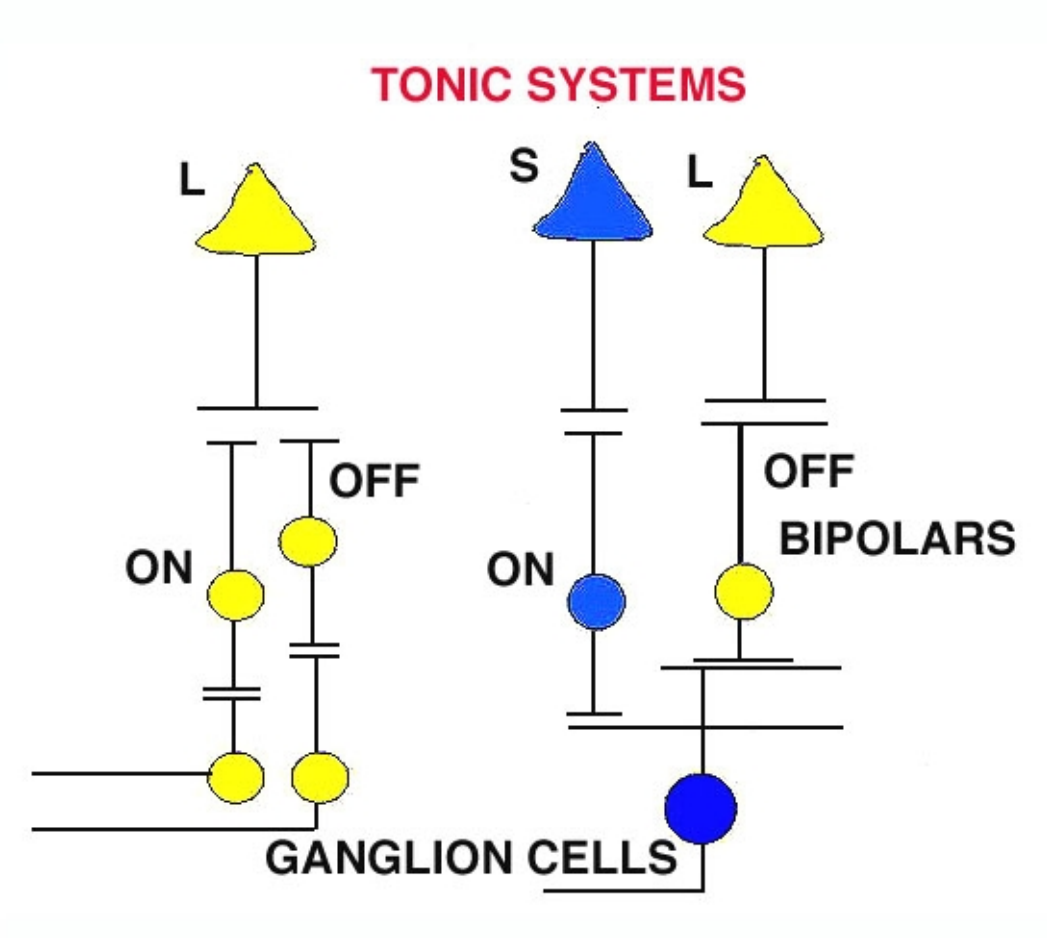

Figure 8. How retino-geniculate inputs are used to build cells with spectral antagonism, i.e., selectivity for certain wave-bands and ultimately color. This figure illustrates interaction between the achromatic system that determines the lightness or darkness of an object and the chromatic system that detects "hue". Together they create color.

By the rules of Fig. 12, a unit area of color space A would appear "blue" if there were short wavelengths and no long wavelengths in area A; the converse would lead to "yellow". This blueness or yellowness would be enhanced if the surrounding areas of color space were activated by the opposite color, i.e. simultaneous color contrast. Such cells have been called "double opponent" cells because they have one form of antagonism between cone mechanisms mediating a local area of color space and an opposite arrangement in neighboring areas of color space. Charles Michaels (18) found such cells in striate cortex of non-human primates following up on observations of Nigel Daw (19) in goldfish retina. Double opponency tends to separate spectral from energy contrast.

Trivariant Color Vision

In primates, high resolution vision and trivariant color vision evolved to enhance survival. A fovea formed to facilitate high resolution achromatic vision and a third opsin evolved from the original mammalian L cone opsin to create a new dimension of color in higher primates (20). The gene for the L cone opsin duplicated itself and one of the paired genes developed polymorphisms to absorb further into the long wavelength region of the spectrum. The original long wave sensitive L cone now became an M cone being the partner of an even longer wavelength sensitive L cone. Fig. 13 shows that a trivariant system can detect a larger variety of spectral reflectances (21). In Fig. 13 above right, one sees that a divariant color vision system can detect spectral contrasts

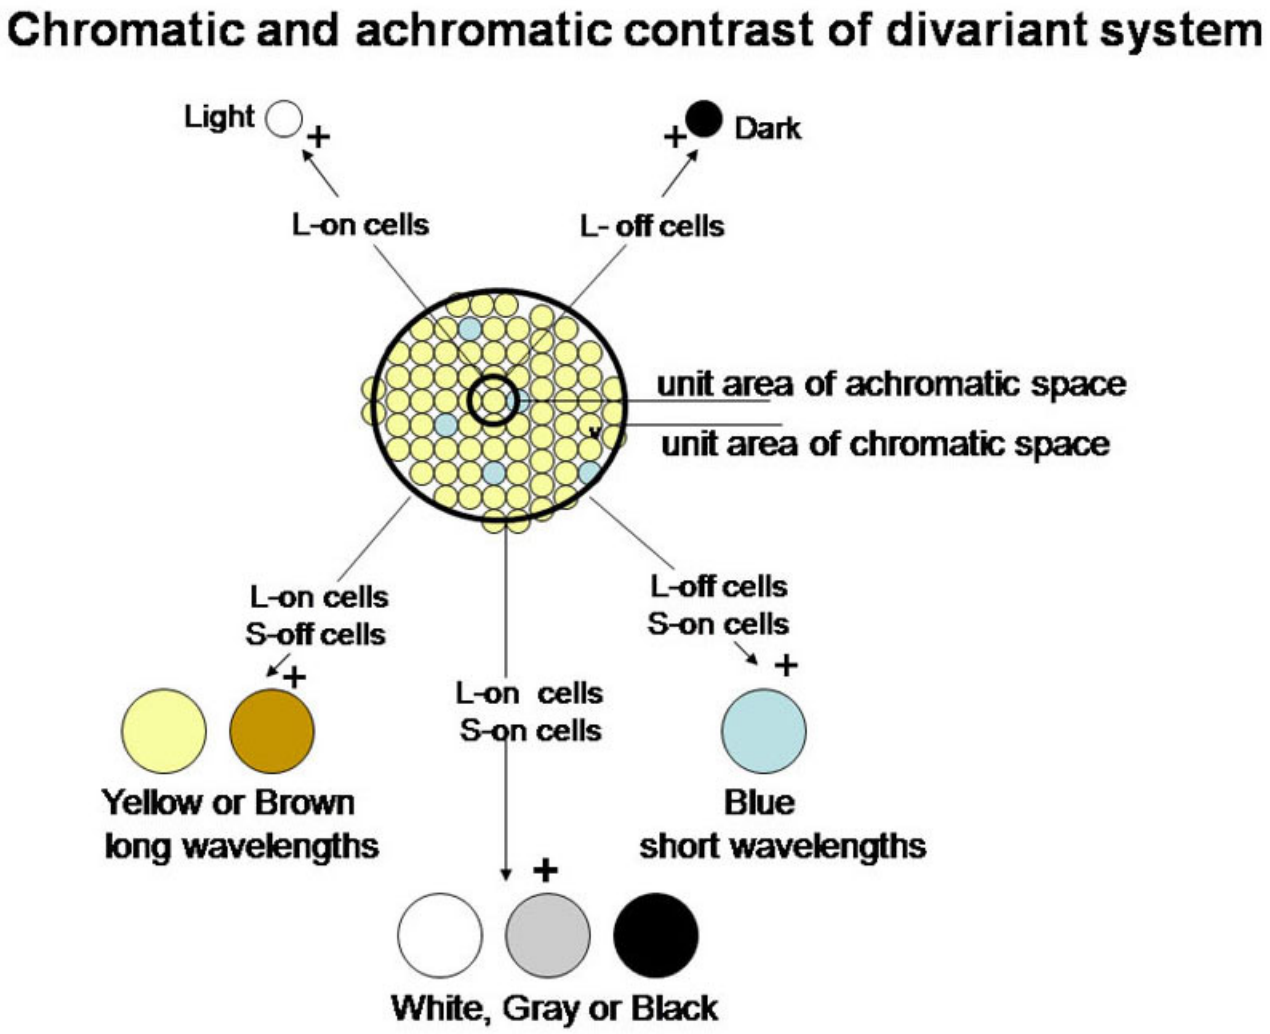

Figure 9. Parallel pathways extract chromatic and achromatic contrast from the same cone mosaic. The unit area of achromatic space is smaller than that of chromatic space.

that reflect more at one end than at the other end of the spectrum; these reflectances tend to tilt the solar spectrum.

If, however, a surface reflects less from both sides of the visible spectrum, i.e. bending the solar spectrum, it might be invisible to a divariant system because both cone types could be absorbing the same amount of light from the object and its background (Fig. 13 lower left). A trivariant system detects this object because it is impossible for all three cones to be absorbing the same amount of light from the object and its background (Fig. 13 lower right). More complex reflecting surfaces might confuse even a trivariant system but they are probably very rare in the natural world. This change split the yellow region of the original spectrum and created two new chromatic percepts, red and green (Fig.14). It is noteworthy that a rise in the beta-band absorption of this new L cone pigment also provided a long wave influence at the short wavelength region of the spectrum.

Fig. 15 shows how a trivariant system facilitates the distinguishing of red and green objects which would remain indistinguishable for a divariant observer.

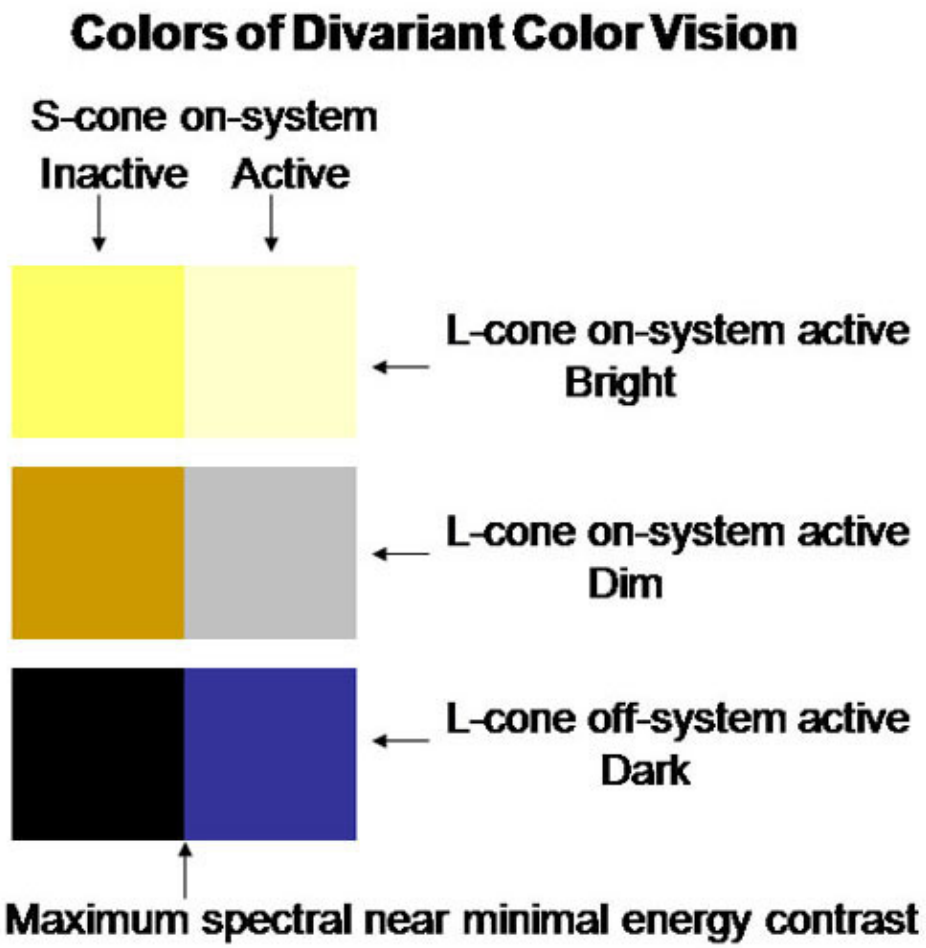

Figure 10. The variety of colors seen by a divariant color vision system using only L and S cones. Each of these colors is related to a certain combination of on and off cell systems.

In the fovea, the same midget cells which had been contacting only single L cones for divariant color vision now contacted either an L or an M cone (Fig. 16), providing the brain with separate channels for these two different cones and another opportunity for chromatic contrast.

In Fig. 16 it is assumed that the bistratified S cone on cell conveys S cone signals from the retina and the midget cell system conveys the signals of L or M cones for color vision (6). The midget cell system is currently assumed to play a role as a "double duty" detector contributing to both high spatial resolution achromatic vision and lower spatial resolution chromatic vision.

Fig. 17 (upper) shows the responses of a midget ganglion cell receiving an excitatory L cone input. This cell is continuously excited by the red adapting field; under these conditions the cell does not respond to the small red spot. A blue adapting field stops this continuous discharge and under these circumstances the cell responds to the small red spot. Fig. 17 (lower) shows the responses of an L cone on midget ganglion cell (large amplitude) and a M cone on midget-like ganglion cell (small amplitude) responding to a small red spot in the presence of the same adapting fields. The red adapting field continuously excites the L cone cell and inhibits the M cone cell; under these conditions the small red spot inhibits the L cone cell, an inhibition mediated by M cones.

Fig. 18 shows an S cone on-cell responding to spectrally narrow stimuli.

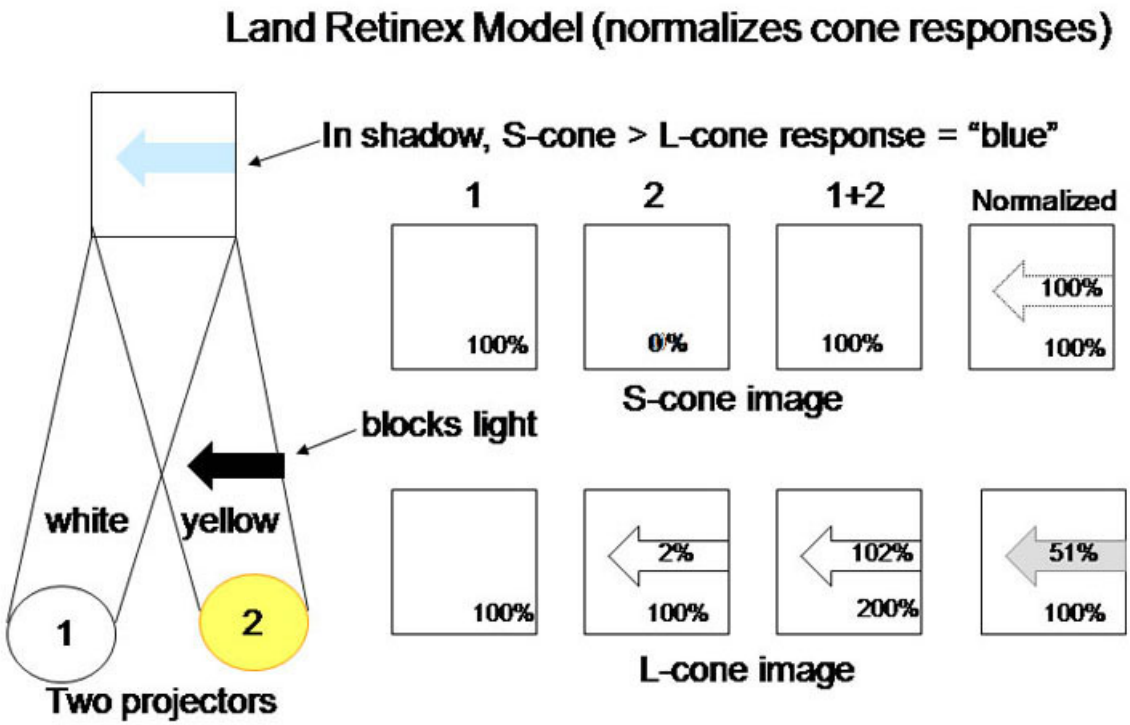

Figure 11. An experiment of Edwin Land. Two projectors cast a mixture of white and yellow light on a screen and an object (arrow) is placed in the yellow beam which leads to the appearance of a "blue" shadow of the arrow on the screen. This somewhat paradoxical appearance of the shadow can be explained if one assumes that the effects of the separate cone mechanisms viewing this screen have their responses normalized across the screen before being compared with each other to produce color.

The cell is excited by the blue spot on the yellow background and is profoundly excited by the turning off of the yellow adapting light. The cell is not responsive to the red spot in the presence of the yellow adapting light but is inhibited by the red spot in the absence of the adapting light.

Fig. 19 illustrates how these midget cells could participate in both chromatic and achromatic vision. The same concentrically organized retinal and geniculate cells feed two different circuits in striate cortex. One achromatic with a large number of orientation selective neurons capable of high spatial resolution and the other chromatic built up from the same center/surround organized midget-like cells. How center/surround cells can build up a circuit which is more co-extensively organized more suitable for chromatic processing remains enigmatic.

David Hubel (22) and the late Bob Rodieck (23) have suggested that the midget system may not be involved in mediating chromatic vision but another much less common ganglion cell type with a receptive field in which L and M cones driving these cells are co-extensively rather than concentrically organized in the receptive field of these cells. It has been difficult to obtain any evidence for such a cell.

The evolution of trivariant color vision in higher primates increased the repertoire of colors we perceive and the power of spectral contrast to detect objects. The original blue/yellow form of color vision was now accompanied by a parallel system of red/green colors occurring in the yellow region of the spectrum where brightness is maximal (24). Where the dynamic range of achromatic contrasts are maximal is where chromatic contrast can contribute most to detecting borders when achromatic contrast is minimal. Fig. 20 shows how the activity of this trivariant cone system contributes to the variety of major colors we see. The borders of effective energy contrast for each of these colors are minimal, which is where color contrast is especially important.

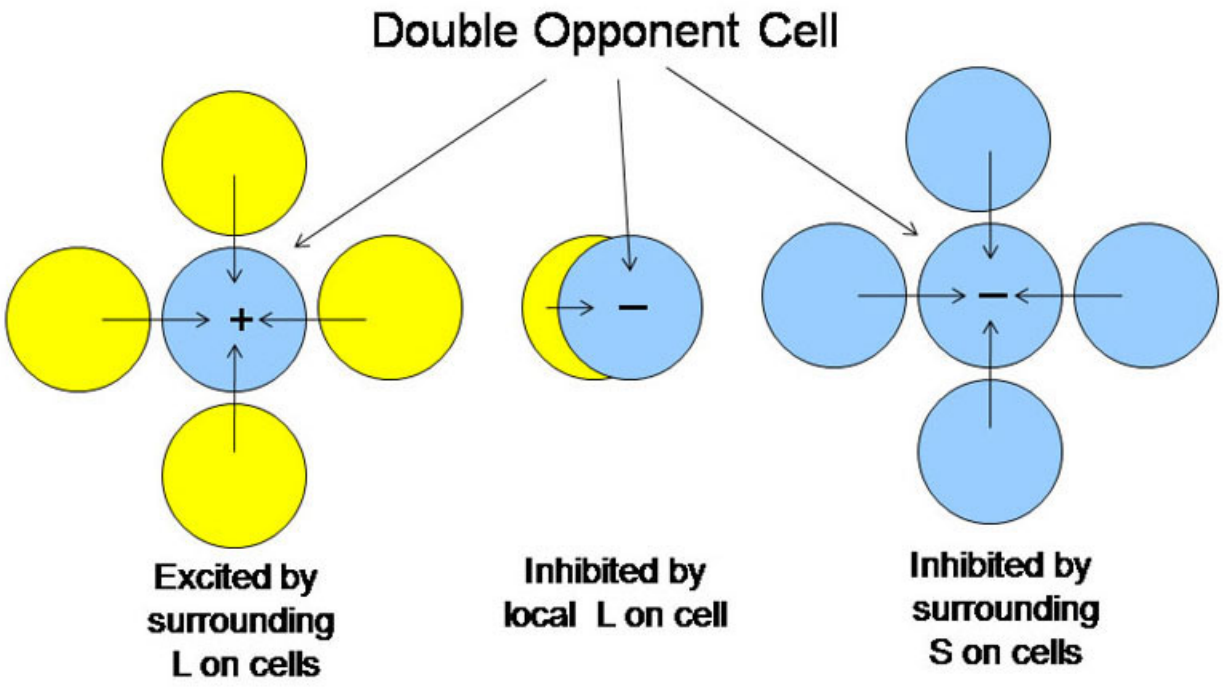

Figure 12. How double opponent cells can be constructed. The central two on cells, one S on and the other L on, inhibit each other. The surround L on cells excite the central S on cell and inhibit the central L on cell. the surround S on cells excite the central L on cell and inhibit the central S cone on cell (not shown).

The Cone Mosaic of Trivariant Color Vision

The division of a single L cone type into two spectrally different L and M cones produced a mosaic of L, M and S cones from which each ganglion cell picks out the input of one or the other of these cone mechanisms to transmit to the brain. Adaptive optics has revealed significant differences in the number of L versus M cones in normal subjects (25) (Fig. 21).

Some subjects have 15 times as many L than M cones and others have twice as many M than L cones but all have normal color vision. This reinforces the idea that a unit area of color space involves comparisons of large groups of cones. What remains problematic is how midget-like ganglion cells in the parafovea select only L or only M cones to form synaptic contact within this variegated cone field.

A Parallel System of Achromatic Ganglion Cells

In addition to midget and midget-like ganglion cells described there is another parallel system of larger ganglion cells with less representation in the fovea than the midget cell system (26). These ganglion cells also have: on- and off-varieties mediated by a separate set of cone bipolar cells and are known to be the "parasol" ganglion cells found by the Golgi method of silver impregnation. They seem to receive their inputs from only L and M cones through a different set of bipolar cells than those serving the midget cell system. Fig. 22 shows two retinal ganglion cells in rhesus monkey retina.

The cell with smaller amplitude is a phasic on-cell that responds at on to all three wavelengths with a shorter latency than the tonic S cone on cell which is excited only by the deep blue light (419 nm) and inhibited by the longer wavelengths (610 and 509 nm). It is thought that a separate relatively wide field bipolar cell feeds these

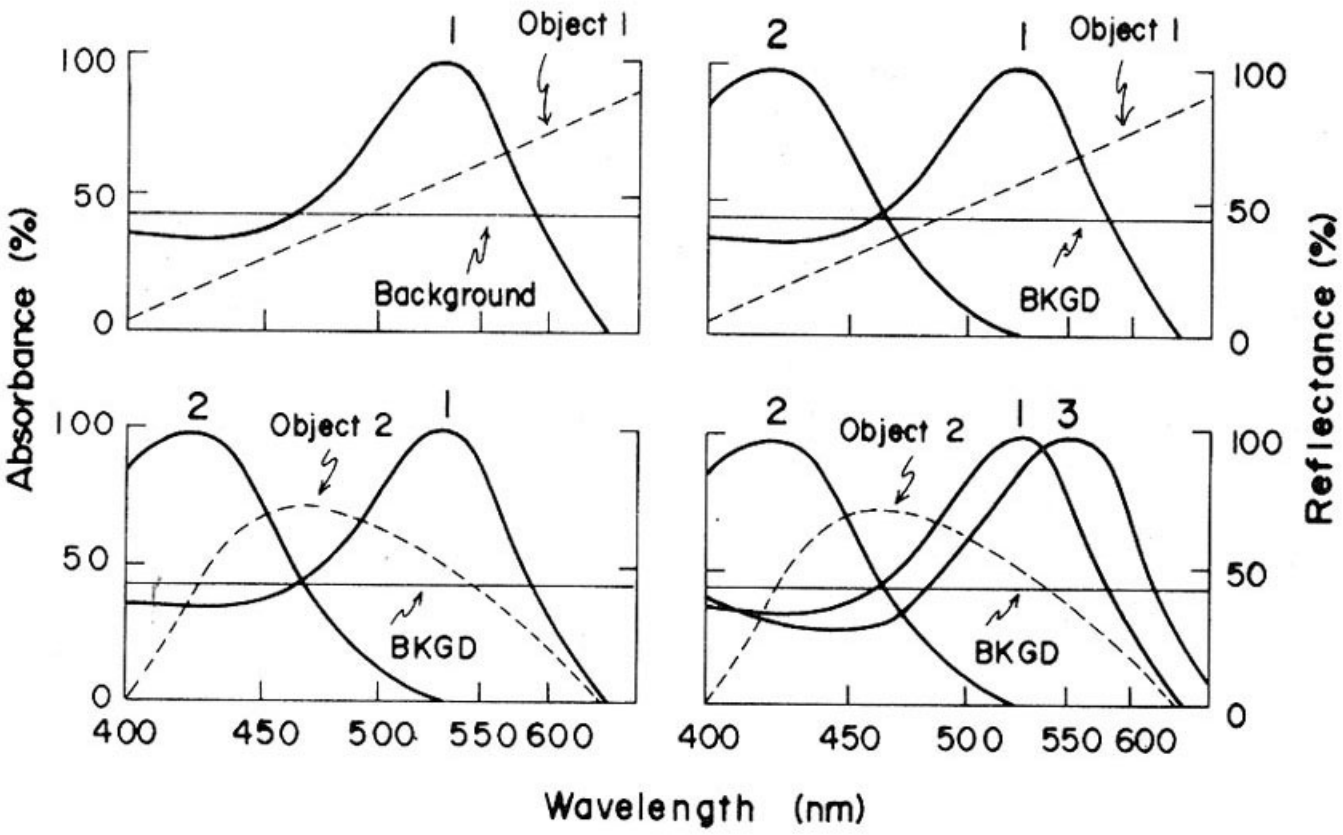

Figure 13. An Object 1 that just "tilts" the solar spectrum but causes as much light absorption as the background will not be detectable by a retina with only 1 photopigment (opsin) in one class of cones (1). In order to detect this Object 1 by its spectral contrast it is essential to have a second type of cone (2) which will always recognize this Object 1 by its spectral reflectance relative to its background. If an object arises such as Object 2 that "bends" the solar reflectance by having a reflectance maxima in the middle of the spectrum it could become invisible relative to its Background for both cones 1 and 2. For such reflectances three types of cones are needed to detect this object under all conditions.

phasic cells. These cells receive similar inputs from both L and M cones and therefore cannot play a role in "red/green" color vision and probably no role in blue/yellow color vision. Fig. 23 is evidence that they receive no input from S cones. The threshold spectral function obtained on a strong yellow adapting field shows no evidence of an S cone input. The S cone on-cell has a threshold spectral function that shows it lowest threshold to blue light. The phasic cells have their lowest threshold resembling that of the photopic luminosity function.

The retinal latencies at of these two types of cells show a significant difference between the tonic and phasic cells indicating a faster transmission of the latter through the inner nuclear layer by the phasic system. In addition the larger size of the axons of the phasic system allows this system to transmit its signals to visual cortex much quicker than the tonic system. The role of the phasic "parasol" ganglion cell system in vision is not entirely clear. It seems to play a role in the detection of motion and to target different areas of visual cortex. Whether it plays any role in color vision is moot.

The Lateral Geniculate Nucleus (LGN)

The LGN reorganizes the parallel ganglion cell systems serving local retinal areas into separate layers from where their axons project to specific layers in striate cortex (12, 15, 27). Signals from nasal retina of the contralateral

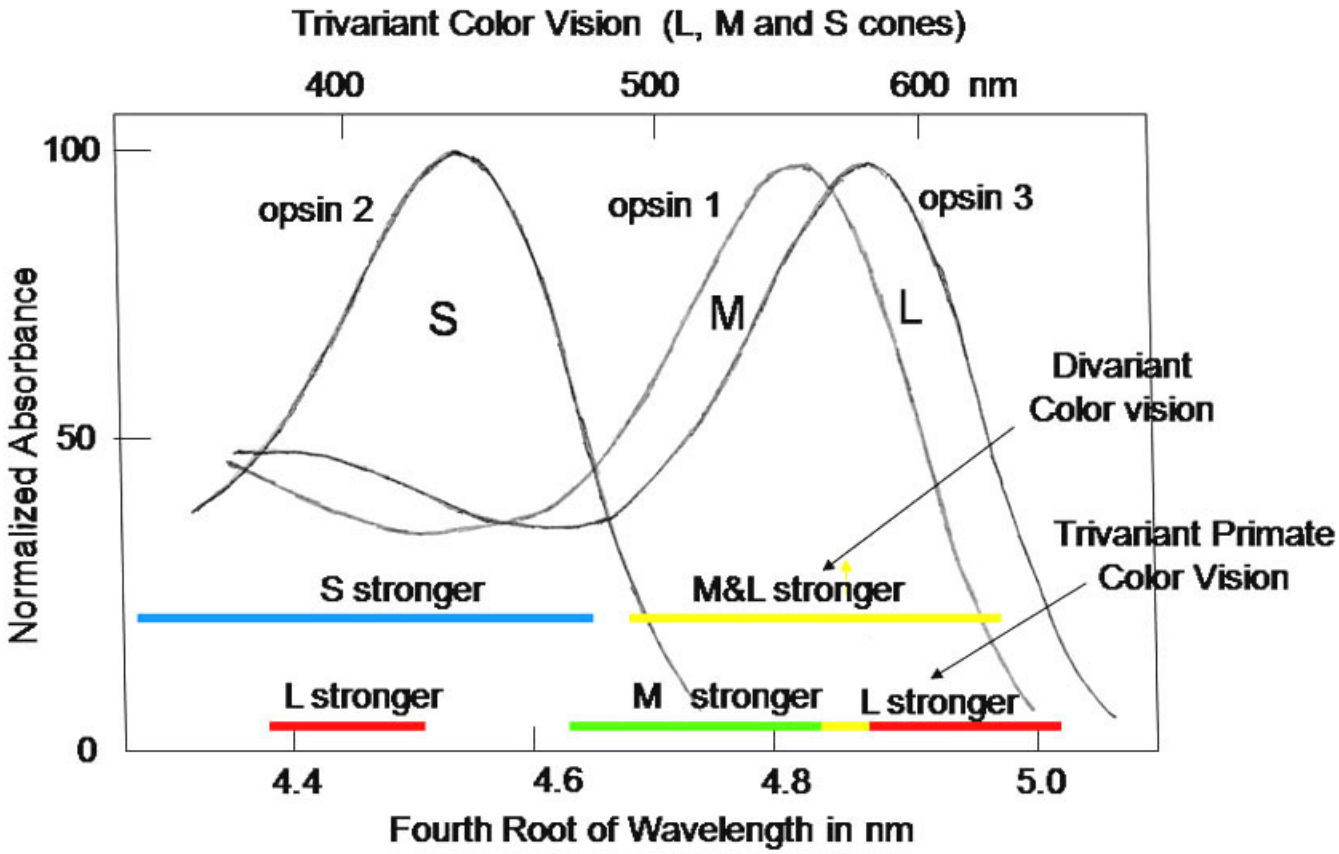

Figure 14. The normalized absorption spectra of the three cone mechanisms that mediate primate trivariant color vision. The original L cone system of divariant color vision split into two slightly different long wavelength sensitive cones straddling the yellow region of the visible spectrum.

eye are separated into different layers from those coming from the temporal area of the ipsilateral eye. This is needed for stereopsis where changes in eye position require comparing signals from different corresponding retinal regions and accordingly different ganglion cells. Binocular interactions begin for the first time in visual cortex. The parallel channels coming from the same retina are also separated into different layers. The phasic achromatic ganglion cell system goes to the magno-cellular layers, one layer for each eye. The midget and midget-like retinal ganglion cells transmitting signals for high resolution achromatic vision and "red-green" color vision are placed in four parvo-cellular layers, two for each eye. The S-cone mediating retinal ganglion cells which are involved in "blue-yellow" color vision go to the konio-cellular layers. These parallel systems of ganglion cells project to specific layers of striate cortex where form, color, movement, direction and stereopsis are processed.

An interesting but unknown role must be played by the numerous centrifugal axons that arise from striate cortical layers and impinge upon the cells in the LGN. Whether this shapes or influences chromatic and achromatic contrasts that are involved in form vision is unknown.

Striate Cortex

The LGN transmits its signals to striate cortex, the first visual area (V1) to process visual signals in cerebral cortex. There is a retinotopic order to the projection of these producing a map of the visual field. The map is distorted because the fovea occupies a relatively large area compared to the more peripheral retina. There are columns of cells extending from the upper to the lower layers, one column receiving signals from one eye and a

Figure 15. Trivariant color vision distinguishes red from green, expanding the repertoire of colors.

neighboring column receiving signals from the other eye (Fig. 24). Within each of these "ocularity" columns there are micro-columns of cells favoring a particular orientation of an extended light stimulus. Together these sets of columns have been called a "hyper-column". Within each hyper-column there is a local area that receives inputs from chromatic selective cells, i.e. the S cone on and off cells and the L and M cone midget and midget-like cells; these areas have been called "blobs", and are thought to be where color is processed.

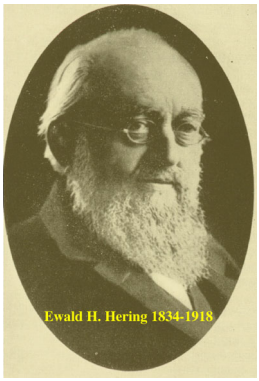

Figure 16. Four varieties of ganglion cells considered to mediate trivariant color vision in primates. The L cone on/ S cone off cells reported to be in the koniocellular layers of the lateral geniculate nucleus are not included here.

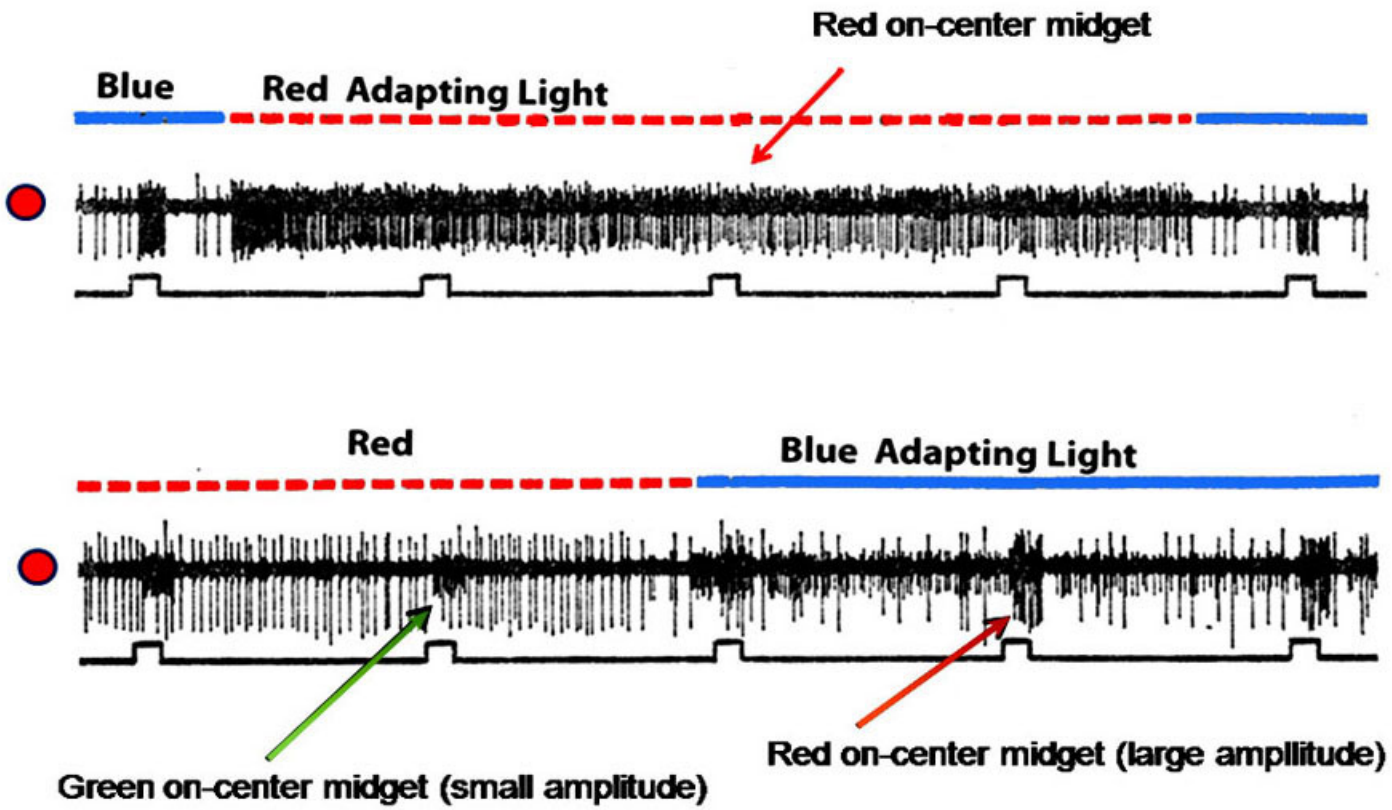

Figure 17. Midget-like ganglion cell responses. Figure 17(upper) shows an L cone on midget-like ganglion cell being stimulated by a red and blue adapting light while the center of its receptive field is being stimulated with a small red spot. The blue light suppresses the discharge but the cell responds to the red spot. The red adapting light excites the cell tonically but the cell no longer responds to the red spot. Figure 17 (lower) shows the responses of two midget-like ganglion cells. The one of small amplitude responds to the red spot on the red background and is excited tonically by the blue background. The one of large amplitude is excited tonically by the red background light and is inhibited by the red spot. It is suppressed by the blue adapting light but is then excited by the red spot. The latter is a L cone on cell with an antagonistic M cone surround; the former cell is the converse.

There are six distinct layers extending from an upper layer 1 down to a lowermost layer, 6. The projections from the functionally different layers of the LGN target different layers to synapse on cortical cells (Fig. 24).

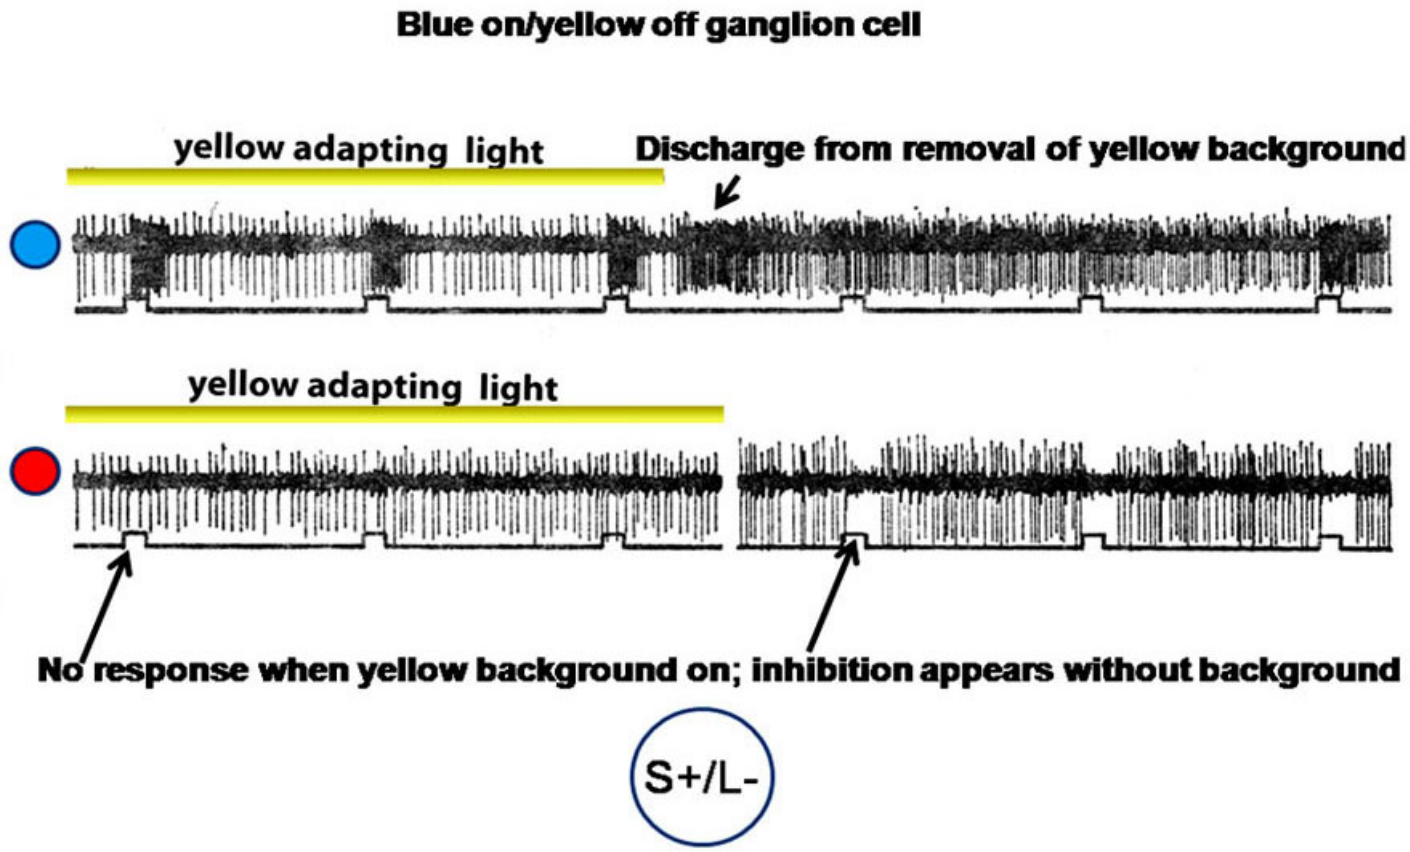

Figure 18. An S cone on/L+M off cell responding to a blue spot (above) and a red spot (below) in the presence and absence of a yellow adapting light.

The L and M midget and midget-like cells, projecting from the parvo-cellular layers, synapse in layer 4Cbeta from which their post-synaptic target cells appear to send axons to layer 3 within "blobs". The S cone system, projecting from the konio-cellular layers, appears to send axons directly to layer 3 within blobs. The fact that the parvo-cellular input, incorporating the L and M cone midget and midget-like cells, makes an intermediary synapse may be due to the double duty role these cells play in handling both achromatic and chromatic vision. The area surrounding blobs process achromatic contrast, undoubtedly receiving their input from the parvo-cellular layers. The magno-cellular layers of the LGN target cells in layer 4Calpha from which postsynaptic cells send axons to layer 4B. Therefore there is segregation of cell systems, some playing a role in chromatic contrast and others playing a role in achromatic contrast and movement. The existence of "double opponent" cells in blobs supports the idea that this zone within each hyper-column is devoted to detecting chromatic contrast for color vision. There are many unknowns in this structure that can only be solved by more single cell physiology combined with anatomical insights into the circuitry. What seems clear is that each unit area of visual space is processed in parallel by achromatic and chromatic mechanisms (28).

Pure Spectral Contrast

Double opponent cells tend to eliminate the influence of energy contrast establishing pure spectral contrast as an indicator of the borders of objects. With trivariant color vision this can be formed by comparing L with M cone responses and/or by S cone versus L&M cone responses. Fig. 25 illustrates the organization of a "red/green" double opponent cell. The system uses spectral contrast.

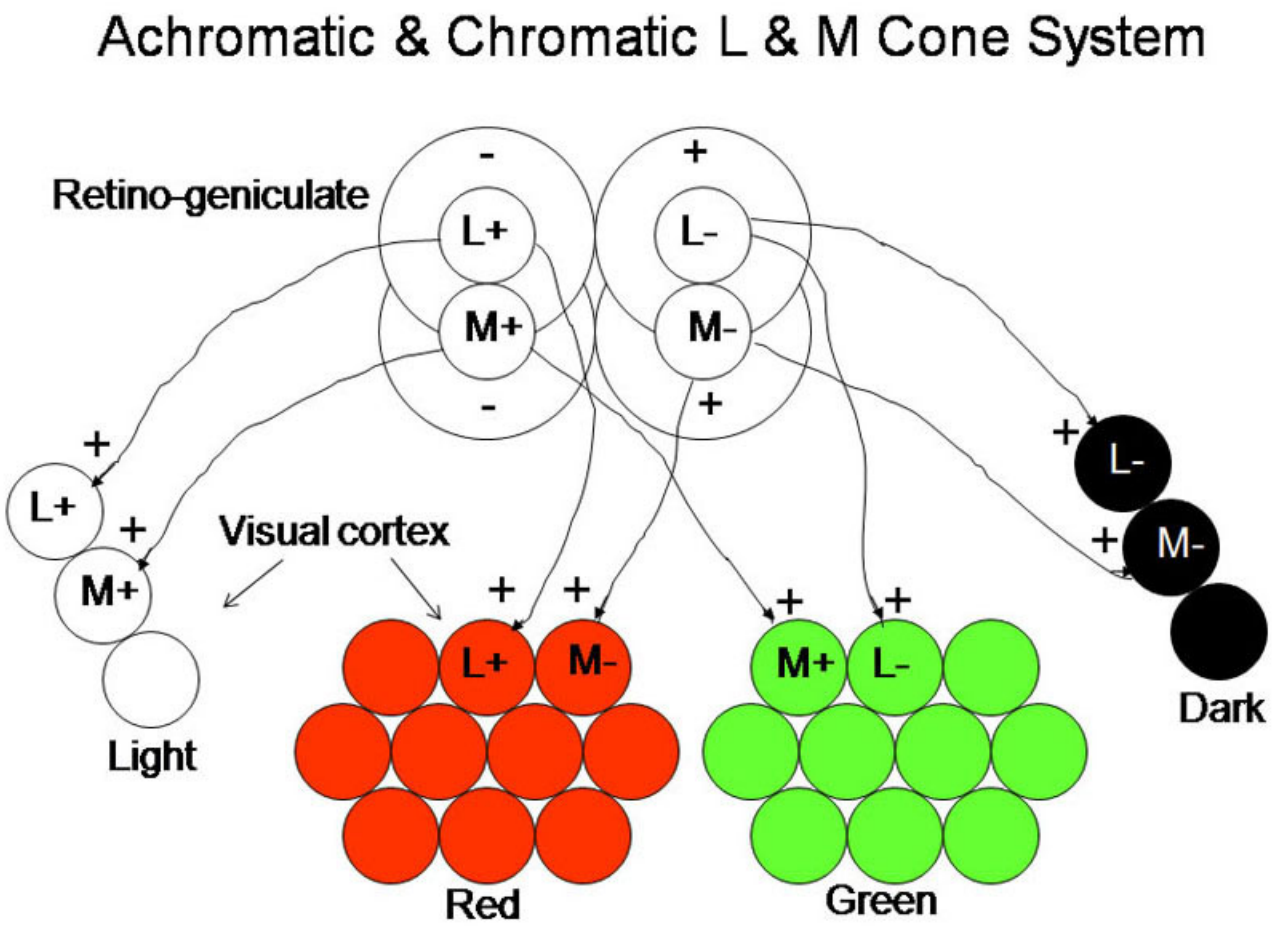

Figure 19. L and M cone midget-like cells can be used to extract achromatic high spatial resolving vision and chromatic "red/green" chromatic vision of lower spatial resolution.

Fig. 25 shows how concentrically organized double opponent cells can be constructed by having identical (red) neighboring cells inhibit a central cell (red) and have opposite neighboring cells (green) excite the central cell (red) making it most sensitive to a red central object in a green background and unresponsive to the converse. Such a cell responds to spectral rather than energy contrast as an indicator of a border. This behavior is illustrated by a cell detected in visual cortex that responds exclusively to spectral and not to energy contrast (Fig. 26). The stimuli with maximum energy contrasts such as a red or green bar on a black background or a black bar on a green or red background produce no response from the cell. But a green bar on a red background where energy contrast is minimal generates a large response. The brain has now separated the two major forms of contrast, spectral versus energy contrast to use them as independent variables to create color.

Simple, Complex and Hypercomplex Double Opponent Cells

One of the remarkable discoveries in visual cortex has been that of a unique body of cells that exhibit definable patterns of responses all based on orientation selectivity. One group called "simple" cells show orientation selectivity which can be predicted by the organization of responses produced within their receptive field. Another group called "complex" cells also show orientation selectivity but are less obviously related to the distribution of responses within their receptive field. A third group of "hypercomplex" cells are orientation-selective but are "end-stopped" being inhibited if the oriented stimulus is too long. These three types of cells are thought to contribute to form vision based on energy contrast. Charles Michael (18) has shown that a similar

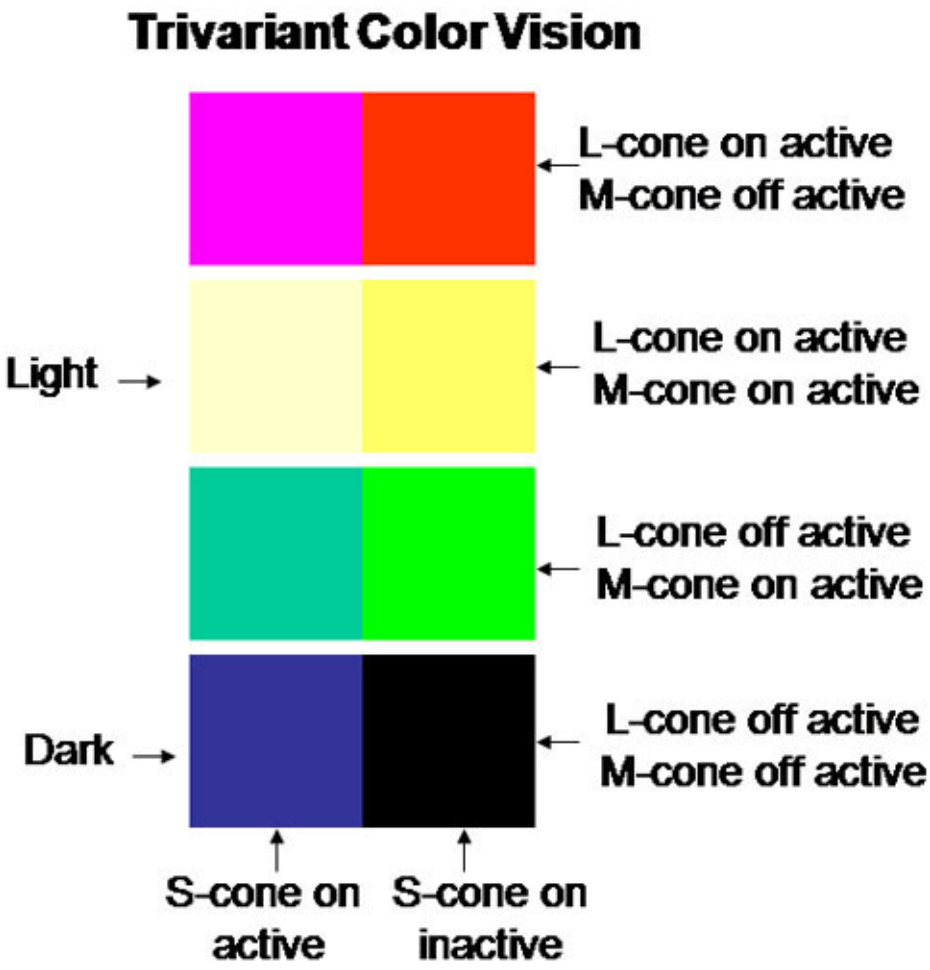

Figure 20. The major colors produced by trivariant color vision in primates. The figure indicates the synaptic pattern in which the three cone inputs of on and off cells make to produce particular colors.

group of double opponent cells exist in striate cortex of monkeys. Fig. 27 shows such a simple cell responding best to strong spectral contrast.

Fig. 27 shows that this cell is excited when an oriented red bar moving upward crosses the red selective area of its receptive field and inhibited when it crosses the green selective area; it produces an off-response when it leaves this green selective area. A green bar produces excitation when it crosses the green selective area only. A green-red and a red-green bar produce strong responses but the responses occur at different points in the receptive field and are therefore totally out of phase with each other. This cell responds poorly to white bars being spectrally selective. Fig. 28 shows a complex cell that responds to spectral and not energy contrasts. It is both orientation and directionally selective and refuses to respond to energy but responds strongly to spectral "red/green" contrast.

Hypercomplex double opponent cells (Fig. 29) are also detectable in striate cortex completing the variety based on energy contrasts. Therefore the same repertoire of orientation selective cells responsive to energy contrasts in striate cortex can also be found for spectral contrast. It is thought that both groups of cells play a role in form vision. Parallel systems of cells are detecting the forms of objects, one based on energy and the others based on spectral contrast. Because energy contrasts allow a higher spatial resolution, more of visual cortex is dedicated to achromatic than chromatic contrast detection.

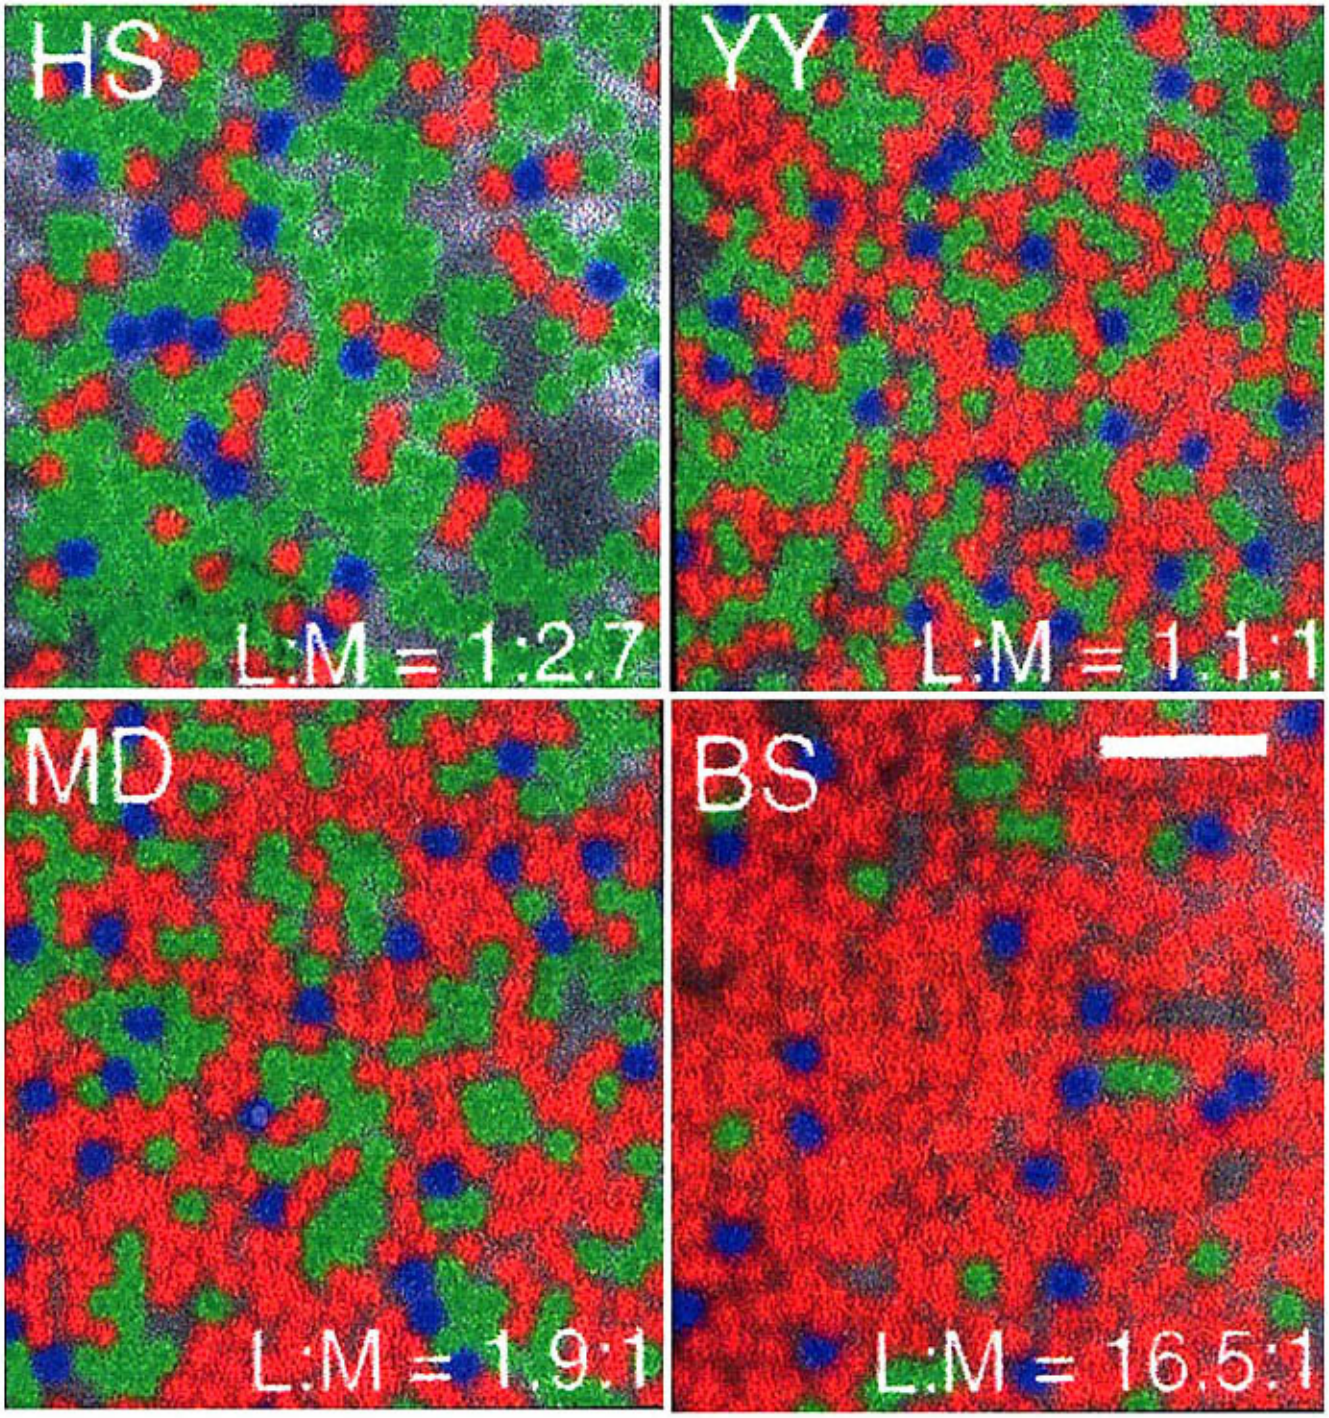

Figure 21. An adaptive optics view of the mosaic of L (red), M (green) and S (blue) cones in four human subjects with normal color vision. The ratio of S to L and M cones is constant but thaf of L to M cones varies from 1:2.7 (M:L) to 16.5:1 (L:M). (Adapted from Williams).

Fig. 30 shows how these two parallel contrast detecting systems could work in detecting a red object. Both simple cells of different orientation selectivity can detect the border of this cross, one set based on energy contrast and with a higher spatial resolution and the other set based on spectral contrast and with a lower spatial resolution. Sharp corners in the object would be detected by end-stopped hypercomplex cells. This creates two different views of the object which may be fused into one colored object just as two similar stereoscopic views are fused into an object in depth. Together they create shapes in full color (Fig. 30).

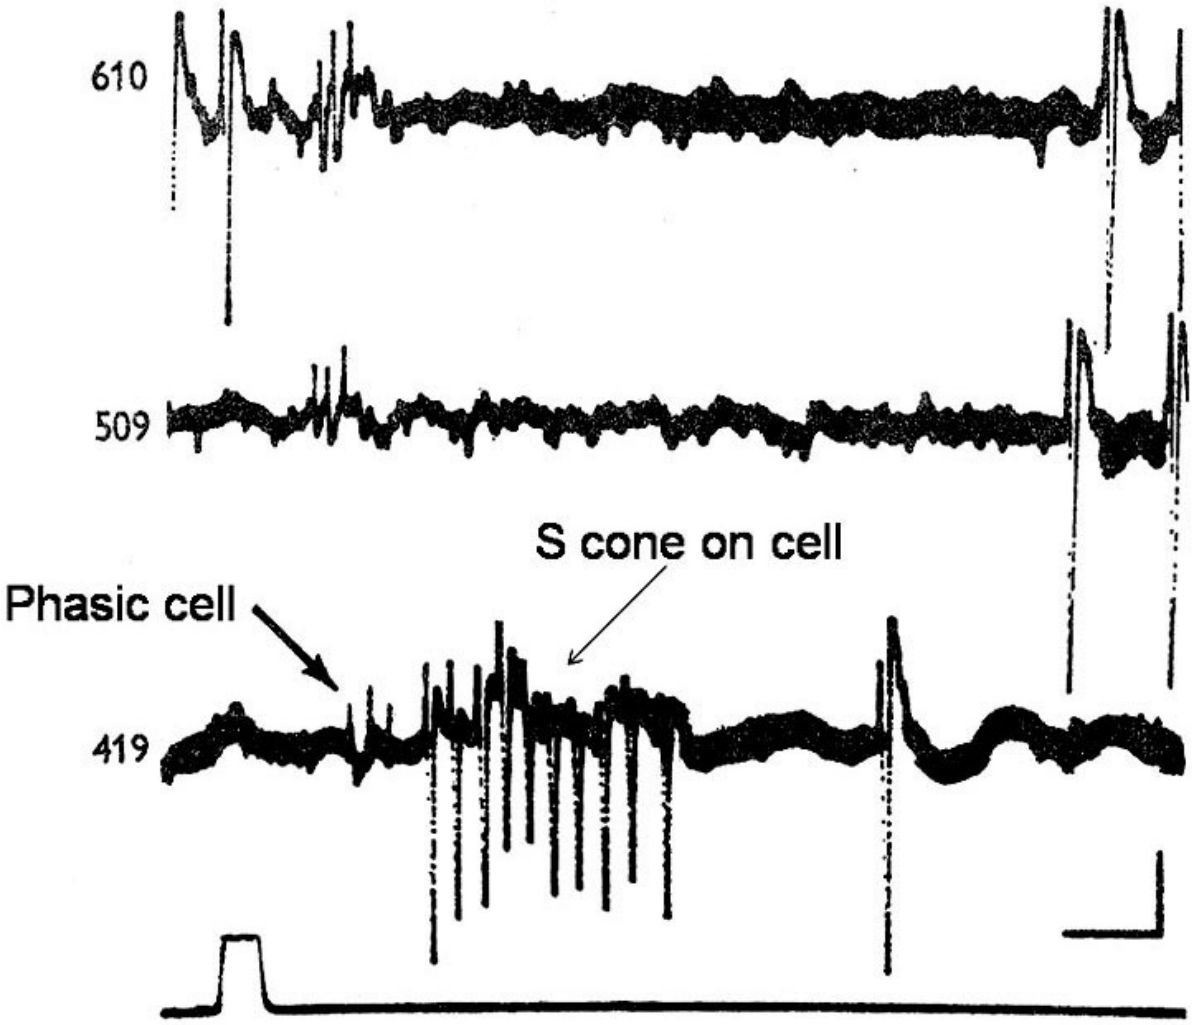

Figure 22. A magno-cellular on cell (small amplitude) and an S cone on cell (large amplitude) responding to three different parts of the spectrum (419, 509 and 610 nm). The calibration, lower right , indicates 200 microvolts vertically and 20 msec horizontally. The lower trace shows the duration of the light stimulus. Positivity is upwards.

A similar system for using spectral contrast created by double opponent S cone versus L cones or L+M cones must create another spectral view of objects by border contrasts (Fig. 31 and Fig. 32). In Fig. 31 groups of double opponent simple cells detect a circular blue form on a yellow background. In Fig. 32, similar simple cells detect a border of contrast between yellow and white, allowing the detection of an object of minimum energy contrast.

This highlights an important role of the S cone mechanism in vision to detect border contrasts of white versus yellow which are difficult for the achromatic system which is mediated only by L and M cones. This scheme implies that for color vision three different views of the same object are formed and then fused to provide colors that represent mixtures of the red/green and the blue/yellow spectral contrasts systems. If there is no activity in the spectral contrast detectors then only the energy (achromatic) system is active and the object is pure white, gray or black. There are some different views on these ideas. Single opponent cells are thought to detect surface color while double opponent cells detect borders (29). Others have suggested that neurons involved in the analysis of color should retain their chromatic properties in the face of changes in other components of stimulation, orientation, size and contrast and this may not be the case for color selective neurons found in striate cortex (30).

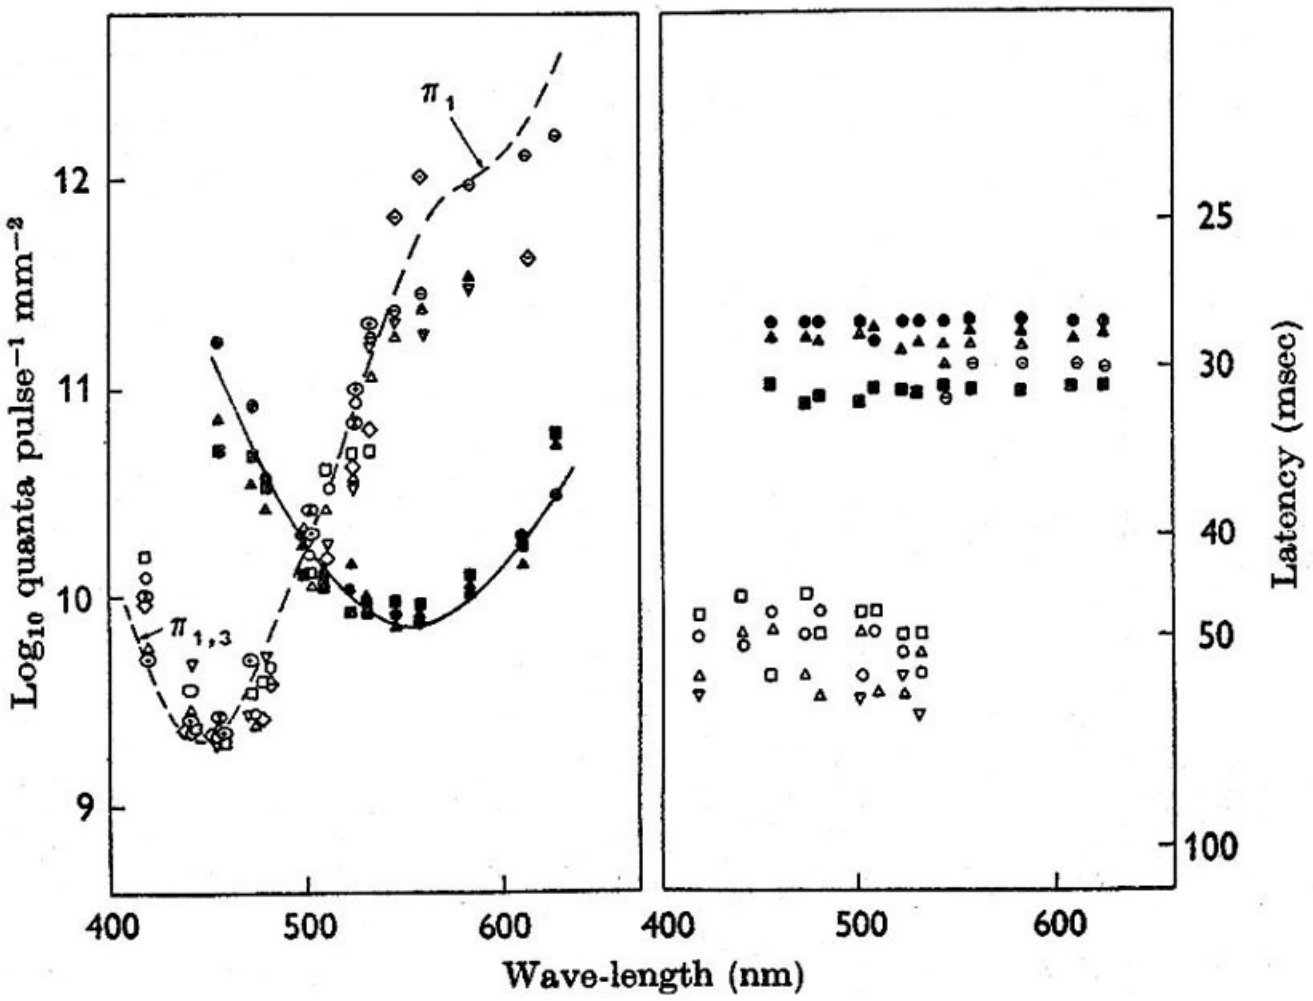

Figure 23. The threshold (left) in log relative quanta of 3 on-center phasic cells (filled symbols) and 7 S cone on/L cone off cells (open symbols) and their latencies at threshold (right) on a reciprocal scale of milliseconds. The dashed line indicates the Stiles' [1] 1 and 4 mechanisms. The continuous line is the CIE (Commission Internationale de l' Eclairage) luminosity function.

The Stabilized Retinal Image

If an image is made stationary on the retina it will disappear in seconds. Fig. 33 illustrates what is perceived by a subject presented with a stabilize image of a red/green boundary based on the research of the Russian physiologist Yarbus (31) and others (32). Initially the subject sees the red/green scene but in several seconds it fades into a featureless field. If a pale blue light is added to both sides only a blue field is seen without the red/green scene. This also fades within seconds. If the pale blue field is removed the subject sees a faint red/green scene but this fades again. This indicates that we only see in transients determined by change in the retinal image.

If the retinal image does not change in space and/or time, it will disappear. Constant small micro-movements of the eye continue to produce transient changes at the borders of objects that are able to maintain an undiminished view of the external world. This supports the idea that objects are seen because of their borders, as depicted by the orientation selective border contrast cells illustrated previously, which must be continuously moved across the retina to maintain their visibility. Fig. 34 illustrates how the responses of on and off cells contribute to maintaining strong responses to movements of borders of contrast. When a long wavelength (red) surface enters the receptive fields of on and off cells, the on-cell (L off) responds more strongly than the off-cell if

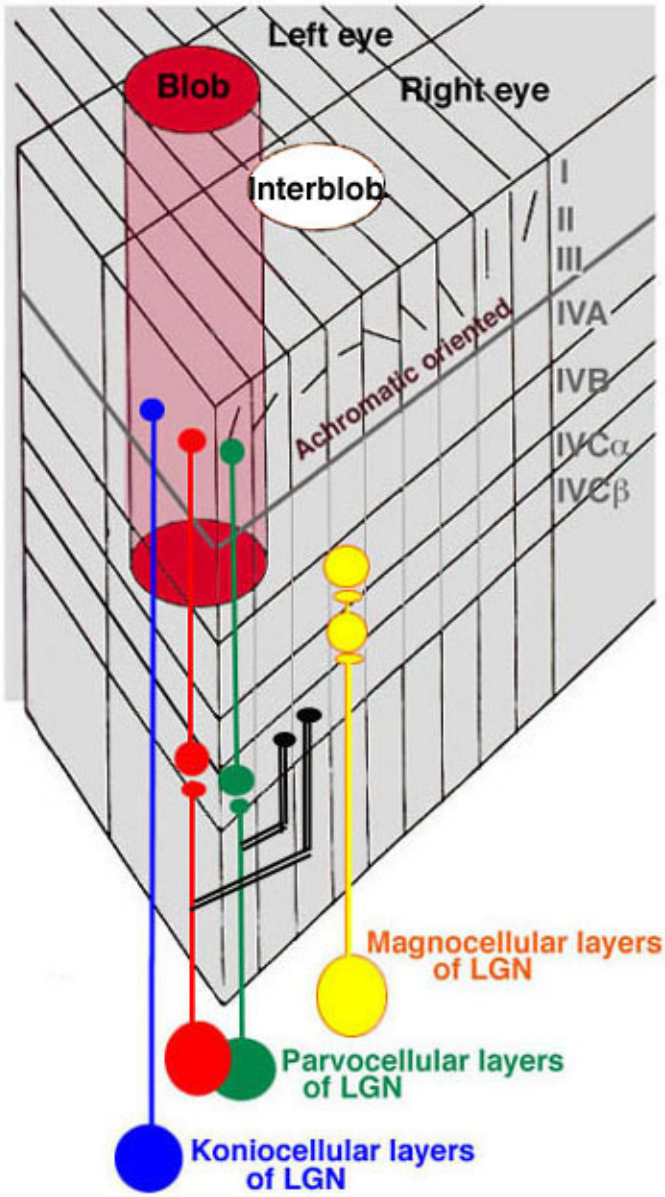

Figure 24. S cone on and off cells of the koniocellular layers and the four varieties of L and M midget-like cells of the parvo-cellular layers of the LGN target different layers of striate cortex. The midget system must project to both the achromatic areas as well as the "blobs" involved in chromatic vision. The parasol cells from the magno-cellular layers of the LGN target a different layer than the previous cells.

there is an increment in energy contrast. But the off-cell (M off) will respond more strongly if there is a decrement in energy contrast. These two systems are showing their ability to respond to increments and decrements of energy contrast but also manage to favor long over other shorter wavelengths, which is a key for their role in color vision. M on and L off -cells would respond weakly to such a moving border.

Color Vision Beyond Striate Cortex

An intriguing but poorly understood aspect of visual cortex is the remapping of visual space into multiple adjacent visual areas where a retinotopic order is maintained. Fig. 33 shows how V1 projects to V2, a second visual area juxtaposed to V1 where there continues to be a segregation of functionally different cells. The "blob" areas of V1 appear to project to "slabs" of cells in V2, which project to "globs" of cells in V4 (Fig. 35).

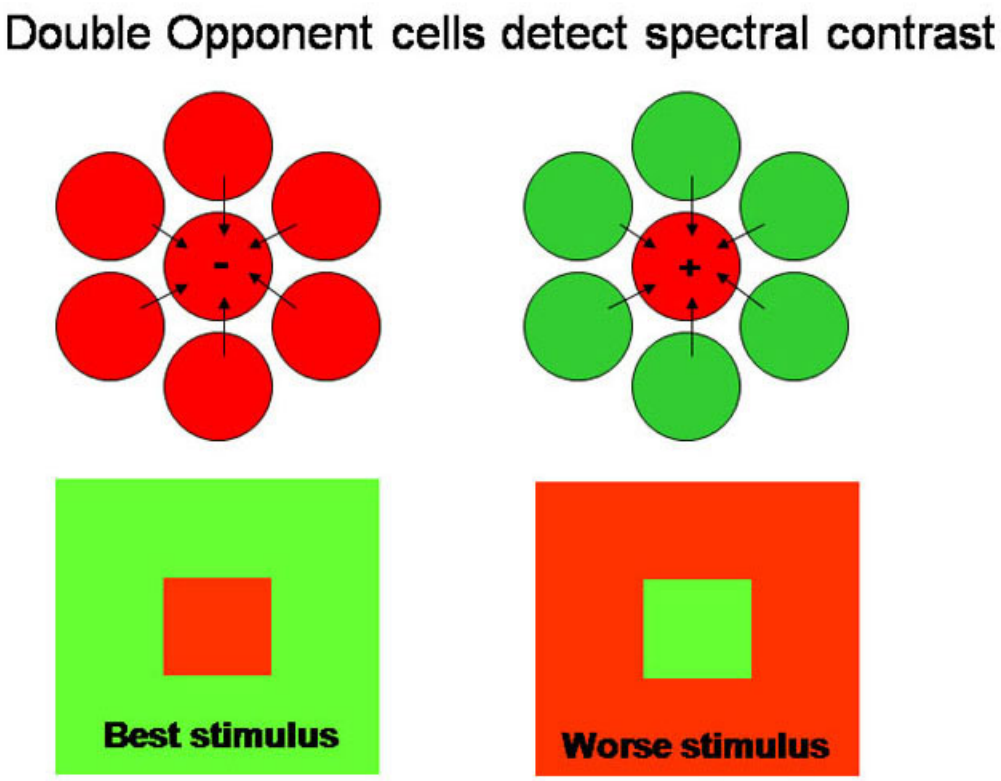

Figure 25. Concentrically organized double opponent cells can be constructed by having identical (red) neighboring cells inhibit a central cell (red) and have opposite neighboring cells (green) excite the central (red) making it more sensitive to a red central object in a green background and unresponsive to the converse.

Within these three interconnected areas spectral contrast is processed, presumably to determine its contribution to color, i.e., hue. Adjacent areas processing energy (achromatic) contrasts contribute to determining the saturation and brightness in colors. The achromatic areas are larger because of the higher spatial resolution of energy contrasts. The receptive field sizes of cells in these higher visual areas tend to be larger than they are in V1 suggesting that, several blobs in V1 project to a single slab in V2 and several slabs in V2 project to a single glob in V4 (33-35). The functional roles of these higher areas could be to recognize objects better as they come closer to the observer when they cast a larger retinal image. It is known that the perception of color increases with the size of an object over sizes as large as 20 degrees of visual angle. Under ideal conditions i.e. a well lit surface, we can perceive at least a million different colors. Fig. 36 shows how more basic hues determined by single cells in blobs could be used to build higher order colors that combine the inputs of the more basic hue determining cells. As one develops more experience with colors even higher order cells could be formed allowing the distinguishing of many different shades of color.

There is a question as to whether a single cell is committed to detecting a particular color or whether a group of cells are involved. This might depend on the practice one has in working with colors such as artists who may form single cells that are sensitive to a particular color and capable of contributing to even higher order colors while those who are less involved have fewer such cells and depend on less fastidious interactions.

There has been a controversy about whether color processing is exclusively segregated to V4 while achromatic processing occurs in another complete area of visual space. Evidence implying this type of organization involves rare individuals who have lost all color vision but can see objects with high spatial resolution in black and white.

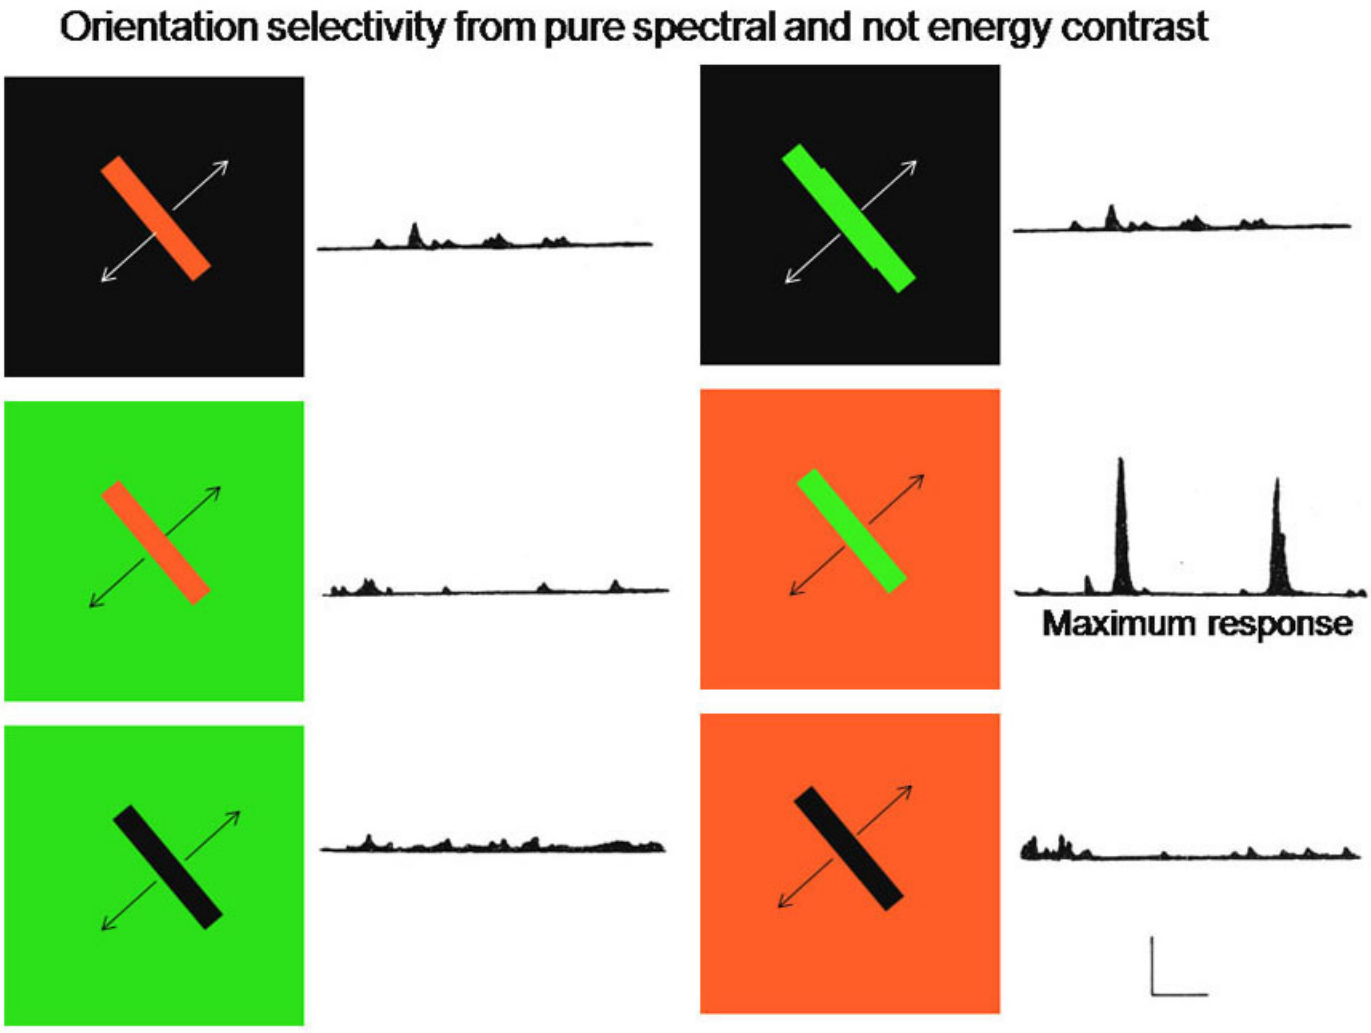

Figure 26. A cell selective for orientation based on pure spectral contrast. It fails to respond to strong energy contrast such as occurs with the movement of the colored bar on a dark background (above) and a dark bar on a color background (below).

This hypothesis was championed by Semir Zeki (36) but the existence of "globs" related to spectral contrast in V4 surrounded by larger areas of achromatic contrast detecting cells tends to weaken this idea. Because "globs" are relatively large it was perhaps possible for an investigator making a limited number of penetrations to conclude that all of V4 is devoted to chromatic vision. Nevertheless there must be an explanation of why in these very rare patients color can be lost without a loss in spatial resolution which depends entirely on achromatic contrast. The enigma may be explicable by damage to higher areas of the brain where interpretation and language are involved linking vision to external communication.

Redness at short wavelengths

It is well known that short wavelengths can produce a reddish sensation that makes blue appear violet. This affect appears to arise from the beta-band of L cone opsin which makes this opsin more sensitive to light than M cone opsin at this region of the spectrum (see Fig. 14). This effect is best observed in midget-like cone opponent retinal ganglion cells which are excited by long wavelengths and inhibited at wavelengths at the middle of the spectrum. In many of these cells excitation appears with short wavelength stimulation implying that the L cone response is overpowering the M cone antagonism. This is supported by the fact the L cone response is

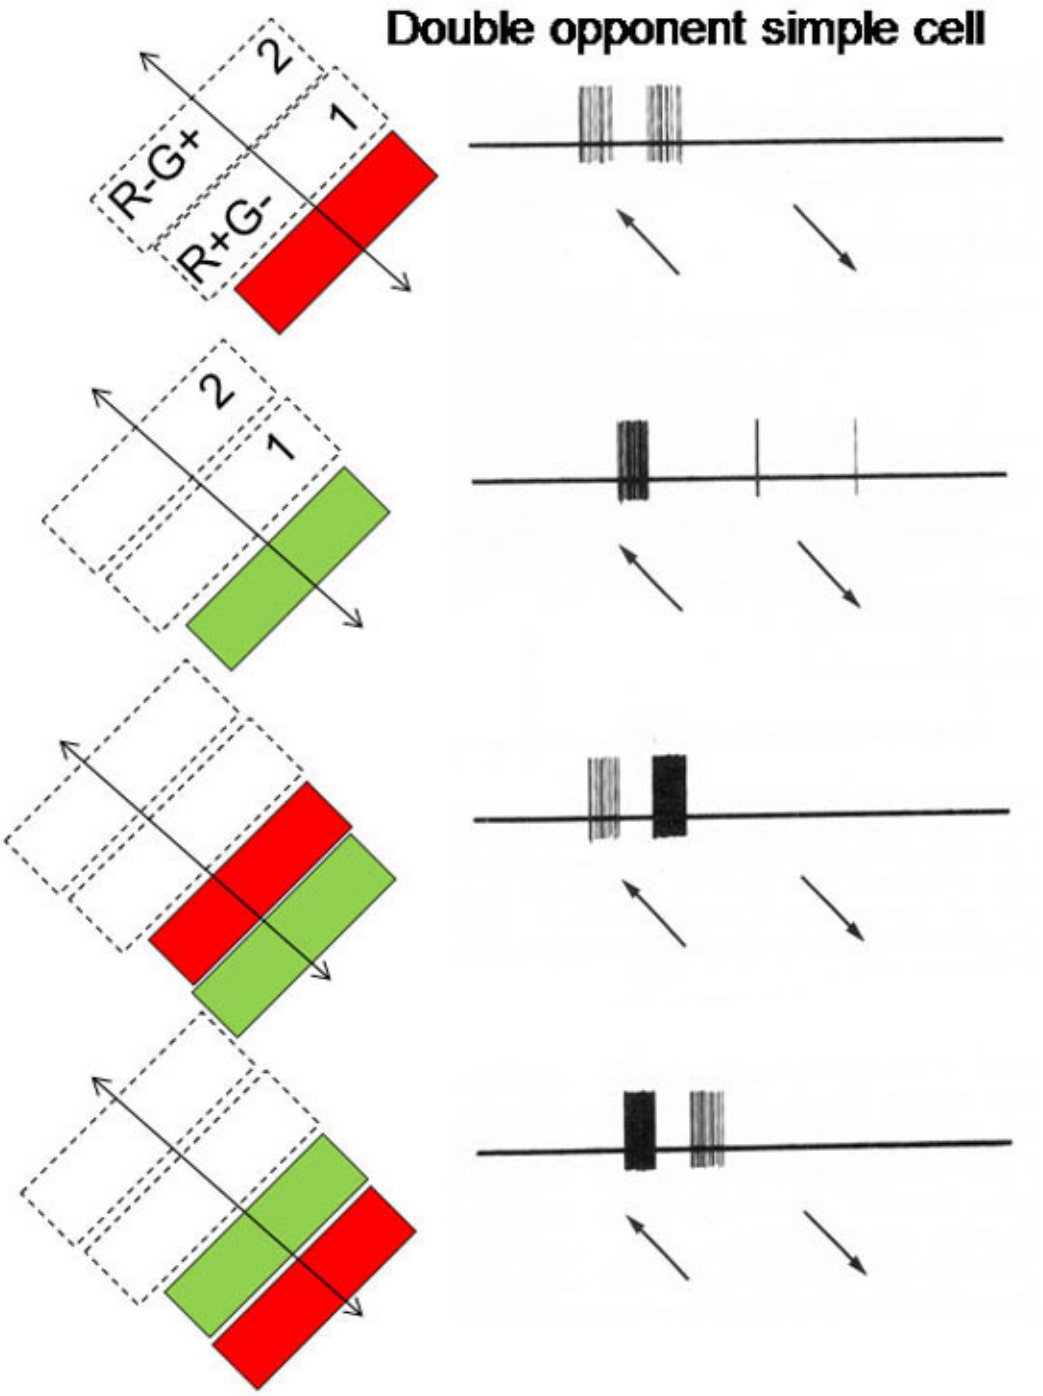

Figure 27. A simple cell responding best to strong spectral contrast.

strengthened by a blue adapting light, which selectively depresses the responses of M cones. Had this short wavelength excitatory input been due to S cones, it would have been weakened by the blue adapting light.

Hering's Theory of Color Vision

An insightful theory was proposed by Ewald Hering (37) in Prague in 1874 which was resisted by many leading scientists in the field, such as Herman von Helmholtz (38). Hering noted that the sensations of blue and yellow

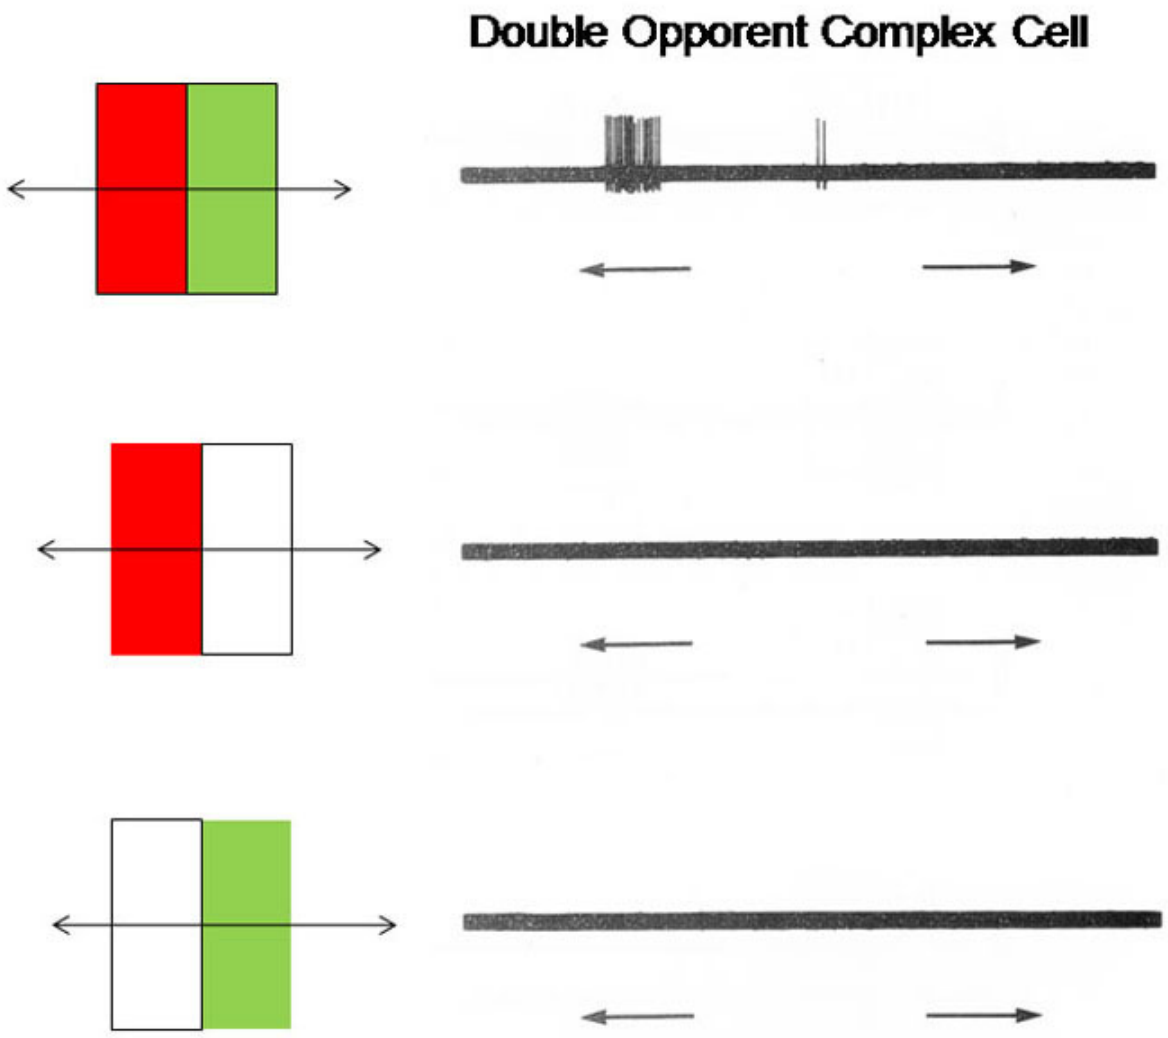

Figure 28. A complex cell responding to spectral contrast but not to energy contrasts.

opposed each other so that when seen simultaneously, the original colors were lost and a new sensation of a totally different color "white" was seen. Similarly the colors red and green exhibited a similar opposing relationship. When mixed they lose all traces of the original colors to create a new sensation "yellow". Hering suggested that there were two pairs of opponent processes underlying human color vision. This contrasted with the fact that there are only three variables underlying human color vision. This three dimensional system was suggested by Thomas Young in 1802 (39) and proven by James Clerk Maxwell in 1872 (2) and strongly promulgated by Helmholtz in 1852 (38). The Hering theory suggested that there are two pairs of basic colors that have a unique opponent relationship for each pair. He was correct in this analysis although his idea that the opponency between colors was occurring in the photoreceptors was incorrect.

At Hering's time the understanding of neuro-physiology was poor and the concepts of excitation and inhibition of neurons in unique and complex ways was unknown. The first suggestion that antagonism between colors could be due to excitation and inhibition between nerve cells, that I have found, was in a paper by the Swedish physiologist Gustaf F. Gothlin in 1944 (40). He had followed Sherington's work on the spinal cord where the idea of excitation and inhibition between nerve cells first evolved. Fig. 37 shows how prophetic Gothlin's ideas were. Here he creates an antagonistic balance between blue and yellow processes as a first stage and then hangs a scale

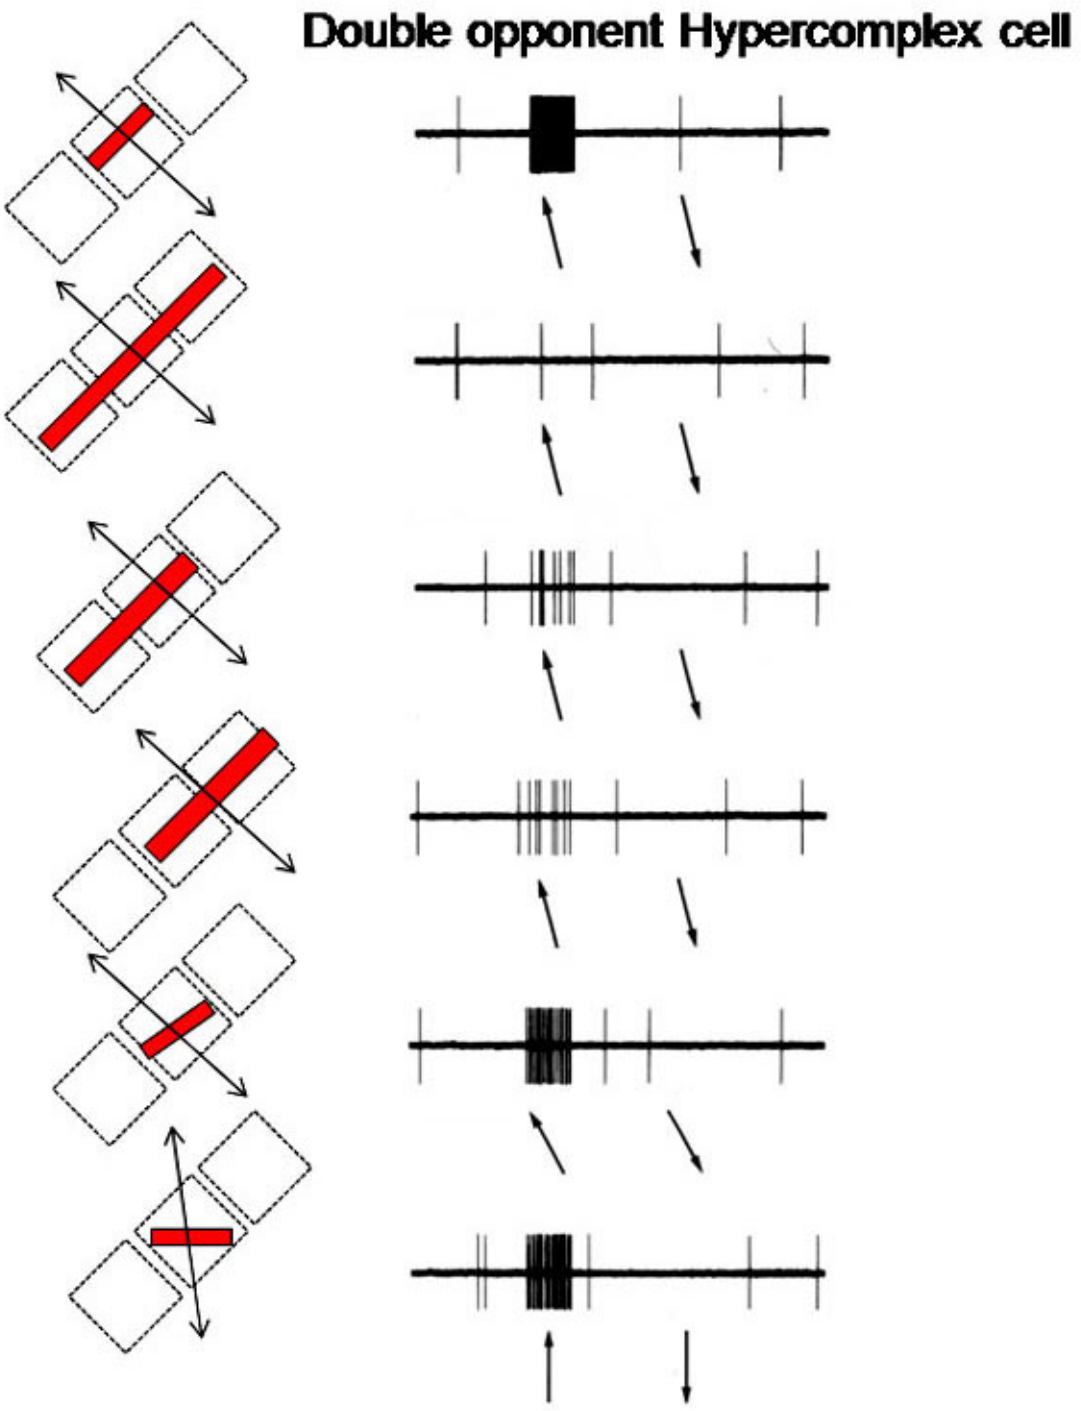

Figure 29. A double opponent orientation and directionally selective hypercomplex cell, characteristically failing to respond if the red bar is elongated.

on the yellow side of the blue/yellow balance to show an antagonistic relationship between red and green. He predicts that these antagonistic interactions were due to excitation and inhibition between neurons. It is interesting that the pioneer of exploring nerve cell responses to spectral stimuli in the retina, the Nobel Prize winner, Ragnar Granit, also a Swedish physiologist, made no reference of Gothlin's concept in any of his writings on retinal responses to color.

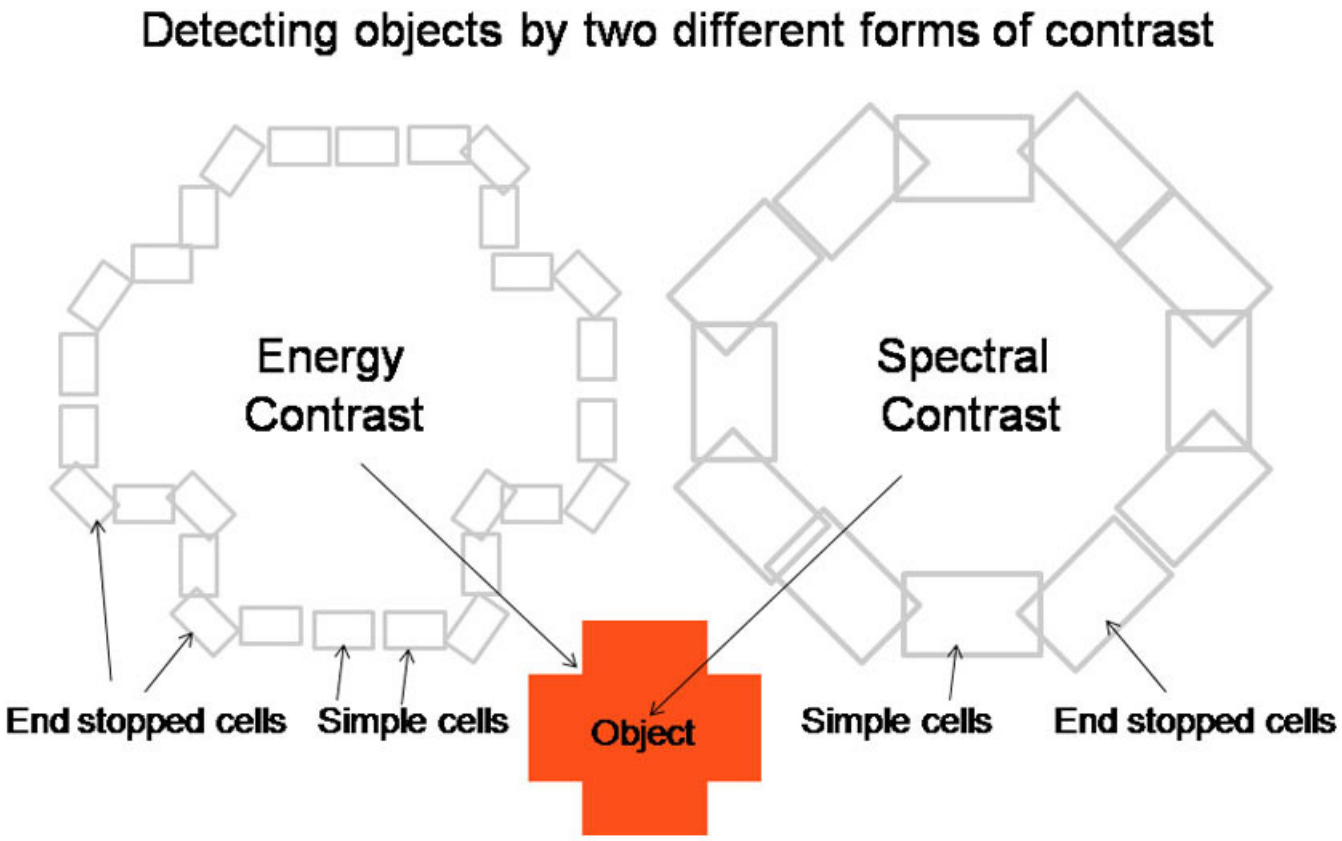

Figure 30. Two systems, one based on achromatic contrast with finer spatial resolution and a second based on spectral contrast, detect the borders of an object using simple cells and end-stopped cells with orientation selectivity (30).

Granit (41) proposed in 1947 a dominator/modular theory of color vision in which there were some retinal neurons which responded to only a narrow part of the visible spectrum, "modulators", and another group that responded to a broad band of the spectrum, "dominators". He thought the modulators were more involved in color vision but never mentioned the concept of excitation and inhibition between colors or cone mechanisms as Gothlin did. The first American studies of single visual neuron responses to monochromatic stimuli were obtained in the monkey's lateral geniculate nucleus by Russel DeValois and associates in 1958 (42). They emphasized the presence of narrow-band responding cells resembling the modulators of Granit but they also noted some cells that gave on responses to red and off responses to green light but again Hering's concept of opponent colors was not mentioned. The experiments that brought Hering's opponent color theory to the forefront were done in fish retina by another Swede, Gunter Svaetichin (1956) using glass instead of metal electrodes, enabling him to record intra-cellularly from horizontal cells. This allowed him to see both depolarizing and hyperpolarizing responses, the latter not obvious with extra-cellular recordings, where one sees only a silence or perhaps an off response from inhibition (hyperpolarizing) which could easily be overlooked. Svaetichin's results gave rise to a resurgence in Hering's opponent color theory (43, 44). This quickly led to the idea that there were three retinal channels representing Hering's color opponent channels, red opposing green, yellow opposing blue and white opposing black. This idea, however, was short lived. First of all it became apparent that the red/green opponent cells had concentrically organized receptive fields with the color opponent inputs coming from adjacent retinal regions. One would expect the color opponent signal should involve the same area of visual space and not neighboring areas. In addition the red-green opponent ganglion cells seemed to be the midget cell system which was the logical mediator of high spatial resolution. This created a dilemma in having a red/green color opponent channel carrying achromatic information for high spatial resolution. In

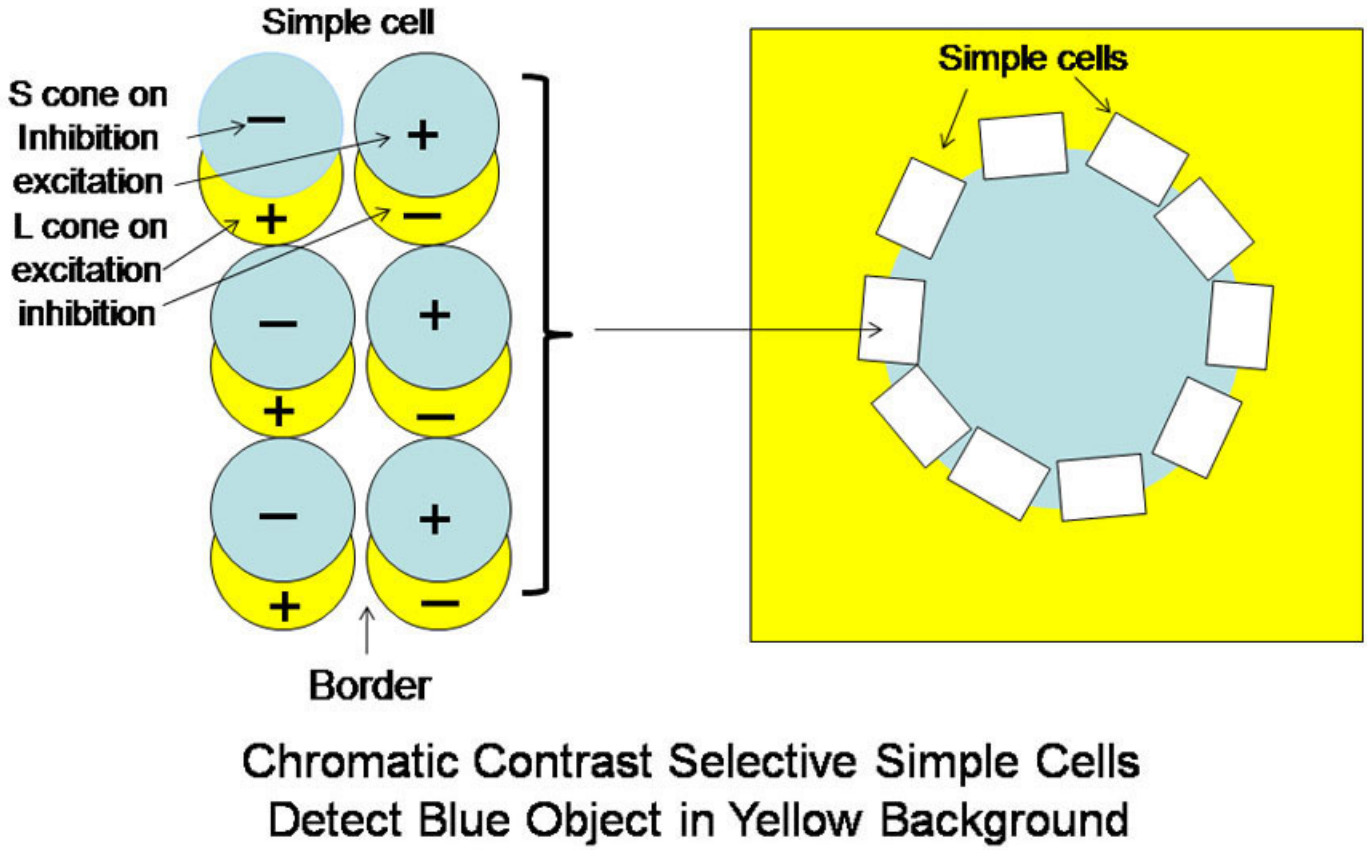

Figure 31. Double opponent simple cells with orientation selectivity detect a blue object in a yellow background. A population of such cells with slightly different orientation preferences detects a circular object.

addition the S cone channel was opposed by yellow light but not strongly enough to stop responses to white. The S cone on ganglion cells appeared to be transmitting a signal that said that the S cones were absorbing light but not that this light was "blue"; it could be white, grey as well. The so called white/black channel was receiving no input from S cones which is not what is expected for a channel signaling white. The contribution of activation of the S cone retinal ganglion cells is illustrate by the after images produced in Fig. 38.

Therefore the link between Hering's opponent color theory and retinal ganglion cell signals was scrapped. Because the neurons in the lateral geniculate nucleus responded similarly to what was found in the retina, attention went to striate cortex to explain opponent color theory by physiology. The initial ideas of channels signaling color at the retinal level were wrong; the opponent signals detectable in the retina were cone opponent and not color opponent. Color vision turned out to be more sophisticated, more arcane but more realistic.

The Future

Certainly the future will involve anatomical definition of how the projections from the lateral geniculate synapse in striate cortex and begin to define the neurocircuitry of this hexalaminar cortical structure. The dendritic input and axonal output of each functionally unique cell must be defined as has been done to a large degree in the retina. This strategy must be repeated in higher areas of visual cortex, perhaps the most intriguing phase of this crusade. New optical techniques that combine both anatomical identification and physiological responses of the same cells could expedite this enormous task. But this is the only way to understand how the most complex

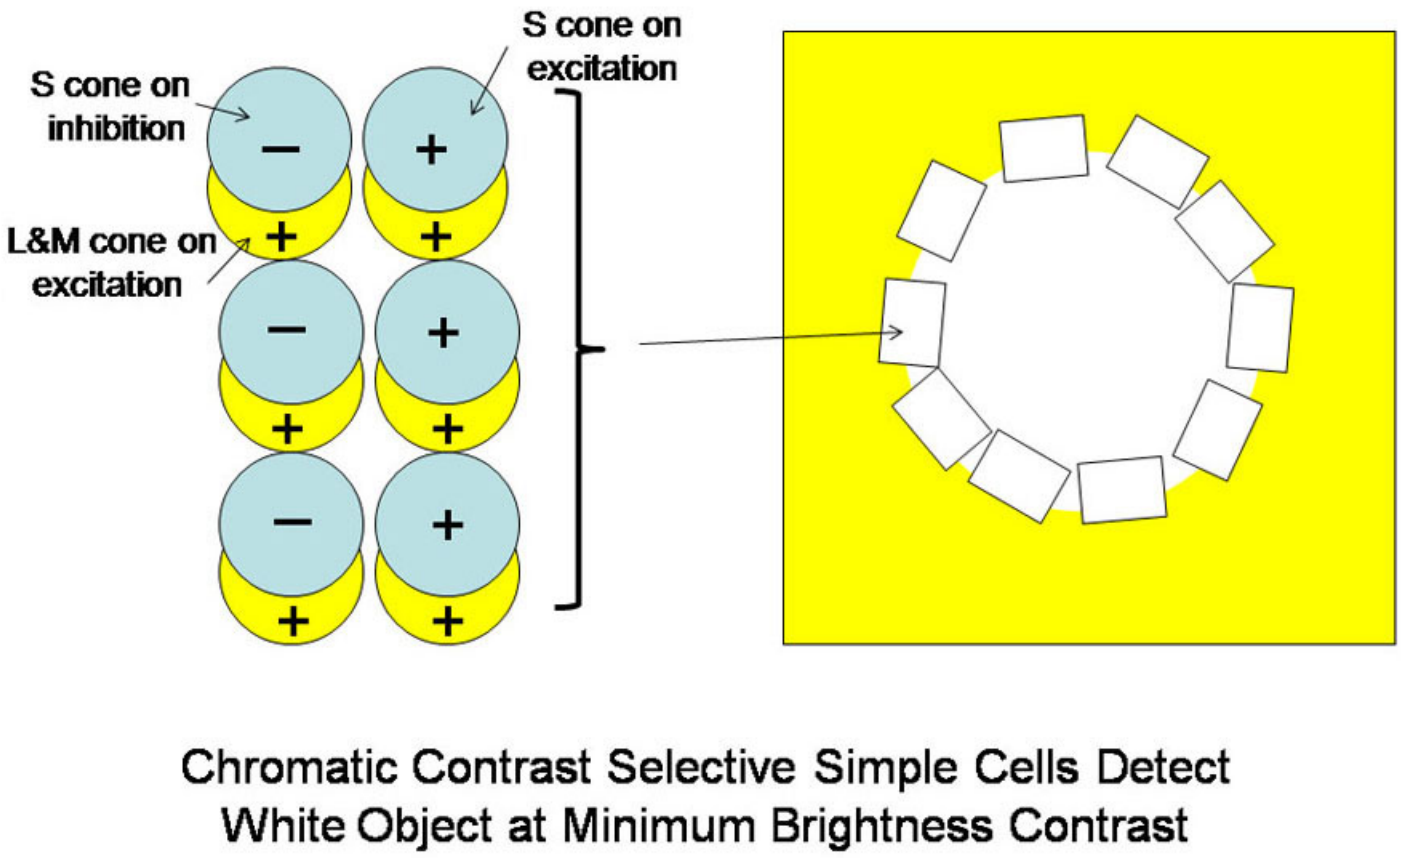

Figure 32. Spectral contrast based simple cells with orientation selectivity detect a white object in a yellow background. A population of cells with slightly different orientation preferences detects a circular object. Note the synergism of L & S cones at one edge of the simple cell.

machine in our universe, the cerebral cortex works. For this color vision is an ideal starting point because it has carried us further into this organ than any other neural process.

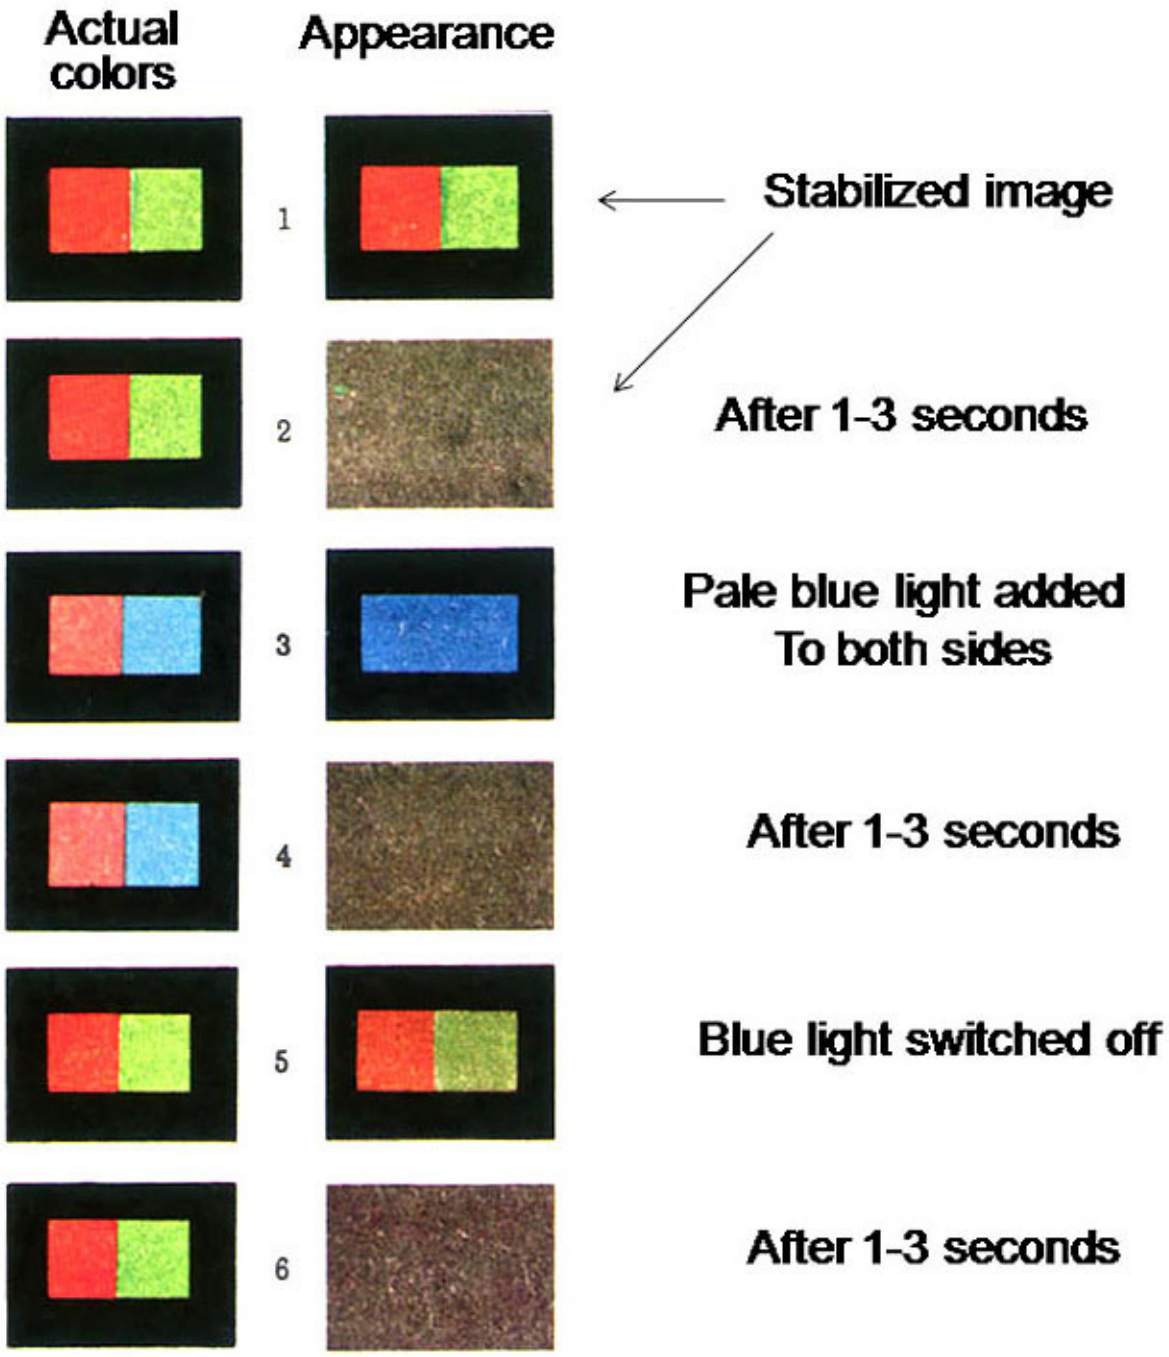

Figure 33. A stabilized retinal image of a red/green scene changes with time and its modification by additional stimulation (from Iarbus, 1967).

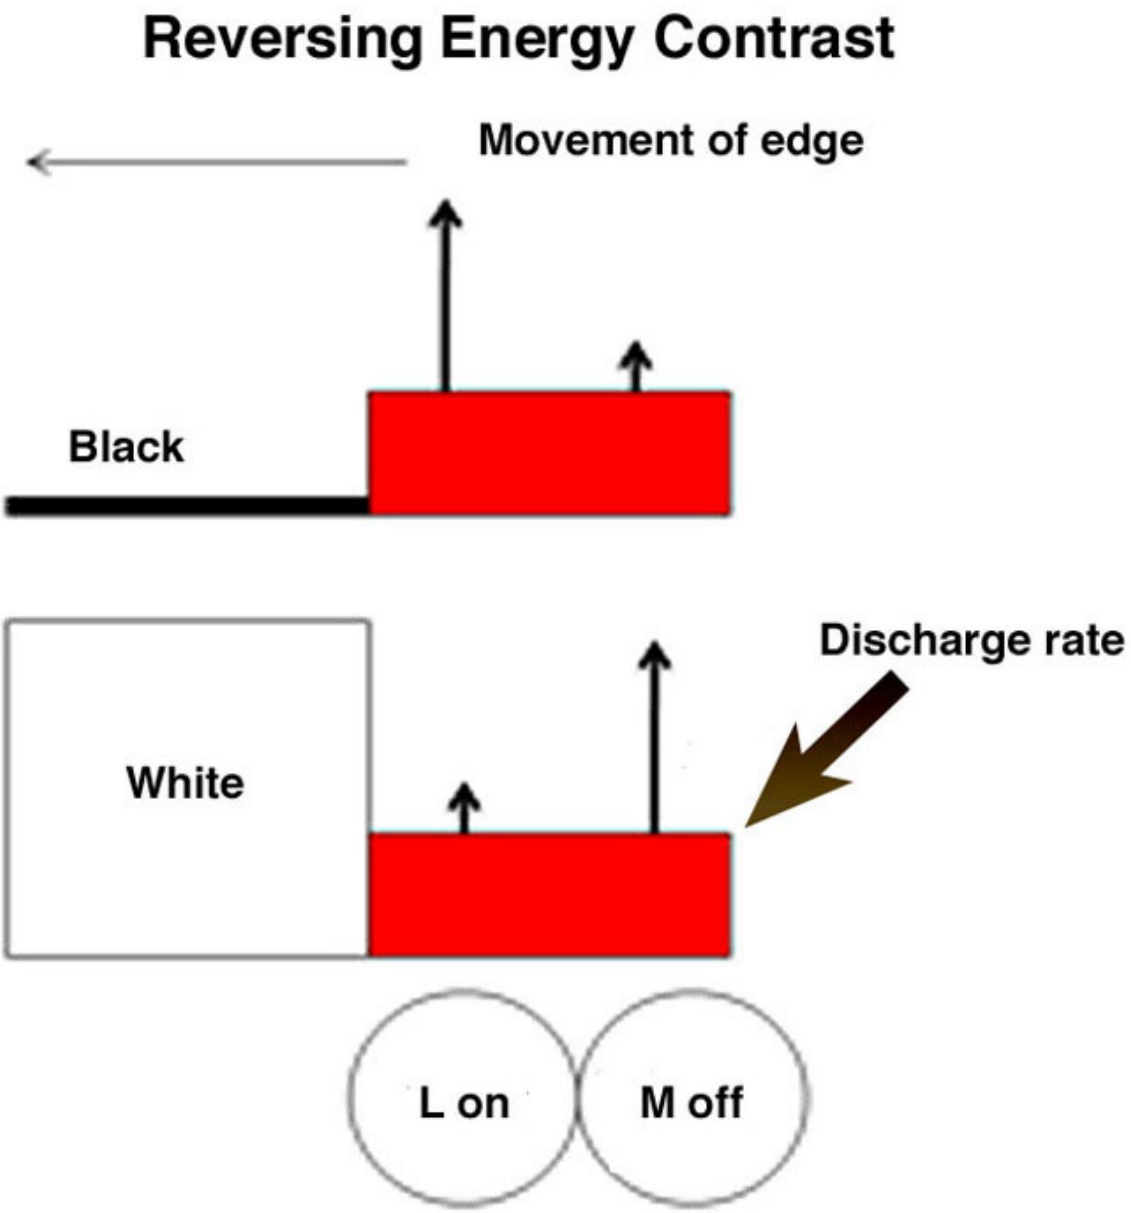

Figure 34. A moving border affects neighboring midget-like ganglion cells when there is a change in wavelength as well as a large change in energy contrast. When there is an increment in energy contrast the L on cell responds more strongly; when there is a decrement of energy contrast the M off cell responds more strongly. Both contribute to the sensation or red.

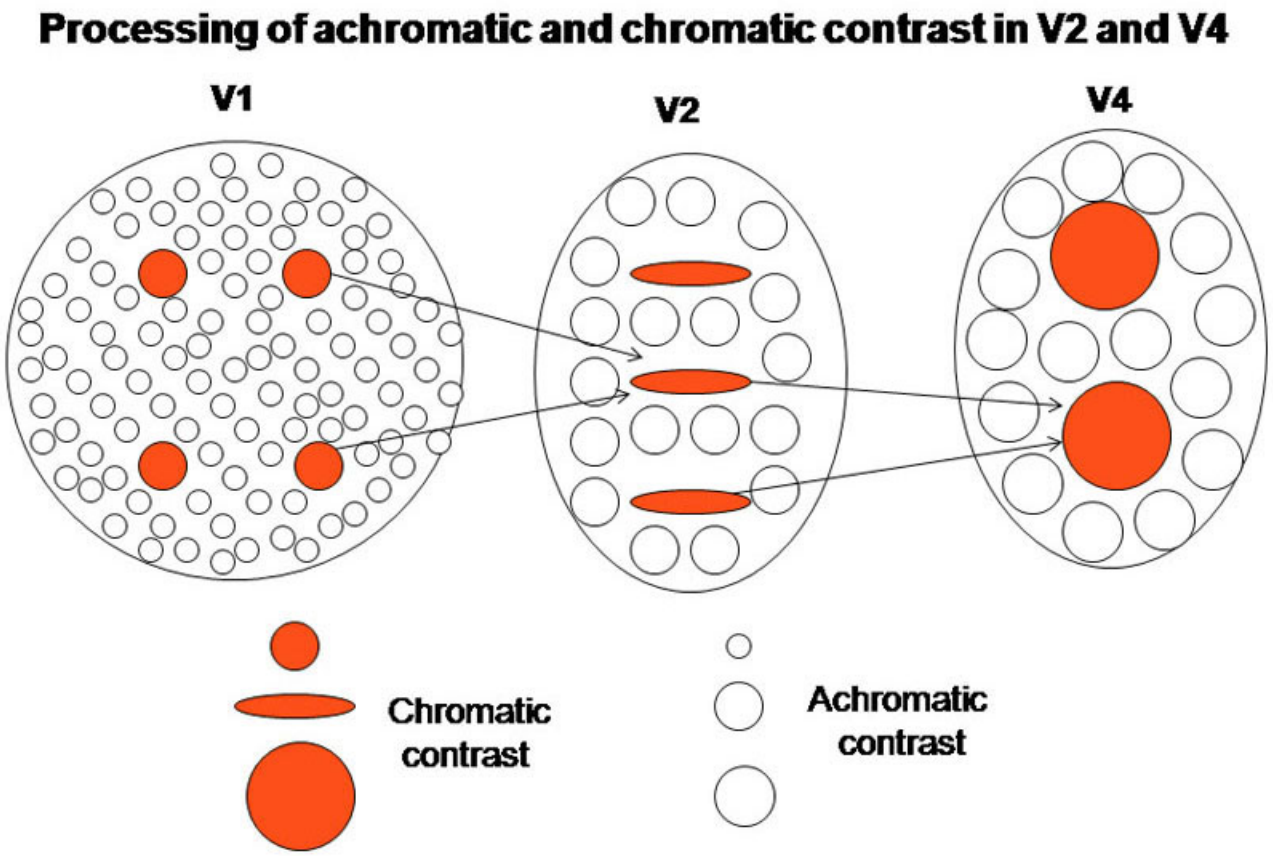

Figure 35. "Blobs" of V1 target slabs of cells in V2 which target "globs" of cells in V4 producing a hierarchy of chromatic processing embedded in areas involved in achromatic vision (33-35).

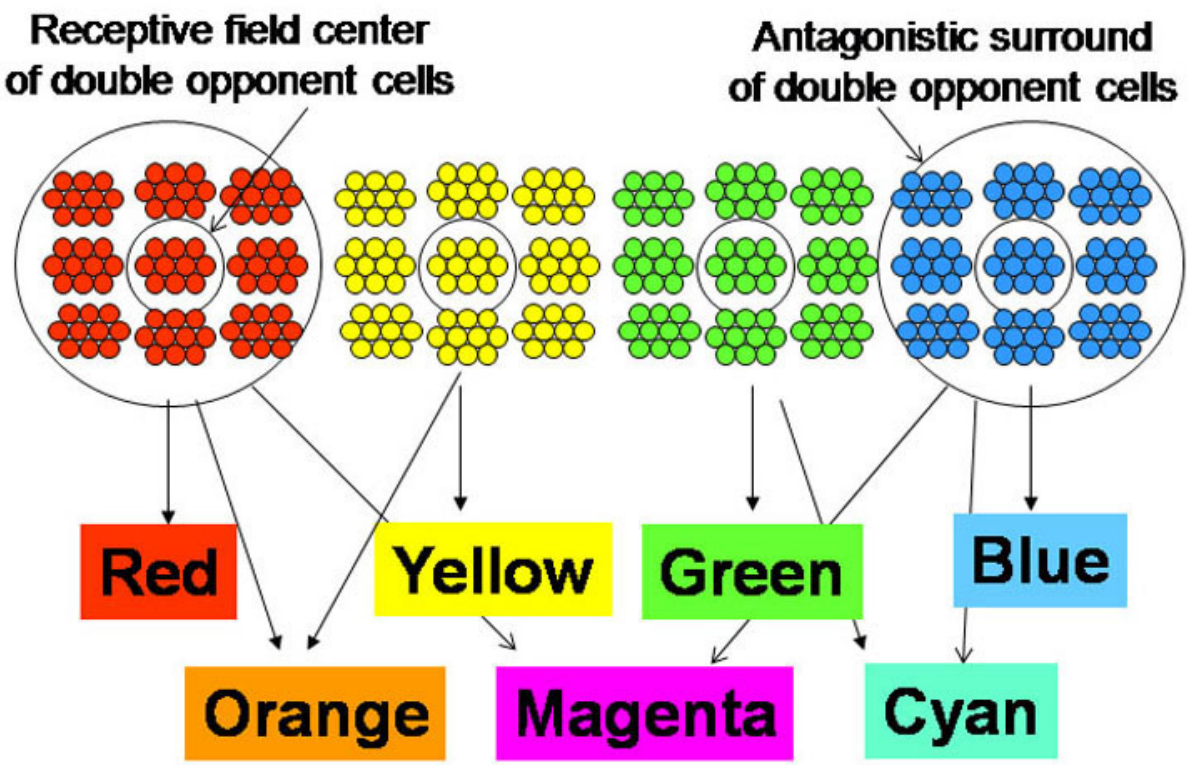

Figure 36. More basic hue responsive cells could be used to create higher order hue responsive cells.

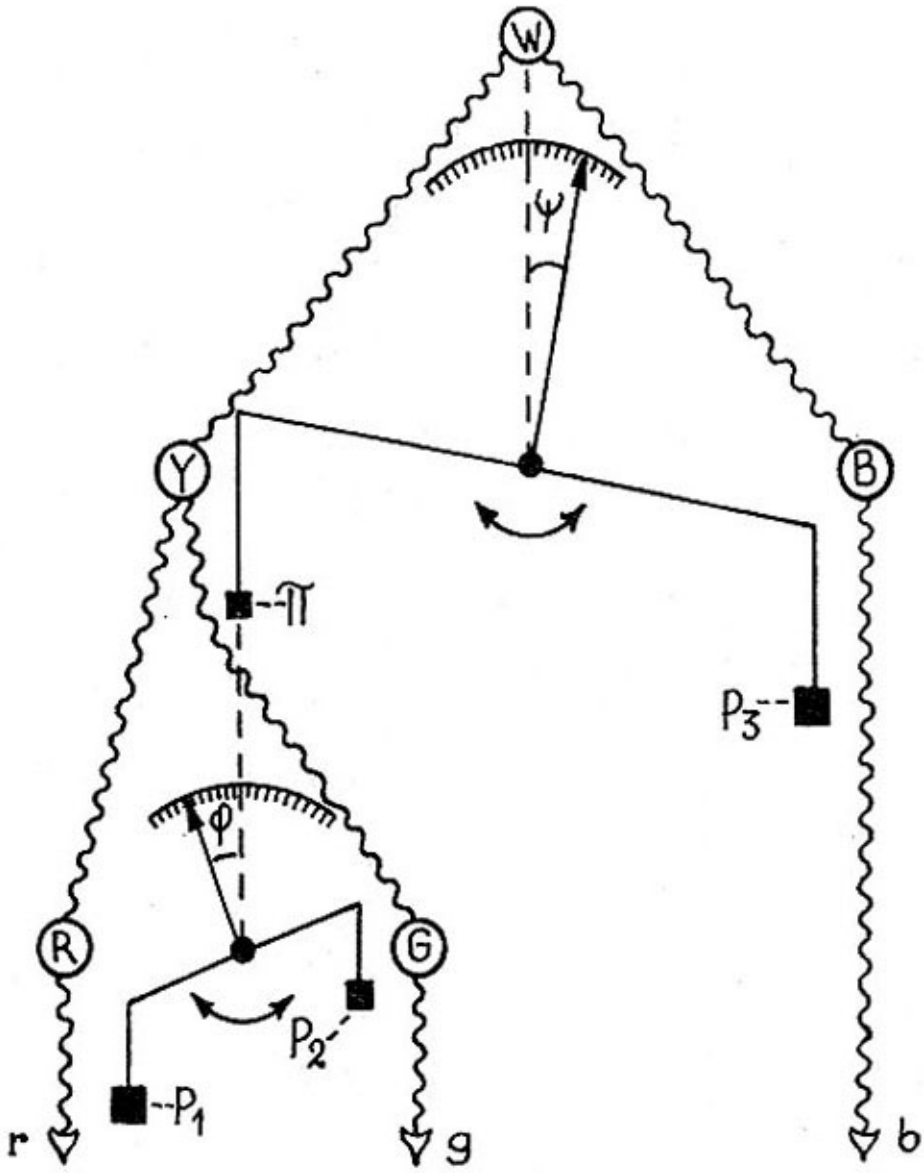

Figure 37. Gothlin's concept of a two stage representation of the three component theory of man's color vision on the assumption that the fundamental colors are red, green and blue but are organized into two antagonistic pairs. The color depicted here is an unsaturated purple.

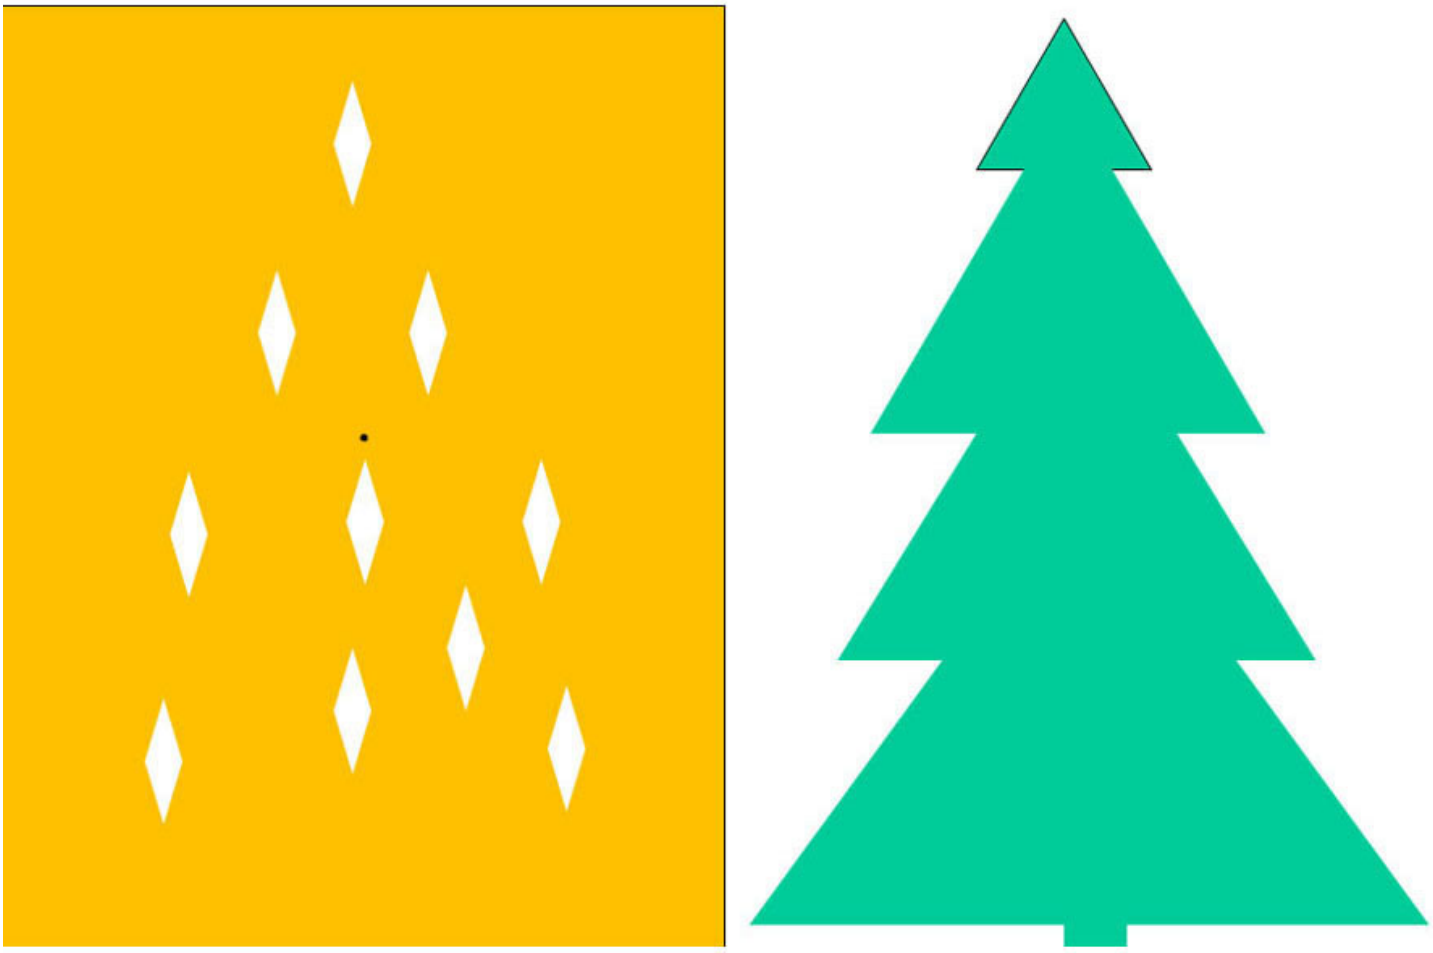

Figure 38. The after image of a white object is the opposing color to blue which is yellow. By fixating on the black spot on the left for a minute and then glancing over to the right, one sees yellow, not black, candles on the tree.

About the Author

Peter Gouras was born in Brooklyn, New York. He received an MD degree from Johns Hopkins University School of Medicine and proceeded directly into a career in eye research at the National Institutes of Health, as part of the Public Health Service, at first in the Neurological Institute and the Division of Blindness and later in the National Eye Institute. Dr. Gouras is renowned in three areas of vision research, all of which he has been a pioneer and leader. For most of his career, he has been active in the fields of basic and clinical research on the ERG. In the late 1960s, he pioneered recordings of primate ganglion cells in the fovea and did pivotal work on the analysis of color pathways from the retina through LGN to the visual cortex. On his moving to the faculty of Harkness Eye Institute at Columbia Medical School, New York City in the mid-1970s, Dr. Gouras made daring strides into the area of pigment epithelium transplantation for the treatment of retinal and macular disease. He is the author of several hundred papers and many chapters and books, particularly concerning color vision and retinal information processing.

Visual Behavior

Principles of Vision

Michael Kalloniatis and Charles Luu.[1]

Created: May 1, 2005; Updated: June 4, 2007.

Introduction

From the earliest dawn of history, man must have wondered how the outside world became apparent to him through his eyes. He must have pondered what forces cause an observing eye to see an object. Why did the world look light or dark or nature have such bright colors? Although early man could not understand the concept of the physics of light or that perception occurred in the brain, he must have understood that the eye was the organ of vision, and without eyes we were blind. Thus, the earliest concerns of the ancient civilizations of India, Babylon, China, and Egypt were certainly to attempt to restore or improve eye sight when it was failing, even without understanding much else. It was the Greek philosophers (Hippocrates, Aristotle, Plato) who provided the first known theories concerning the eye, its function, anatomy, and treatment. Originally, the Aristotelian idea was that rays of light emanated from the eyes to illuminate the world around. When it was dark, the air became murky so the rays could not penetrate, but a candle could burn off the opacity in the air, allowing sight to penetrate. Also strangely enough, the Homeric Greeks lacked a word for blue. Homer described the sea as "wine colored".

Eventually, Aristotle proposed that visual sensation passed from the eye to the **heart**, which was at that time considered the center of sensation and psychic function. The brain was thought to be a cooling device (3). This **cardiocentric** nature of sensation continued into the Middle Ages (as depicted by the sixteenth century illustration in Fig. 1), despite the direct experimental evidence of Galen (A.D. 129–200). Galen, a Greek scientist working within the Roman empire, showed that pressing on the heart in human subjects did not lead to loss of consciousness or loss of sensation, but severing the spinal cord in animals abolished sensory responses after brain stimulation.

The ideas of the Greeks from centuries B.C. were perpetuated and preserved by the writings and drawings of the Arab world until well into the Middle Ages A.D. Thus, one of the earliest diagrams of the eye was from an ancient Arab manuscript (circa A.D. 860), and this was probably a copy of an older Greek illustration now lost (Fig. 2) (4).

According to early ideas, the eye had a central crystalline lens that had a photoreceptor role. Furthermore, the belief was that the optic nerve was hollow and that a mysterious **visual spirit** existed in front of the lens (Fig. 2). Interestingly, the general theory advanced by the majority of Greek anatomists was that the retina, because of its abundant blood vessels, was an organ of nutrition rather than of sight, although one Greek, Galen, hypothesized correctly, as we now know, that the retina was a displaced part of the brain. It was not until the 12th century A.D that a Moor scientist, Averroes, living in Spain, proposed that the retina and not the lens was the visual receptor (3). And it was not until 500 years after Galen that Kepler and others expanded on this principle (4).

Our knowledge of the eye continued to show the Arab influence up until the 16th century (Fig. 3, left). Even the great anatomist and artist Leonardo da Vinci (1452–1519) based his anatomical sketches of the eye on the older incorrect Arab drawings. Leonardo was convinced that the image was formed in the eye but did not know how, and for the good reason that there was still not yet an understanding of physiological optics. In fact, it was not until the early 17th century that more correct drawings of the eye were made independently by the little known anatomists and scientists, Girolamo Fabrizzi d'Aquapendente and Christopher Scheiner (Fig. 3, right) (4). By

Author Affiliation: 1 Department of Optometry and Vision Sciences University of Melbourne, Australia.

this time, the Swiss anatomist, Platter in 1583, had proposed that the role of the lens was to collect light rays, and the retina was the photoreceptor.

Again it was the early Greek physicists (Euclid, Archimedes, and Ptolemy) that hypothesized concerning the fundamental properties of light: that light traveled in straight lines and could be reflected from polished planes and curved mirrors. It seems likely that the Greeks and then the Romans used polished glass as early magnifiers. These items were preserved in the lava covering the destroyed city of Pompeii (destroyed A.D. 79). There is little evidence for any real design of spectacles though, until about the 13th century A.D. One of the earliest depictions of spectacles to correct eyesight (Fig. 4) is shown in a man's portrait found in a church at Rothenburgh, Germany, dating from the year 1466 (4).

Johannes Kepler (1571–1630) in his "Dioptrice" established the principle of dioptrics, which is fundamental to an understanding of how the image is formed in the eye. He understood that the cornea and lens collected and refracted the light rays, and that the image was "painted" on the retina as an aggregation of many image points. Kepler was also able to explain presbyopia and myopia. Kepler was indeed the father of the science of optics (4). Subsequently, many great scientists, including Rene des Cartes (1596–1650) (Fig. 5) and Sir Isaac Newton (1642–1727) with their work put the study of optics and ocular dioptrics on a solid scientific foundation, from which stems all our modern knowledge of how the eye functions and the visual image is formed.

Perceptual studies of how we see became possible as a result of the development of mathematical formulae and other measuring techniques proposed in the early 17th century. They include Newton's great discovery of the spectrum, which is the foundation for the study of color vision (3). The discipline, known as psychophysics—psycho = perception and physics = physical nature of the stimulus—is an essential discipline for probing perception. In the chapter that follows, we outline common psychophysical procedures and methods in use today, likely to be encountered in vision science, optometry, and ophthalmology.

Measurement of Light

Light can be measured and specified in two units: radiometric units and photometric units. We consider "light" to be a form of visible electromagnetic radiation. It is part of the electromagnetic spectrum between the wavelengths of 380 nm (blue light) and 750 nm (red light) (Fig. 6). Electromagnetic radiation is emitted from a source in small packets of energy called quanta or photons.

In a vacuum, a photon travels at a velocity of 3×10^8m/second. The velocity, frequency (cycles/vibrations per second of the photon), and the wavelength is related by Eq. 1:

$$\text{Equation 1: } c = \nu\lambda$$

where c is the velocity of light in a vacuum (e.g., m/s), ν is the frequency in Hertz (e.g., cycles per second), and λ is the wavelength (e.g., in meters) (see Fig. 7 for this relationship). It is important to note that the frequency is inversely proportional to the wavelength as the velocity of light is fixed.

The velocity of light in a vacuum (c) is higher than in any other medium (V_m). Therefore, the refractive index in any given medium (n_m), is defined as the ratio of the two velocities. Furthermore, for any given frequency, the wavelength in a vacuum, (λ_c) and the wavelength in a medium (λ_m), gives the refractive index (Eq. 2):

$$\text{Equation 2: } n_m = c/V_m = \lambda_c/\lambda_m$$

Energy and frequency of the photon can be related using Einstein's equation (Eq. 3):

$$\text{Equation 3: } E = h\nu$$

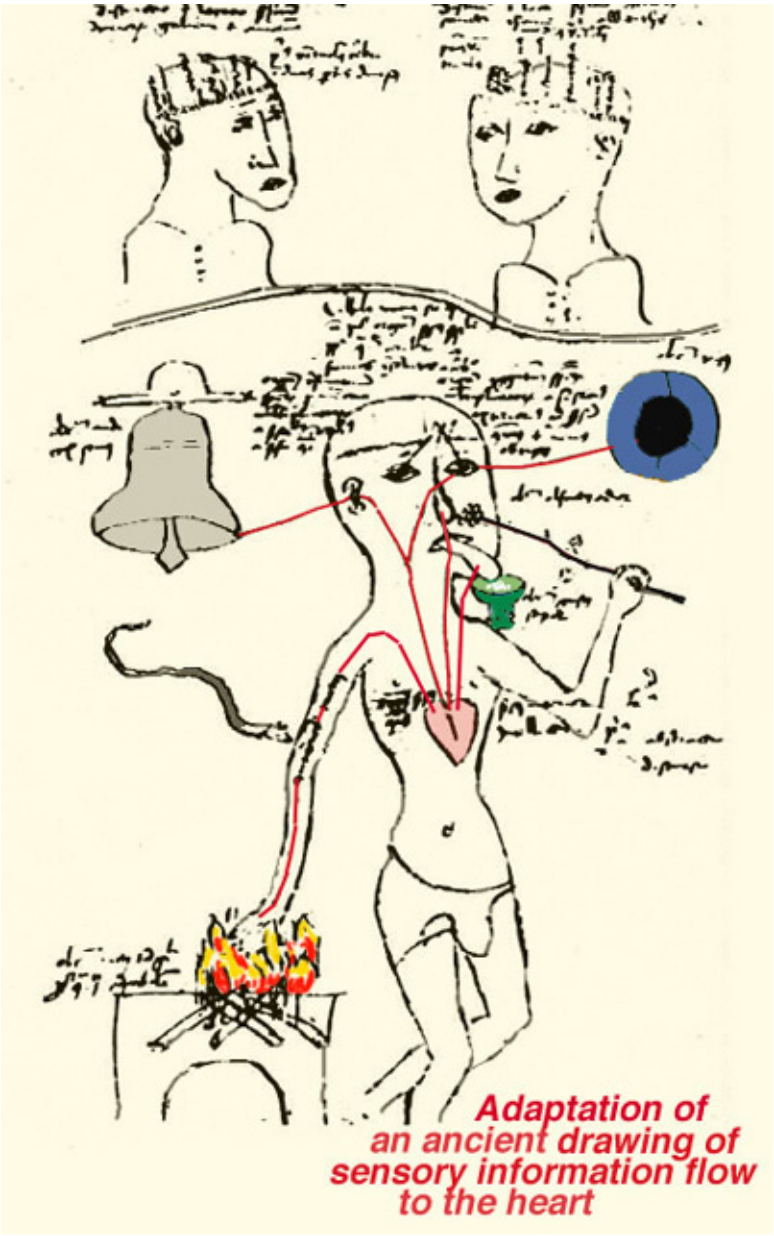

Figure 1. Aristotelian concept of five senses projecting to the heart, either directly or via the "sensus communis" in the anterior part of the head (lower panel). The upper panel shows the four (Galen's and Avicennas's) or five (Albertus Magnus's) brain compartments. From Jung (3).

where E is the energy in Joules, h is Planck's constant ($6.624 \times 10{-}^{34}$ joule · sec) and ν is the frequency in Hertz (cycles per second of the photon). The unit for energy is joules (J).

As frequency is inversely proportional to its wavelength (Eq. 4):

$$\text{Equation 4: } \nu = c/\lambda$$

where λ is the wavelength in meters and ν is the frequency in Hertz (cycles per second of the photon).

The above two equations can be combined to give (Eq. 5):

$$\text{Equation 5: } E = hc/\lambda$$

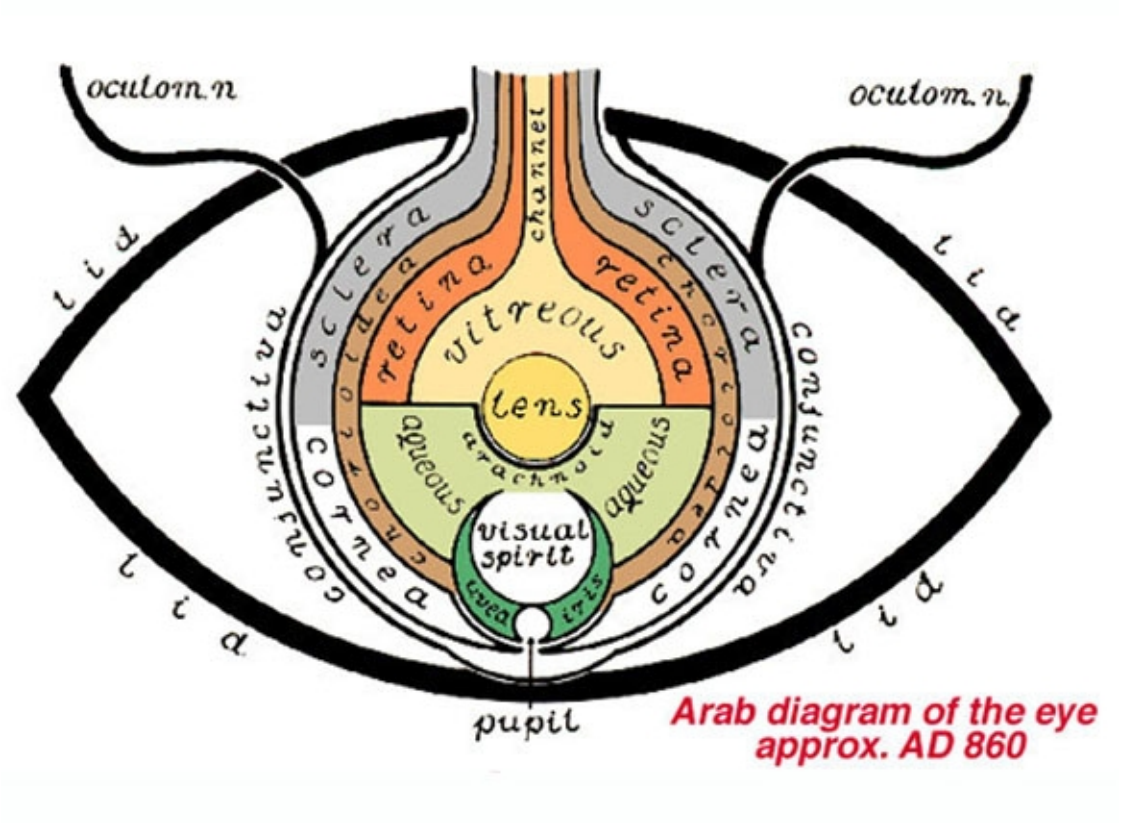

Figure 2. The earliest Arabic drawing of the structure of the eye. From Polyak (4).

Or (Eq. 6):

Equation 6: $E = hV_m/\lambda_m$

This fundamental equation is important in relating energy and wavelength of light. Because energy and wavelength are inversely proportional, this implies that short wavelength photons have higher energy. Furthermore, it is important to bear in mind that it is only photon energy and frequency that are conserved when light passes from one medium to another.

Another important term is power. Power is defined as the rate of work done, that is, the amount of work or energy output over a given time. The watt (W) is the SI unit for power. One watt is equivalent to one joule per second.

Radiometry

There are two parallel sets of units for measuring light. One is based on the psychophysical impact of the light on a human observer, the other on detection by physical radiometric devices. The two units are interconvertible, but sometimes only with difficulty. Measurement of light energy from a source can be specified in radiometric units. Radiometric units specify the amount of radiant energy present in light (see Table 1 for radiometric concepts and SI units).

All light measurement is derived from radiant flux. Subsequently, radiometric units are defined with respect to direction and surface, and all photometric units are derived from radiometric units using the photopic luminous efficiency functions or the scotopic luminous efficiency function.

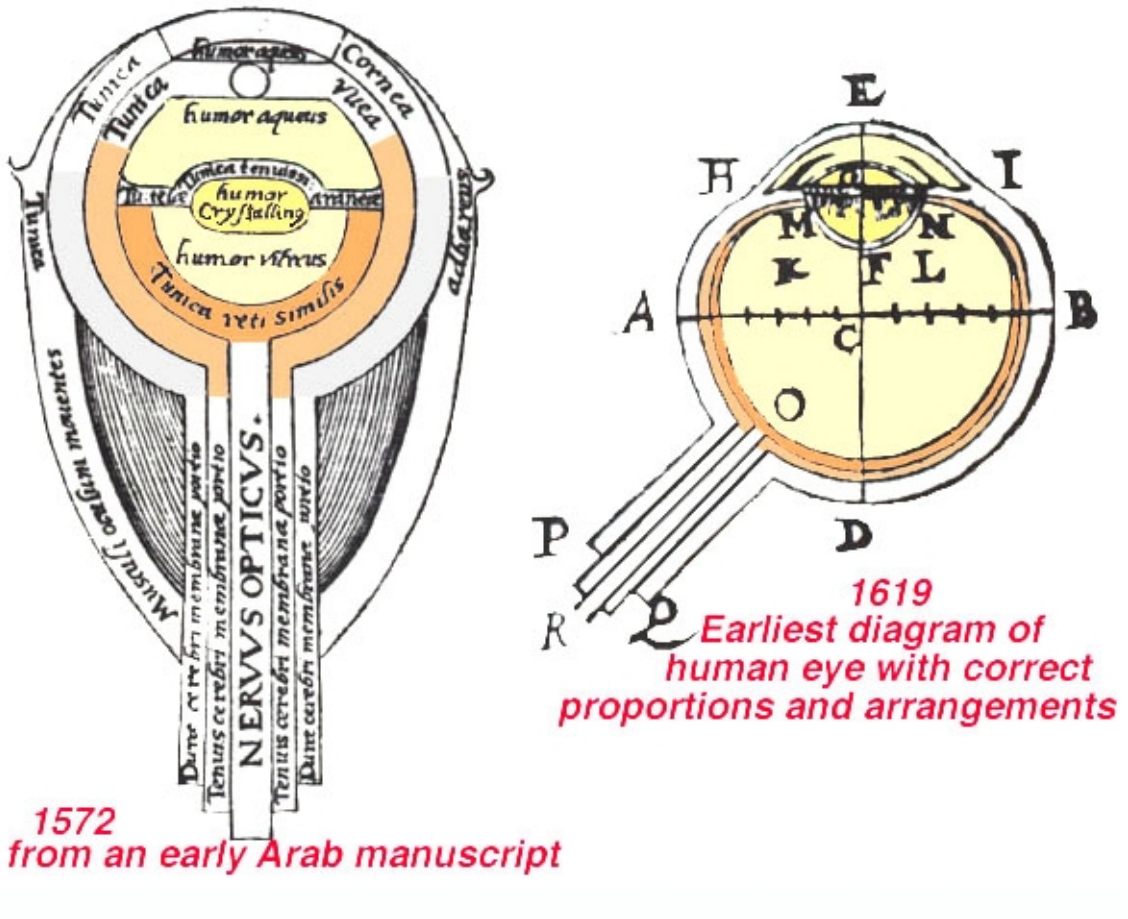

Figure 3. Drawings of the structure of the eye from the 16th and 17th centuries. From Polyak (4).

There are two main ways in which energy produces photons: incandescence and luminescence. These correspond to thermal and non-thermal mechanisms, respectively. With incandescence, photons are released from thermally agitated electrons. The frequency of photons from this type of radiation is relatively wide and continuous, regardless of the substance, with a spectrum dependent only on temperature. Luminescence involves electron excitation in an atom, molecule, or crystal. Emission of photons results from the energy given up by the electron as it moves from one excitation shell to another. The frequency of the photon emission has a pattern characteristic of the substance.

Luminescent production of photons can be achieved in a gas discharge tube. These tubes contain gas vapor such as sodium, mercury, or neon. Electrons are accelerated from one electrode to the other in these tubes. These high-velocity electrons bombard the gas atoms and cause a displacement of electrons. When the electrons return to the normal state, this excitation energy is emitted as photons. Neon and mercury sources are often used in optics.

Fluorescence is another example of luminescence. In fluorescent tubes, electrons collide with atoms of mercury, resulting in a quanta of ultraviolet light being emitted. Part of the energy of the ultraviolet quanta is absorbed by the phosphor coating of the tube and subsequently releases a quanta of light in the visible spectrum.

A tungsten filament lamp is an example of incandescence. Tungsten spectral emission resembles that of a black body. A black body is a theoretically perfect radiator. As the energy is increased, the spectral emission changes. Color temperature is a term used when the color of the radiator is the same color as the black body at a certain

Figure 4. An early painting of a man wearing spectacles. Portrait dated 1466. From Polyak (4).

temperature (measured in Kelvin). For example, a black body with a temperature of 2700 K would have a similar color to tungsten; therefore, tungsten is said to have a color temperature of 2700 K.

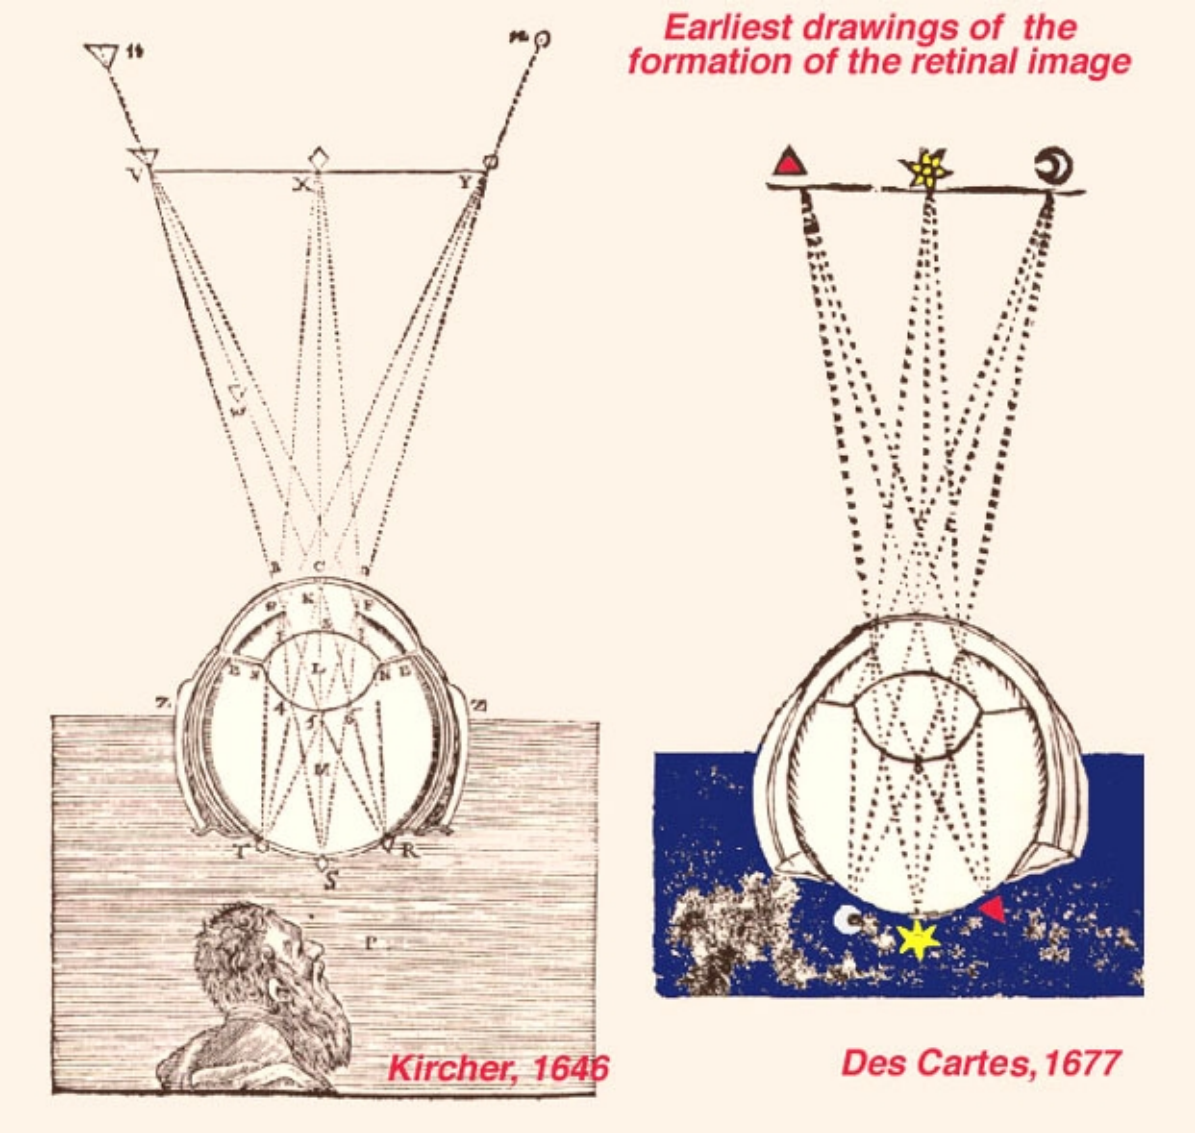

Figure 5. Diagrams showing the formation of the retinal image from Kirscher (1646) (left) and Des Cartes (1677) (right). From Polyak (4).

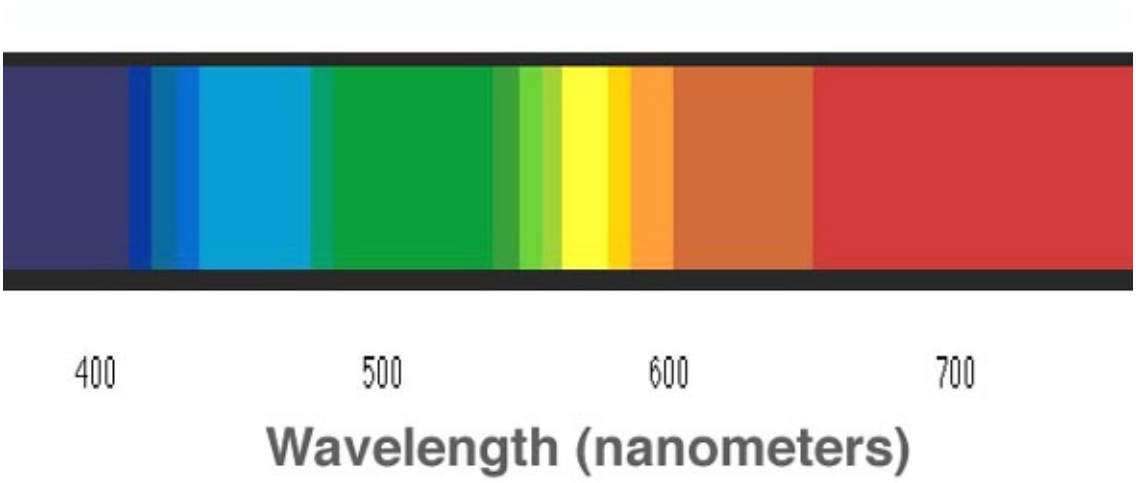

Figure 6. Visible spectrum of electromagnetic radiation.

Table 1. **Radiometric concepts and units.**

Term	Symbol	Defining Equation	Applications	SI Unit
Radiant Flux	F_e	$F_e = \frac{\delta Q}{\delta t}$	Specification of the total quantity of light emitted from a source.	watt = joule/sec (W)
Radiant Intensity	I_e	$I_e = \frac{\delta F_e}{\delta \omega}$	Specification of the total quantity of light emitted by a point source, in a given solid angle.	watt/ω
Irradiance e	E_e	$E_e = \frac{\delta F_e}{\delta A_r}$	Specification of density of light incident on a surface or in a given plane.	watt/m^2
Radiance e	L_e	$L_e = \frac{\delta I_e}{\delta A_s \cos\theta}$	Specification of the amount of light emitted or reflected from an extended source in a given direction.	watt/ω/m^2

δQ is the total energy emitted by a source (in watts)
δt is the time (in sec)
$\delta \omega$ is the solid angle (in steradian) of the source
A_r is the surface area of the receiving element
A_s is the surface area of the source (in m^2)
θ is the angle between the given direction and normal to the emitting surface

Photometry

Photometry is the measurement and specification of light relating to its effect on vision. The eye can be regarded as a radiant energy detector with a selective spectral response. In a well-lit environment, it is maximally sensitive to light of about 555 nm (yellow-green light) and relatively insensitive to far-red and -blue light. The function describing the response of the human eye to different wavelengths is known as the relative luminous efficiency function.

Measurement of light from a source can be specified in photometric units. Photometric units take into account both the quantity of radiant energy and sensitivity of the eye to the wavelength(s) of the radiation. In other words, the photometric quantities specify the capacity of radiant energy to evoke a visual response (see Table 2 for photometric concept and SI units).

All light measurement is derived from radiant flux, converted to luminous flux. As with radiometric units, subsequent photometric units are also defined with respect to direction and surface (Fig. 8).

A patient's visual fields are commonly examined in clinical practice. The luminance of the background (bowl) of the visual field analyser are as follows: 1) Humphrey automated visual field analyser, 10 cd/m^2; 2) Goldmann visual field analyser, 4 cd/m^2; and 3) the Medmont automated visual field analyser, 4 cd/m^2. From these values, retinal illuminance can be calculated. Also, from Table 3, we can see that the luminance of the visual field analysis places the patient just above mesopic light levels.

V(λ) *versus* V'(λ) is the relative luminous efficiency function used to describe the response of the human eye to different wavelengths. The values used are those defined by the International Commission of Illumination (CIE) for a standard observer, as adopted in 1924 (for photopic vision) and 1951 (for scotopic vision). Thus, the photometric quantity of luminous flux is given by the equations below (Eq. 7 for photopic conditions and Eq. 8 for scotopic conditions, respectively):

$$\text{Equation 7: } F = K_m \int F_e(\lambda) V(\lambda)\, d\lambda$$

and

$$\text{Equation 8: } F_s = K'_m \int F_e(\lambda) V'(\lambda)\, d\lambda$$

where $F_e(\lambda)$ is the corresponding radiometric quantity (in this case, radiant flux) and $V(\lambda)$ is a luminous efficiency constant (which equals 683 lm/W for photopic conditions and 1700 lm/W for scotopic conditions), and K_m is a luminous efficiency constant. Eq. 8 outlines scotopic flux (F_s) in scotopic lumens from which other scotopic units, such as scotopic troland, can be obtained. Convention dictates that unless otherwise stated, all units are photopic quantities.

A candela is the unit for luminous intensity. In a given direction, it is defined as a source that emits monochromatic radiant energy of frequency 540×10^{12} Hertz and whose radiant intensity is 1/683 watts per steradian in that direction.

A lumen (unit of luminous flux) is the luminous flux emitted within a unit solid angle (one steradian), by a point source having a uniform luminous intensity of 1 candela. Therefore, a lumen can be defined as the luminous flux of monochromatic radiant energy whose radiant flux is 1/683 watt and whose frequency is 540×10^{12} Hertz (converts to 555 nm in air). The definition for a candle at 555 nm is identical for scotopic and photopic system. Consequently, the peak of the two functions will be different, as shown in Fig. 9. The amount of light required to stimulate the eye under scotopic conditions is much less than under potpie condition (Fig. 9). The difference in absolute sensitivity is reflected by the different constants, K_m and K'_m values for the photopic and scotopic luminous efficacy, respectively.

Fig. 10 shows normalised data, where the maximum value is set at 1 for comparison. Therefore, the curves peak at the same level. To set the maximum at unity, the constants K_m and K'_m, which correspond to the peaks of the photopic and scotopic luminous efficacy curve, respectively, are used. These constants are used to relate back to the actual photopic luminous efficacy, $K(\lambda)$, and actual scotopic luminous efficacy, $K'(\lambda)$. The relationship between $K(\lambda)$, $V(\lambda)$, and K_m are given as this equation (unnumbered):

$$K(\lambda) = K_m V(\lambda) \text{ and } K'(\lambda) = K'_m V'(\lambda)$$

The visual system is sensitive over a wide range of luminance. Table 3 illustrates this range. The top row shows luminances that extend from the minimum required for detection to levels at which damage to the visual system is possible. The second row relates the luminance to familiar viewing conditions by indicating the luminance of

white paper under illumination from starlight to sunlight. Finally, the bottom row links the physical stimulus to a variety of visual functions. When patients are asked to read the chart to measure their visual acuity as in Fig. 3, their visual system is functioning in the low photopic range.

SI (International Standard) units should always be used when reporting photometric quantities (Table 4). See the Units and Conversion Tables (Table 4) for conversion factors for some common (and not so common) non-SI units. To convert to SI units, multiply the non-SI unit by the conversion factor. The best source of light measurement units is from the Light Measurements Handbook.

A convenient measure of retinal illuminance is based on the unit of the troland. One troland (Td) of retinal illuminance is produced by an extended source of 1 cd/m^2 seen through a pupil of 1 mm^2. Thus, retinal illuminance *E* in trolands is given by Eq. 9:

$$\text{Equation 9: } E = LA$$

where *L* is the luminance in $cd/m^2$and *A* is pupil area in mm^2. Thus, the unit for troland is $cd/m^2.mm^2$. If scotopic units are used, luminance is defined as scotopic cd/m^2, and the troland is called a scotopic troland.

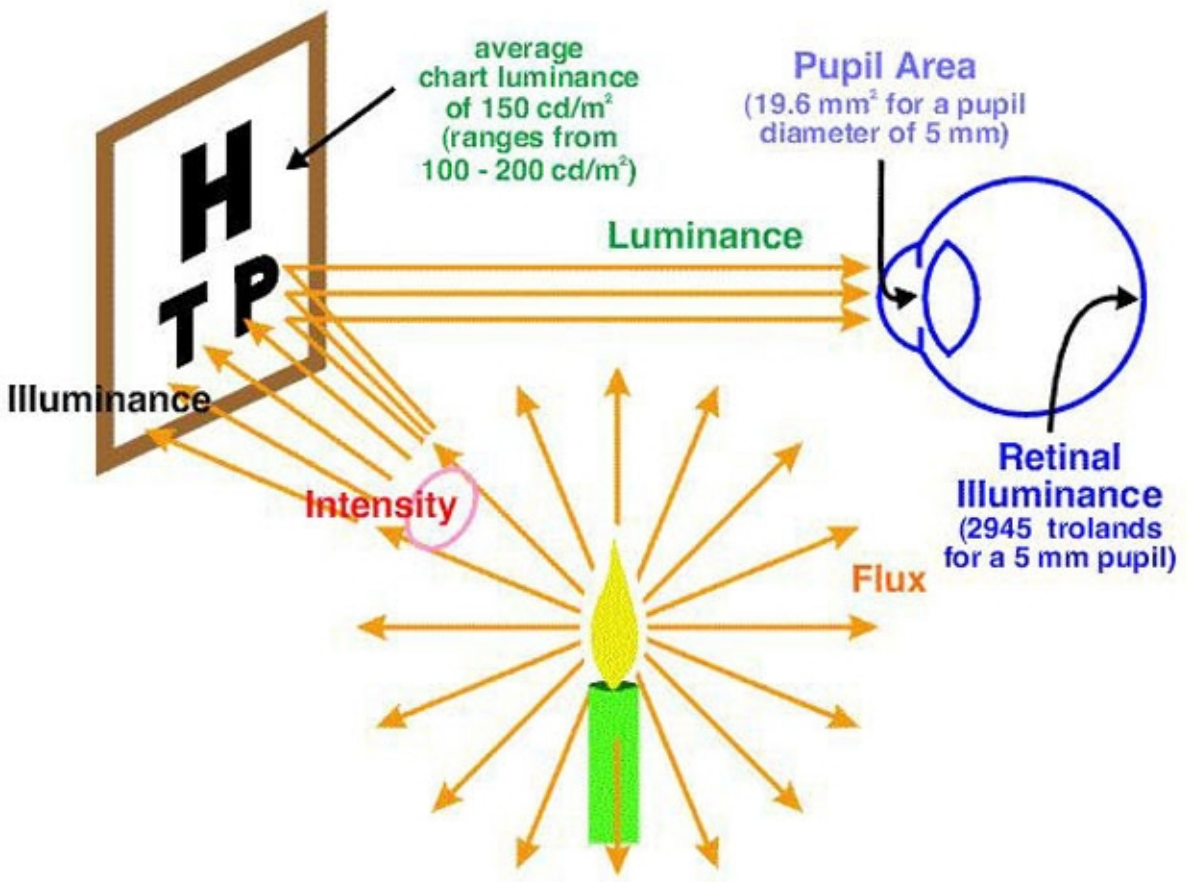

Figure 8. Photometric quantities illustrating flux, intensity, illuminance, and luminance. Retinal illuminance of 2945 trolands is achieved through a pupil diameter of 5 mm and a chart luminance of 150 cd/m^2.

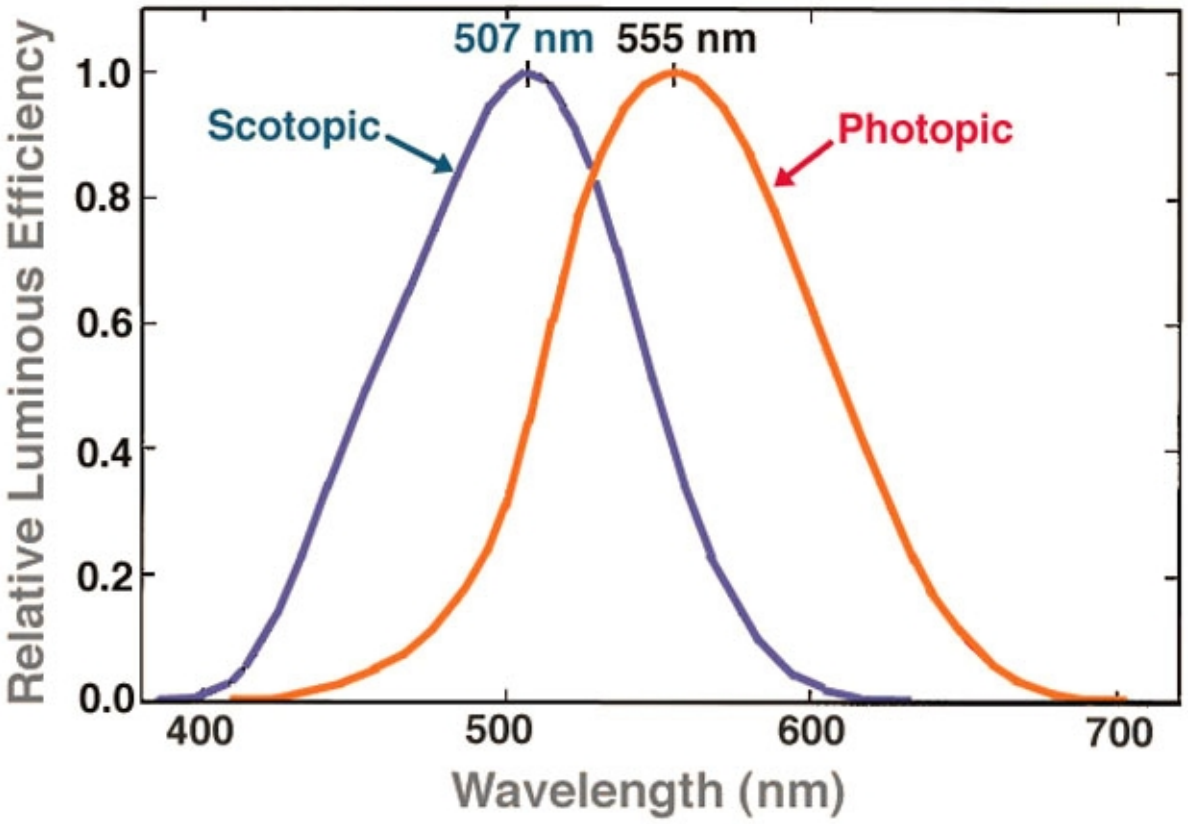

Figure 10. The scotopic and the photopic curves of relative spectral luminous efficiency as specified by the CIE (normalized values).

Table 2. **Photometric concepts and units.**

Term	Symbol	Defining Equation	Applications	SI Unit
Luminous Flux	F	$F = K_m \int F_e(\lambda) V(\lambda) d\lambda$	Specification of the total quantity of light emitted from a source.	lumen (lm)
Luminous Intensity	I	$I = \frac{\delta F}{\delta \Omega}$	Specification of the total quantity of light emitted by a point source, in a given solid angle.	candela (cd) (lumens/ω)
Illuminance	E	$E = \frac{\delta F}{\delta A_r}$	Specification of density of light incident on a surface or in a given plane.	lumens/m^2 (lux)
Luminance	L	$L = \frac{\delta I}{\delta A_s \cos\theta}$	Specification of the amount of light emitted or reflected from an extended source in a given direction.	cd/m^2 nit (nt)

K_m is the maximum spectral luminous efficacy
$F_e(\lambda)$ is the radial flux at specific wavelength
$\delta\Omega$ is the solid angle (in steradian) of the source
A_r is the surface area of the receiving element
A_s is the surface area of the source (in m^2)
θ is the angle between the given direction and the normal to the emitting surface

Inverse Square Law

The illuminance (E) of a surface due to a point source of light is proportional to the luminous intensity (I) of the source in the direction of that surface and inversely proportional to the square of the distance (d) between the surface and the source. The angle θ is the angle of incidence (Eq. 10):

$$\text{Equation 10: } E = I/d^2 . \cos\theta$$

Remember, the rule of thumb for all laws dealing with light measurement is that radiation is derived from a point source. For practical purposes, a source is considered to be a point source when the distance from the source is greater that five times its diameter.

Luminance and Illuminance Calculations

When light falls on a surface, the luminance from this surface is proportional to its reflectance and the angle of incidence (Eq. 11):

$$\text{Equation 11: } L = Er/\pi \cdot \cos\theta$$

where L is luminance of the surface (cd/m^2), E is the illuminance (lux), r is the reflectance, and θ is the angle of incidence of the luminous flux.

Filters

Neutral density filters are used to decrease the transmittance. Transmittance is calculated using the following formula (Eq. 12):

$$\text{Equation 12: } T = L/L_o$$

where L is luminance of the source with no filter in place and L_o is the luminance of the source with the filter. The optical density of the filters is given by Eq. 13:

$$\text{Equation 13: } D = -\log_{10} T$$

where T is the transmittance.

According to Beer's law, the optical density of a solution is given by Eq. 14:

$$\text{Equation 14: } D = a\ e\ l$$

where a is the concentration of the solution in gram-molecules per liter, e is the molar extinction coefficient, and l is the path length in cm. Eq. 13 and Eq. 14 can be equated to relate Beer's law to transmittance.

In visual field measures, the attenuation of light from the maximum available is expressed in decibel (dB) values. For example, in the Humphrey Visual Field analyser, the luminance of the light can be modulated over a 5.1 log unit range (i.e., 51dB, where 0.1 log unit of attenuation = 1 dB). The maximum brightness spot is 3,183 cd/m^2, and when it is attenuated with a 51dB filter, it has a luminance of 0.025 cd/m^2.

Psychophysical Measurements

Psychophysical methods and procedures are useful in determining threshold, including visual field analysis. For a perfect observer, threshold is the point where the stimulus can just be detected or where you just cannot detect the stimulus. Humans are not perfect observers, and often thresholds are defined in probabilistic terms: for example, half the points presented would be detected and half would not. So under certain psychophysical techniques, threshold can be considered the point where 50% of the stimuli are detected. Threshold variability most likely depends on neural noise. One aspect of visual psychophysics deals with noise and is termed Signal Detection Theory, but this will not be covered here.

Measurement of visual response can be achieved through several methods. These methods include: 1) Method of Adjustment; 2) Method of Limits; 3) Staircase Method (modified Method of Limits); and 4) Method of Constant Stimuli.

The **Method of Adjustment** involves asking the subject to either increase the stimulus intensity from non-seeing until the stimulus can just be seen or to decrease the stimulus intensity until the stimulus has just disappeared. This method also suffers from both errors of habituation and anticipation (these two errors are discussed below) but is useful to obtain an estimate of threshold that can be investigated with more complex techniques (see Fig. 11).

The **Method of Limits** involves presenting a stimulus well above threshold and decreasing the stimulus intensity in small steps until the subject cannot detect the stimulus (threshold). This is called descending limits. Ascending limits is when a stimulus is first presented well below threshold, then the stimulus intensity is increased to reach threshold. Ascending limits and descending limits are used to estimate the threshold. Threshold is considered the average of the threshold points estimated by several ascending and descending limits (Fig. 11).

Ascending and descending limits is a quick method of determining threshold; however, like the Method of Adjustment, two errors can occur; the errors of habituation and the errors of anticipation. The error of habituation occurs when subjects develop a habit of responding to a stimulus. For example, in ascending limits, the subject may respond to seeing the stimulus three steps past the threshold every time, thus giving a false threshold point. The error of anticipation occurs when subjects prematurely report seeing the stimulus before the threshold has been reached. Clear instructions, demonstrations, and practice runs can reduce the errors of habituation. Errors of anticipation can be minimized by changing the starting intensity for each trial.

A variation of the method of limits is the **Staircase Method**, which involves both the ascending and descending limits in a trial. Stimulus intensity is progressively increased (ascending limits) until the subject reports seeing the stimulus. At this point, the intensity value is recorded, and the stimulus intensity is then progressively reduced (descending limits) until the subject reports not seeing the stimulus. Threshold is considered the average of several of these reversal points (see Fig. 12). Threshold estimates using this method are also prone to the errors noted above, and consequently, multiple simultaneous staircases are used to minimize such errors.

The **Method of Constant Stimuli** involves the repeated presentation of a number of stimuli. The threshold value of 50% lies somewhere within this range. Other psychophysical techniques are used to estimate threshold and determine stimuli intensities to be used for presentation. These stimuli are randomly presented. The percentage of detection is determined as a function of stimulus intensity. Some high-intensity points will always be detected, whereas other low-intensity points will never to detected. The percentage of detection *versus* the stimulus intensity is graphed in Fig. 13. This graph is called the psychometric function and looks like an S-shaped curve, sometimes referred to as an ogive. The threshold value is defined as the value where 50% of the stimuli are detected. Thus, the threshold for the data below is 23.5.

Psychophysical procedures are used to minimize the variability in obtaining threshold by requiring subjects to commit to an answer.

The **YES-NO PROCEDURE** involves the subject judging the presence or absence of the signal. A stimulus is presented, during which the subject has to make a yes or no response. A correct response can range from 0% to 100%, as shown in Fig. 13.

The **FORCED CHOICE PROCEDURE** involves forcing the subject to choose from alternative choices, one of which contains the stimulus. A two-alternative forced choice (2AFC) describes a subject choosing between two alternatives. Choosing from four alternatives and six alternatives are called 4AFC and 6AFC, respectively. The percentage correct for the various stimuli intensities can be used to construct a psychometric function to determine threshold. Because there is already a 50% chance of a correct response with 2AFC, threshold is commonly considered as 75% (see Fig. 14).

For a 4AFC, threshold is considered to be at the 62.5% seen level, because this is halfway between 25% and 100%. The ogive starts at 25% because there is already a 25% chance of a correct response with 4AFC, as shown in Fig. 15.

Stimulus Intensity	A	D	A	D	A	D	A	D

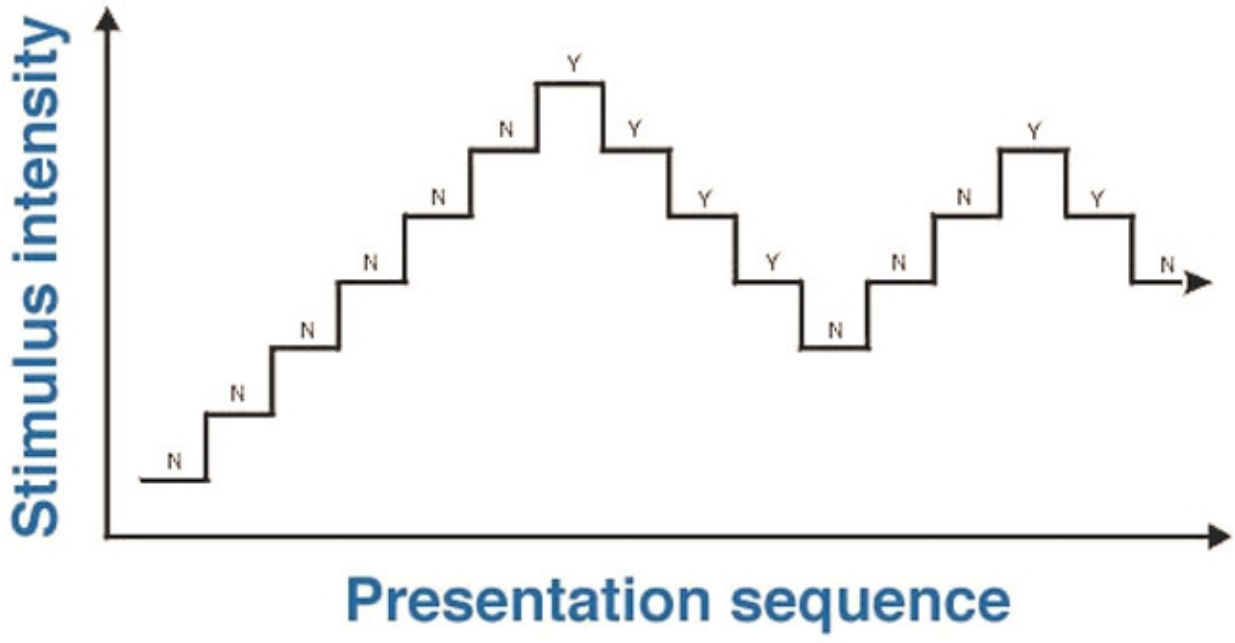

Figure 12. Staircase method. Y = Yes, the stimulus can be seen; and N = No, the stimulus cannot be seen.

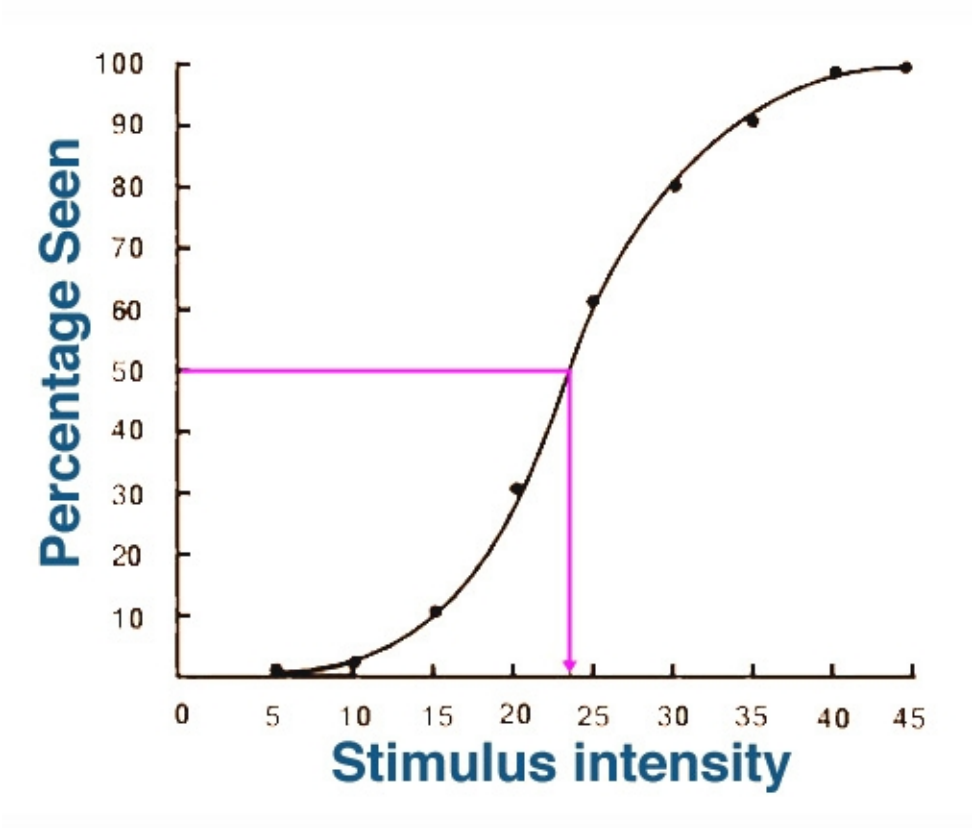

Figure 13. Psychometric function for a YES-NO paradigm.

Adaptive Psychophysical Methods

ADAPTATIVE METHODS involve presenting signals based on the performance of the subject's previous response while in **FORCED CHOICE TRACKING** a forced choice procedure is used. When subjects correctly respond three times, stimulus intensity is decreased by one step. An incorrect response will result in a one step increase in stimulus intensity. The size of the ascending and descending steps remain the same throughout the session. The session ends when a narrow range of stimuli level is reached. Threshold is considered the average of the intensity level within the period of stable tracking.

The size of the steps is an important factor. If the steps are too small, the subject may not be able to discern differences in intensity. Reaching the threshold range with small steps will also be time consuming. Large steps may miss the threshold range altogether, with swings from well above threshold to well below threshold.

PARAMETER ESTIMATION BY SEQUENTIAL TESTING (PEST) was designed to address the problem of step size and starting intensity. PEST techniques begin the session with large steps (large changes in intensity), with the intensity progressively halved until the smallest specified step to determine threshold (Fig. 16). PEST is actually a little more complicated than explained here.

MAXIMUM LIKELIHOOD METHODS. With both forced choice tracking and PEST, subsequent changes in stimulus intensity relies on the subjects previous two or three responses. In maximum likelihood methods, the stimulus intensity presented at each trial is determined by statistical estimation of the subjects threshold based on all responses from the beginning of the session. After each trial, a new estimation of threshold is determined, and the stimulus intensity is adjusted accordingly. Threshold is taken at the point where there is little change in stimulus intensity.

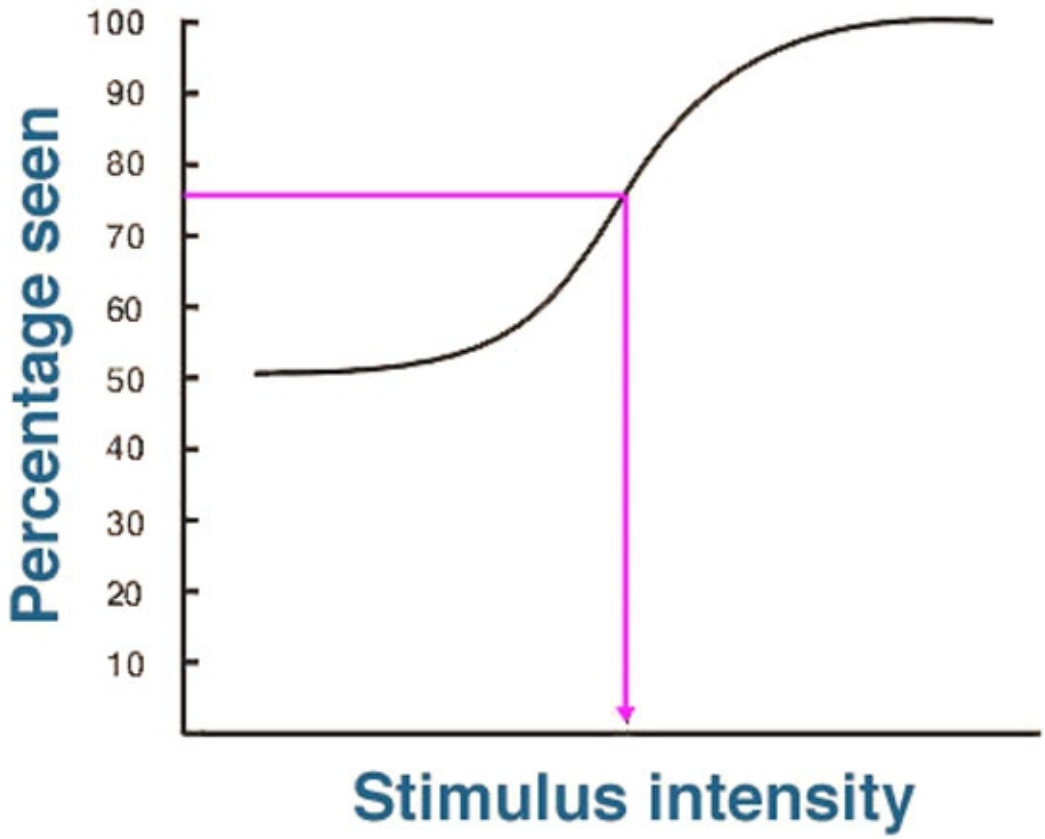

Figure 14. Psychometric function for 2AFC. Threshold is taken at the 75%-seen level.

Several examples of maximum likelihood methods are QUEST (quick estimate by sequential testing), ZEST (zippy estimate of sequential testing), and SITA (Swedish interactive threshold algorithm, which is a modified ZEST). These methods require prior information about the population's distribution of threshold and is used to construct a probability distribution function (PDF). Prior PDF is based on previously published data, pilot studies, or the expectations of the experimenter. On the basis on the PDF, the mode (QUEST) or the mean (ZEST) stimulus intensity that is most likely to be the subject's threshold is presented. The subject's response is then used to construct a new PDF using Bayes' rule of combining probability. The next stimulus intensity is presented at the new level that is most likely threshold. At the end of the procedure, the mode (QUEST) or the mean (ZEST) of the final PDF is considered the best estimate of the subject's threshold.

For additional readings, see Geischeider (1), Graham (2), Schwartz (5), and Wyszecki and Stiles (6).

About the Authors

Michael Kalloniatis was born in Athens Greece in 1958. He received his optometry degree and Master's degree from the University of Melbourne. His PhD was awarded from the University of Houston, College of Optometry, for studies investigating colour vision processing in the monkey visual system. Post-doctoral training continued at the University of Texas in Houston with Dr Robert Marc. It was during this period that he developed a keen interest in retinal neurochemistry, but he also maintains an active research laboratory in visual psychophysics focussing on colour vision and visual adaptation. He was a faculty member of the Department of Optometry and Vision Sciences at the University of Melbourne until his recent move to New Zealand. Dr. Kalloniatis is now the

Robert G. Leitl Professor of Optometry, Department of Optometry and Vision Science, University of Auckland.
e-mail: m.kalloniatis@unsw.edu.au

Charles Luu was born in Can Tho, Vietnam in 1974. He was educated in Melbourne and received his optometry degree from the University of Melbourne in 1996 and proceeded to undertake a clinical residency within the Victorian College of Optometry. During this period, he completed post-graduate training and was awarded the post-graduate diploma in clinical optometry. His areas of expertise include low vision and contact lenses. During his tenure as a staff optometrist, he undertook teaching of optometry students as well as putting together the "Cyclopean Eye", in collaboration with Dr Michael Kalloniatis. The Cyclopean Eye is a Web based interactive unit used in undergraduate teaching of vision science to optometry students. He is currently in private optometric practice as well as a visiting clinician within the Department of Optometry and Vision Science, University of Melbourne.

Visual Acuity

Michael Kalloniatis and Charles Luu.[1]

Created: May 1, 2005; Updated: June 5, 2007.

Introduction

Visual acuity is the spatial resolving capacity of the visual system. This may be thought of as the ability of the eye to see fine detail. There are various ways to measure and specify visual acuity, depending on the type of acuity task used. Visual acuity is limited by diffraction, aberrations, and photoreceptor density in the eye (1). Apart from these limitations, a number of factors also affect visual acuity, such as refractive error, illumination, contrast, and the location of the retina being stimulated.

Types of Acuity Tasks

Target **detection** requires only the perception of the presence or absence of an aspect of the stimuli, not the discrimination of target detail (Fig. 1). The Landolt C and the Illiterate E are other forms of detection used in visual acuity measurement in the clinic. The task required here is to detect the location of the gap (Fig. 2).

Target **recognition** tasks, which are most commonly used in clinical visual acuity measurements, require the recognition or naming of a target, such as with Snellen letters. Test objects used here are large enough that detection is not a limiting factor (Fig. 3), but careful letter choice and chart design are required to ensure that letter recognition tasks are uniform for different letter sizes and chart working distances (2).

Snellen letters are constructed so that the size of the critical detail (stroke width and gap width) subtends 1/5th of the overall height. To specify a person's visual acuity in terms of Snellen notation, a determination is made of the smallest line of letters of the chart that he/she can correctly identify. Visual acuity (VA) in Snellen notation is given by the relation:

$$VA = D'/D$$

where D' is the standard viewing distance (usually 6 meters) and D is the distance at which each letter of this line subtends 5 minutes of arc (each stroke of the letter subtending 1 minute) (Fig. 4).

The reciprocal of the Snellen Notation equals the angle (in minutes of arc) that the strokes of the letter subtend at the person's eye. This angle is also used to specify visual acuity (Fig. 5). It is called the minimum angle of resolution (MAR) and can also be given in log10 form (logMAR).

Some European countries specify their visual acuities in decimal form, which is simply the decimal of the Snellen fraction (Table 1).

Target resolution thresholds are usually expressed as the smallest angular size at which subjects can discriminate the separation between critical elements of a stimulus pattern such as a pair of dots, a grating, or a checkerboard (Fig. 6).

Target **localization** involves discriminating differences in the spatial position of segments of a test object, such as a break or discontinuity in contour. Visual acuity measured in this way is called Vernier acuity (a type of hyperacuity), and the discontinuity is specified in terms of its angular size (Fig. 7).

Author Affiliation: 1 Department of Optometry and Vision Sciences University of Melbourne, Australia.

Resolution, localization, or detection tasks produce hyperacuity or levels of performance over and above the recognition (normal visual acuity) limit and indicate that the mechanisms involved in making such judgements are not restricted to the retinal level (3, 4).

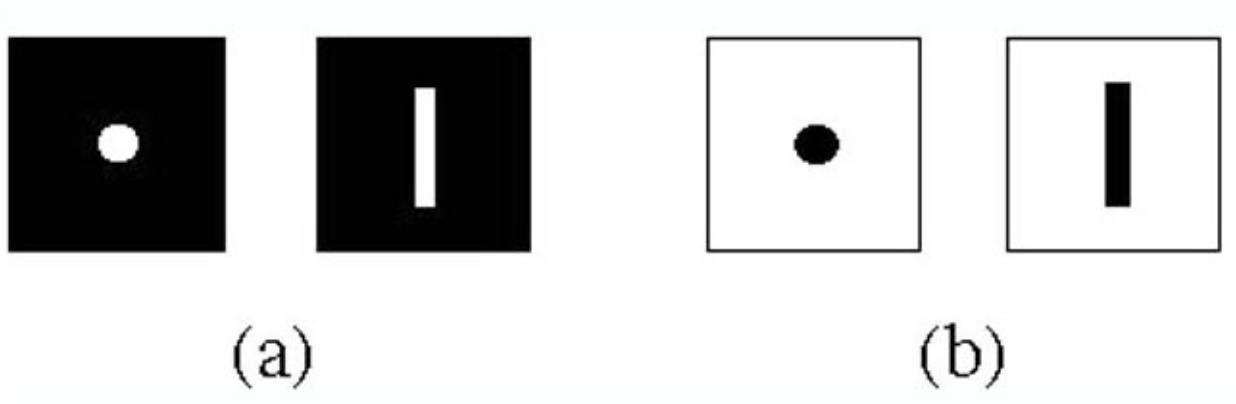

Figure 1. The task of detection involves stating whether the spot or line is present. (a) Bright test object on a dark background. (b) Dark test object on a bright background.

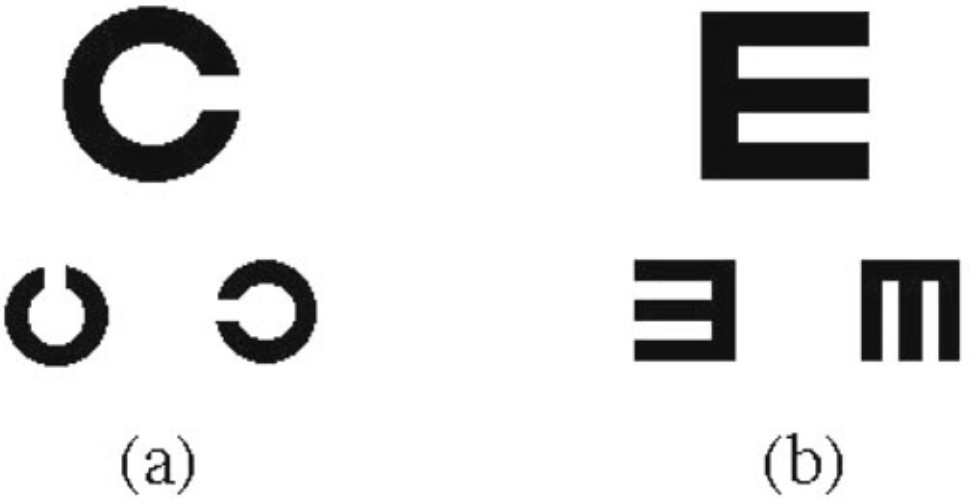

Figure 2. (a) Landolt C. (b) Illiterate E.

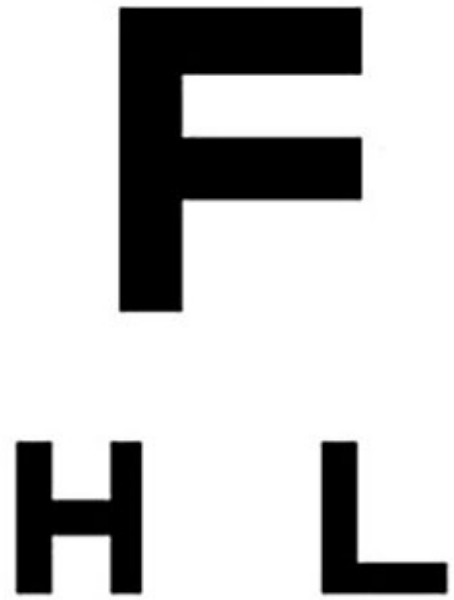

Figure 3. The task of recognition. Naming the test objects, in this case, letters of the alphabet (Snellen).

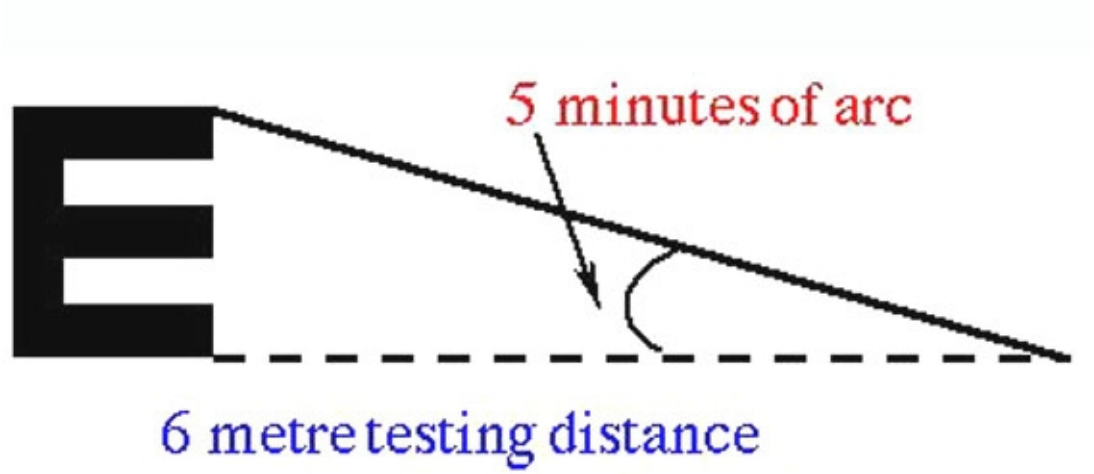

Figure 4. For a visual acuity of 6/6, the whole letter subtends an angle of 5 minutes of arc at the eye and is viewed at 6 meters (20 feet).

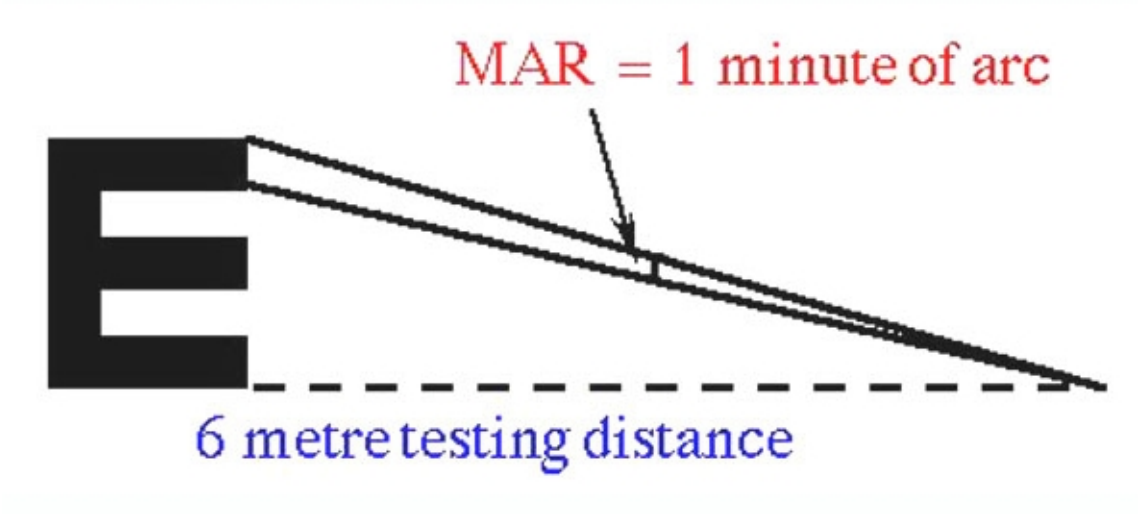

Figure 5. For a visual acuity of 6/6 (20/20), one of the strokes of the letter subtends one minute of arc at the eye. Therefore, theminimum angle of resolution (MAR) is one minute of arc and the logMAR is 0.

6/3.0	20/10	0.50	−0.3	2.00

Visual Acuity Limitations

For the smallest point to be detected or the finest detail to be resolved requires a good optical system and appropriately spaced detectors. Visual acuity will be limited by one of these. Objects we look at will be imaged at the back of the eye. If we take a point source, the image will be distributed on the retina as a point spread function due to distortions created by the optics of the eye (Fig. 8).

A point spread function describes the light distribution on the retina of a point source in visual space. An Airy disk pattern would be formed from a point source due to the diffraction of light (Fig. 9). A line spread function describes the light distribution of an extended source and is often used to simplify calculations.

The angular radius, *a*, of the first ring is given by:

$$a = 1.22\ l/d$$

where *l* is the wavelength of light and *d* is the diameter of the pupil. The angular radius is in radians. To convert from radians to degrees, multiply by 180/*p*. Two point sources produce two-point spread functions at the back of the eye (Fig. 10). These two points are said to be just resolved if they meet Rayleigh's criterion (see below). Clearly, if the retinal image of the two point sources was not degraded, it would be possible to have higher resolution limits (with the appropriate detector array).

Raleigh's Criterion

Raleigh's criterion is used to calculate the resolution of the eye for stimuli that are degraded by the optics of the eye. The criterion states that two points or lines are just resolved if the peak of the point spread function lies on the first trough of the other point spread function (Fig. 11).

Two points are resolved if their angular separation, α_S, is:

$$\alpha_S = 1.22\ l/d$$

In effect, this equation mathematically states that resolution is possible if two objects are separated by the width of their point spread function. If two objects are within this distance (Fig. 12), our perception of them is that of one uniform distribution (part b); and hence, we will not be able to discern the two objects.

Dimension of the Retinal Mosaic

Other than diffraction limiting visual acuity according the Raleigh's criterion, retinal cone spacing is another limiting factor, at least with in the central two degrees (5). Helmholtz (6) proposed that a grating would be resolved if there is a row of unstimulated cone between rows of stimulated cones. This is considered the Yes-No-Yes response of the cone receptors. For example, if two lines are to be resolved, a detector array needs to be fine enough to detect a gap between the two lines (Fig. 13). From Fig. 13, it can be seen that detectors A and B will not be able to resolve the two lines. However, with a fine detector array of detectors C, D, E, and F, the two lines would be resolved.

The same principle applies to sinusoidal gratings where a detector array must be fine enough to detect the gap between the lines or gratings. The bars of a sinusoidal grating do not change abruptly as with square wave gratings (Fig. 14).

Gratings can be used as another method of measuring visual acuity. Visual acuity in Snellen notation can be expressed in spatial frequency and *vice versa* (Fig. 15).

Sinusoidal gratings were used by Campbell and Green (7) to determine the maximum resolution of the eye. They used interference patterns generated by a laser to bypass the optics of the eye to create a sinusoidal grating at the back of the eye. They found that the maximum resolution was about 60 cycles per degree, whereas a free viewing screen resulted in reduced resolution capabilities. More recent work on photoreceptor density and spatial resolution has shown that the receptor array in the human visual system can resolve in the order of 6/1 (20/3) or ~150 cycles/degree (8, 9). Cone spacing at the fovea is approximately 2.5 μm (8) or approximately 28 seconds of arc. On the basis of cone spacing, a maximum of about 60 cycles per degree is possible, which is well above

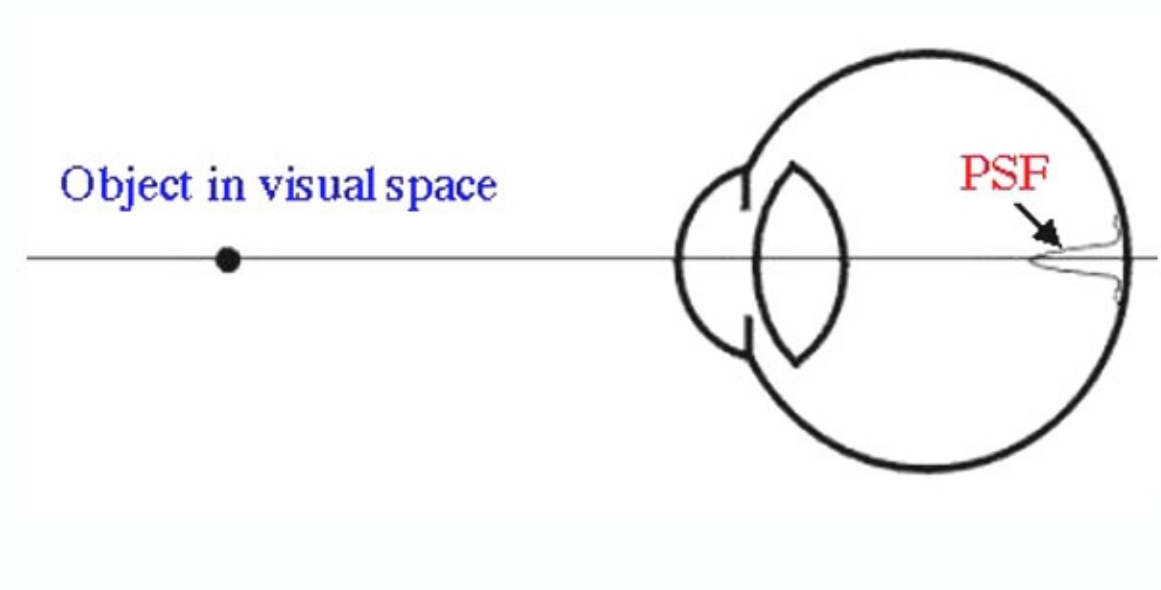

Figure 8. Image of a point at the back of the eye.

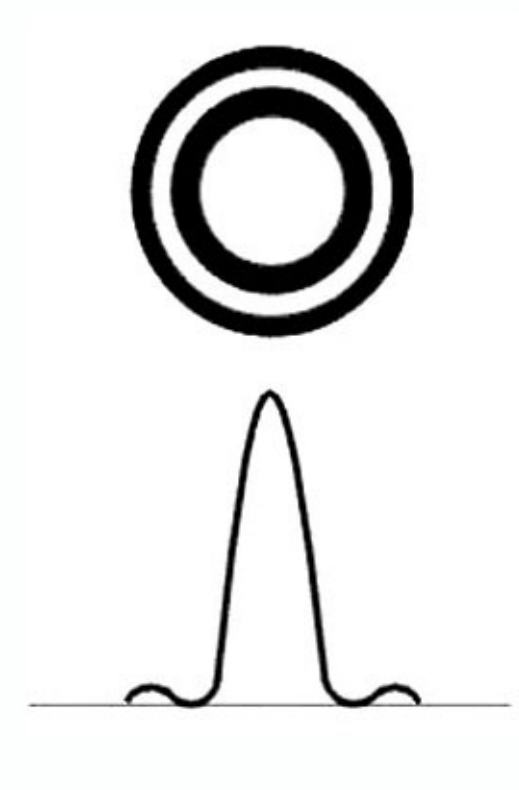

Figure 9. Point spread function (Airy disk pattern) of a point source. The upper component represents the perception of the light distribution when viewing an Airy disc.

conventional clinical measures because this does not compensate for the optics of the eye and post-receptoral neural processing.

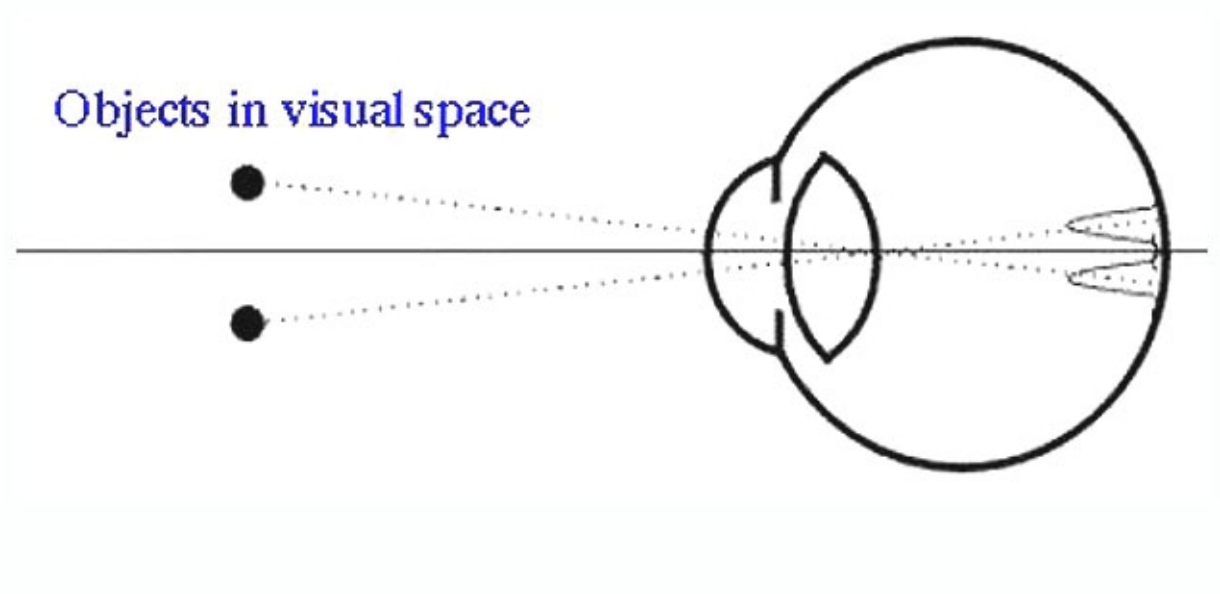

Figure 10. Two point sources and their point spread function at the back of the eye.

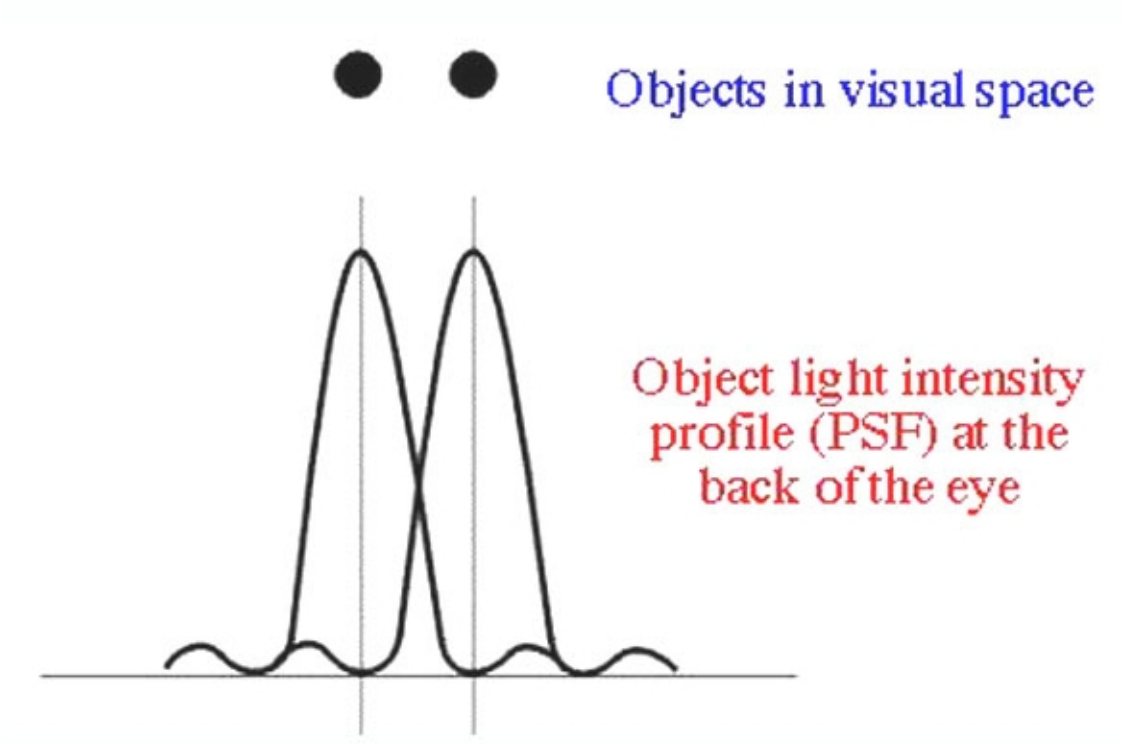

Figure 11. Raleigh's criterion.

Factors Affecting Visual Acuities

Apart from the two main limiting factors above, visual acuity also depends on a number of factors including:

- refractive error
- size of the pupil
- illumination

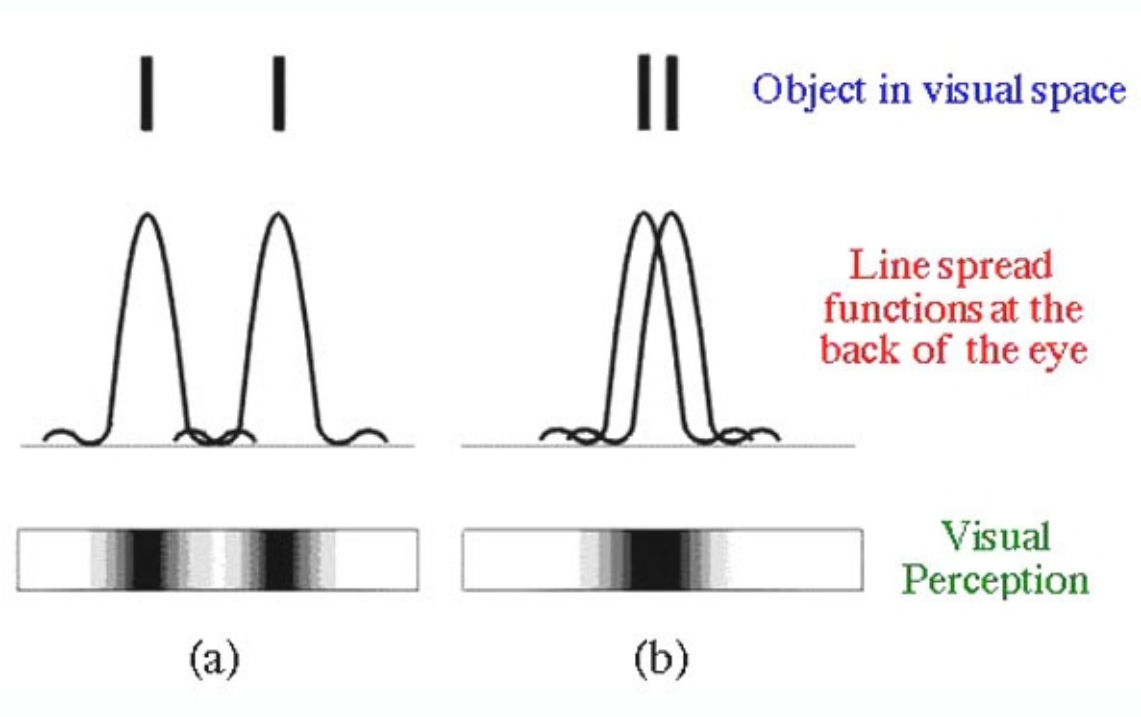

Figure 12. The representation between two lines, their line spread function, and a person's perception of the two lines. (a) Two lines are resolved. (b) Two lines that cannot be resolved and are perceived as one thick line.

- time of exposure of the target
- area of the retina stimulated
- state of adaptation of the eye
- eye movement

Refractive Error

Refractive errors will affect visual acuity by causing defocus at the retina. Defocus will blur out fine detail, sharp edges, and contrast sensitivity by affecting its point spread function (Fig. 16). Refractive errors such as myopia (short-sightedness) and hyperopia (long-sightedness) causes the point spread function to spread more laterally, affecting resolution (Fig. 17). The image at the back of the eye of an object is focused sharply on the retina in an emmetropic eye. In a myopic eye, the optical system can be considered to be too strong, thus the image is focused in front of the retina. The reverse occurs with a hyperopic eye where the optical system is too weak so the image is focused behind the retina.

Pupil Size

The size of the pupil is an important factor affecting visual acuity. Large pupils allow more light to stimulate the retina and reduces diffraction, but resolution will be affected by aberrations of the eye. On the other hand, a small pupil will reduce optical aberrations, but resolution will be diffraction limited. Therefore, a mid-size pupil of about 3 to 5 mm would be optimal, because this is a compromise between the diffraction and aberration limits (1, 10). As noted earlier, pupil area affects the size of the point spread function, and hence resolution.

Illumination

For recognition tasks, visual acuity is greatly affected by the level of background luminance (Fig. 18). Two branches are evident: the lower branch belongs to the rod (scotopic) function, and the upper branch belongs to

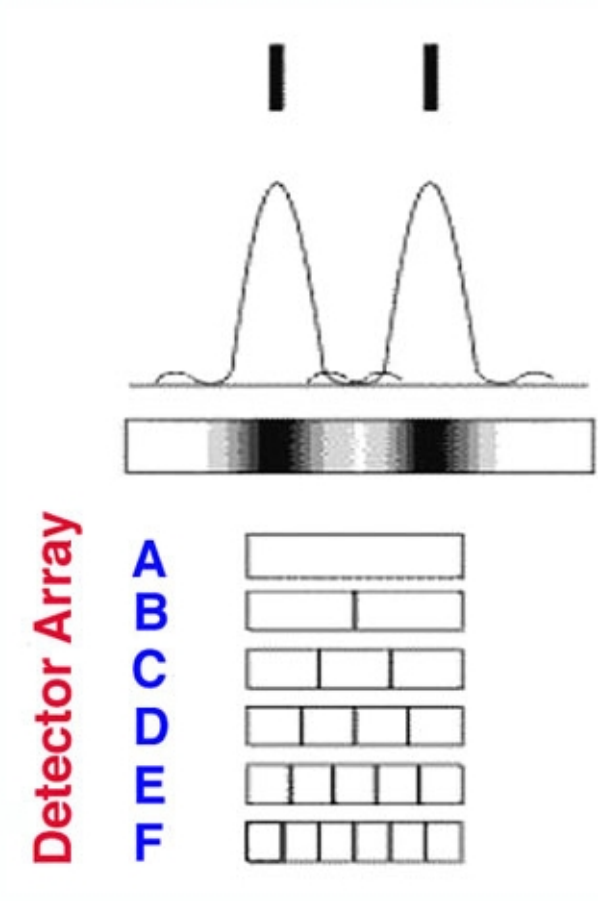

Figure 13. Two lines with their line spread function, person's perception of the two lines, and various detector arrays. Only detector arrays C (3 detectors) through F (6 detectors) have a fine enough detector density to resolve the two lines, i.e., detect the gap. Detector array A or B, which have one and two detectors, respectively, cannot signal a yes-no-yes response.

the cone (photopic) function. Note the asymptote for both, indicating the maximum visual acuity (arrows). The cone branch has a long "linear" range of about 3 log units, with the asymptote at the photopic level of about 300 cd/m^2.

One theory put forward by Hecht (11) is that within the rod population and within the cone population, there are differing sensitivities that are distributed randomly. Therefore, at high luminance, all cells are active for a high level of visual acuity. At low luminances, only cells sensitive to that level of luminances are active, and because they are distributed randomly, the retinal mosaic is coarser; thus, a lower level of visual acuity is achieved (12).

Another possible explanation is that under limited quantal availability, quantal capture is more probable in the para-central and peripheral retinal because of greater spatial summation. Because photoreceptor density in this area is low, resolution is poorer. As light levels increase, quantal capture occurs more successfully at the central retinal (macula and fovea). A higher level of visual acuity is achieved because of the high photoreceptor density.

Time of Exposure of the Target

To detect a small bright spot, detection is greatly dependent on the quantity of light rather than the exposure time. However, to detect a line, the acuity (reciprocal width of the line) is proportional to the exposure time. There is no simple acuity–exposure time relationship for the resolution of the target.

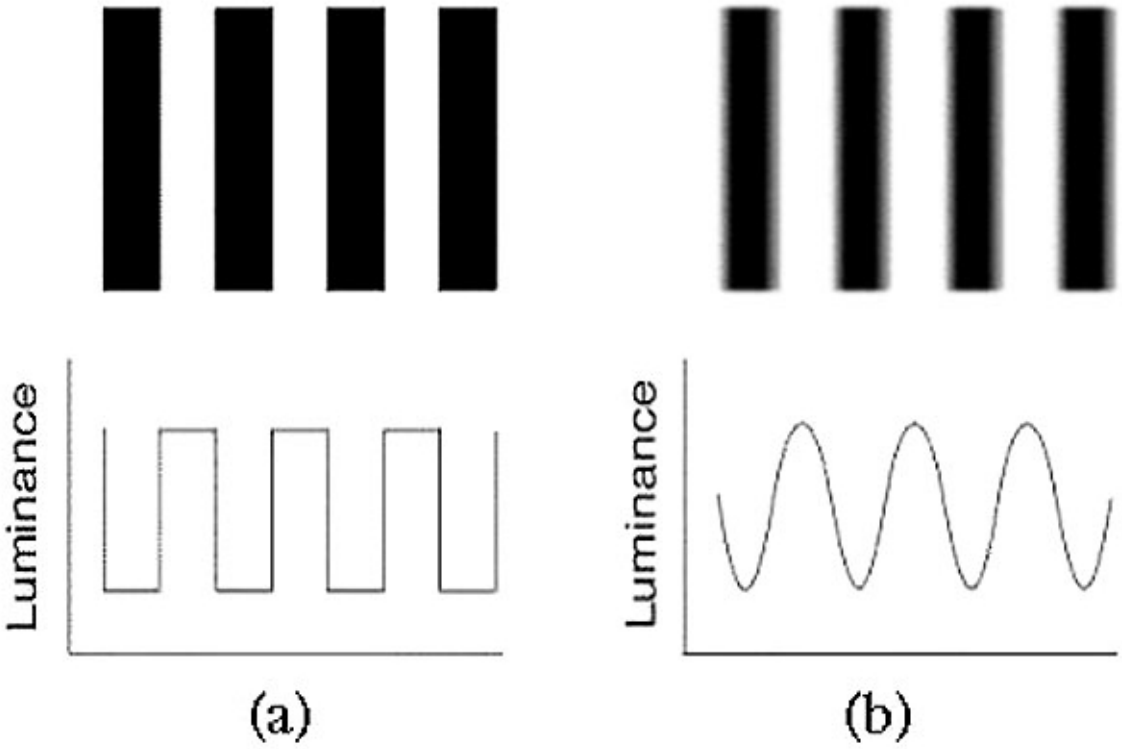

Figure 14. Square wave grating (a) and sinusoidal wave grating (b) with their luminance profile.

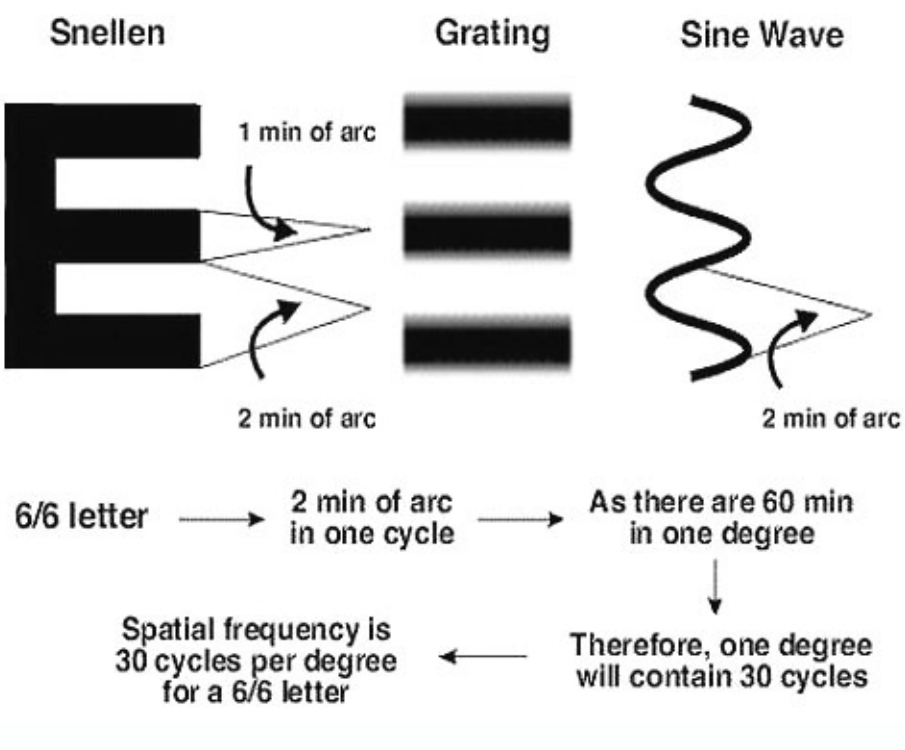

Figure 15. Visual acuity in Snellen notation and its conversion to spatial frequency.

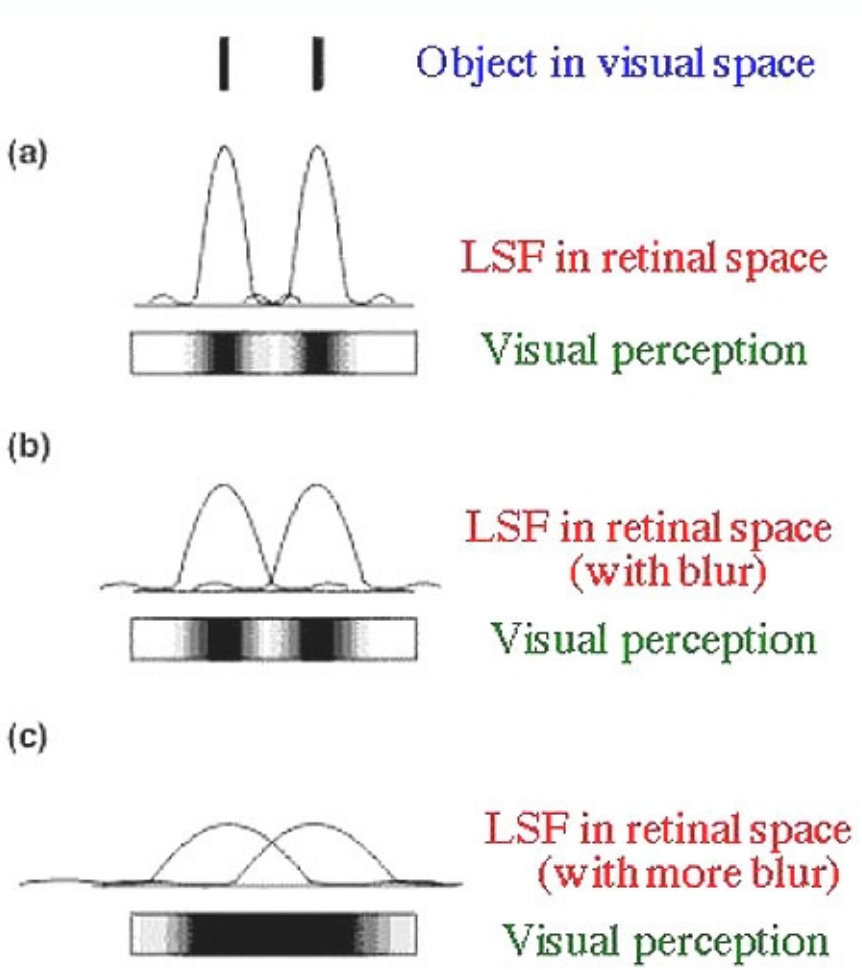

Figure 16. Line spread function (LSF) of two lines with various amounts of blur. With increasing blur, the discrimination of the two lines is lost.

Area of the Retina Stimulated

Because of the densely packed cones at the fovea, visual acuity is the greatest at the center of fixation. At a distance of 5 minutes of arc from the center of fixation, there is a measurable loss in visual acuity. At 10 minutes of arc (1/6 of a degree) from fixation, there is a 25% loss of visual acuity (Fig. 19). When comparisons were made of cone packing density and photopic resolution, close correlation was evident up to approximately 2 degrees eccentricity (5). At larger eccentricities, visual acuity is worse than that predicted by cone spacing, which may indicate that another post-receptoral retinal element is the limiting factor (see the discussion below for scotopic visual acuity).

State of Adaptation of the Eye

The highest level of visual acuity is achieved if the eye is adapted to the same level as the test luminance for test luminances of 34 cd/m^2 to 34,000 cd/m^2. For test luminances less than 34cd/m^2, adapting to a lower luminance will achieve a slightly better acuity.

The high density of cones at the fovea is responsible for the high levels of visual acuity under photopic conditions. Under scotopic conditions, the AII amacrine cell, which is an interneuron identified in the primate retina (13, 14), appears to limit resolution. Maximum scotopic acuity occurs at ~5-15° eccentricity, which corresponds to the AII amacrine cell density, whereas peak rod density occurs at about 15-20°. The arrow in Fig.

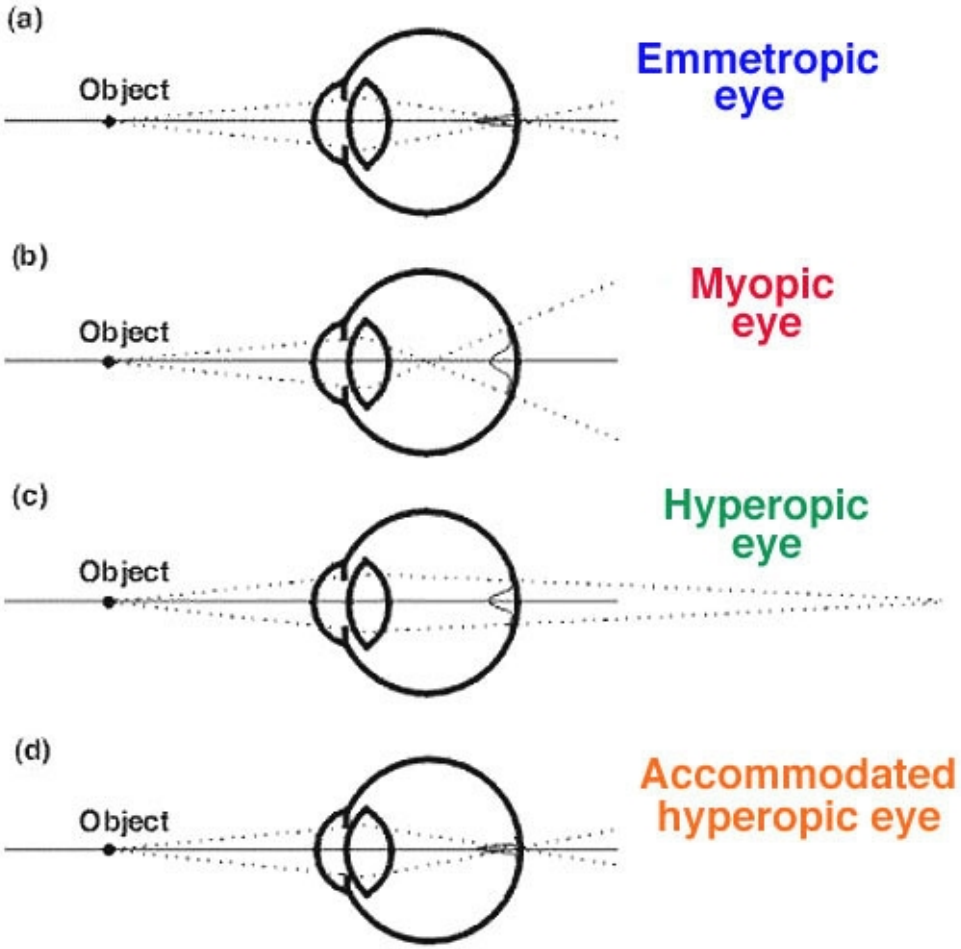

Figure 17. Point spread function at the back of the eye with different refractive errors.

20 shows that at eccentricities less than 15°, scotopic acuity is limited by the AII amacrine cell. Beyond 15°, scotopic acuity is limited by the midget ganglion cell (P cell) (15).

As noted above, a similar process may occur in the photopic system (5), where photopic resolution beyond an eccentricity of 2° falls below that predicted by cone density. The works by both Green (5) and Mills and Massey (15) provide evidence that post-receptoral processing is another factor that may limit visual acuity.

Eye Movement

During steady fixation, the eyes are in constant motion. Under these conditions, retinal images traverse a distance of about 3 minutes of arc in one second.

Contrast Sensitivity

Contrast is an important parameter in assessing vision. Visual acuity measurement in the clinic uses high contrast, that is, black letters on a white background. In reality, objects and their surroundings are of varying contrast. Therefore, the relationship between visual acuity and contrast allows a more detailed understanding of our visual perception.

Grating patterns are used as a means of measuring the resolving power of the eye because the gratings can be adjusted to any size. The contrast of the grating is the differential intensity threshold of a grating, which is defined as the ratio:

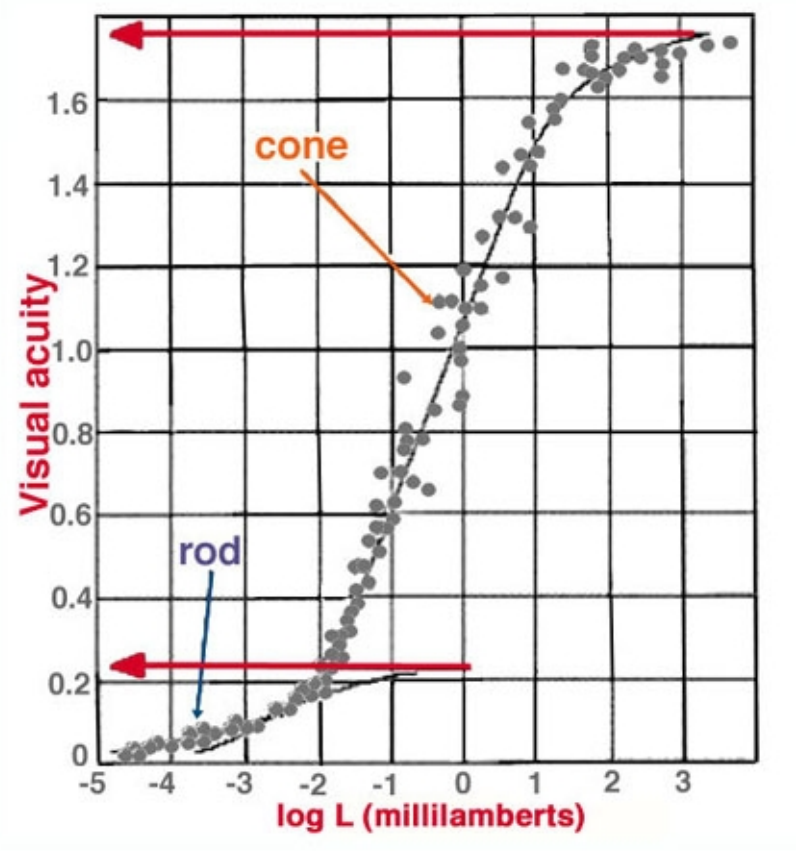

Figure 18. Relationship between visual acuity (decimal notation) and background luminance. The shallow curve at low luminances is attributable to the rod response, and the large sigmoidal curve is attributable to the cone response. The horizontal arrow identifies the maximum resolution of rod and cone systems. Konig's data from Riggs (21).

$$C = (L_{max} - L_{min})/(L_{max} + L_{min})$$

where C can have a value between 0.0 and 1.0; sometimes C is called the modulation, Raleigh or Michelson contrast (Fig. 21). The luminance of contrast gratings vary in a sinusoidal manner (Fig. 21). This allows the contrast of the grating to be altered without changing the average luminance of the screen displaying the gratings.

The size of the bars of the grating can be expressed in terms of the number of cycles (one cycle consists of one light bar plus one dark bar of the grating) per degree subtended at the eye. This is called the spatial frequency of the grating and can be thought of as a measure of the fineness or coarseness of the grating. The units can be cycles per degree (Fig. 22).

We can determine the sensitivity of the visual system as a function of grating size (spatial frequency). The contrast of the grating patterns is adjusted to determine the threshold for a given spatial frequency. That is, with a given spatial frequency, the contrast can be lowered until detection of the grating becomes impossible (contrast threshold). The reciprocal of this contrast threshold is called contrast sensitivity.

The contrast required for the visual system to reach a certain threshold can be expressed as a sensitivity on a *decibel* (dB) scale (contrast sensitivity in dB = $-20 \log_{10} C$). A plot of (contrast) sensitivity *versus* spatial frequency is called the **spatial contrast sensitivity function** (SCSF, or usually abbreviated to CSF).

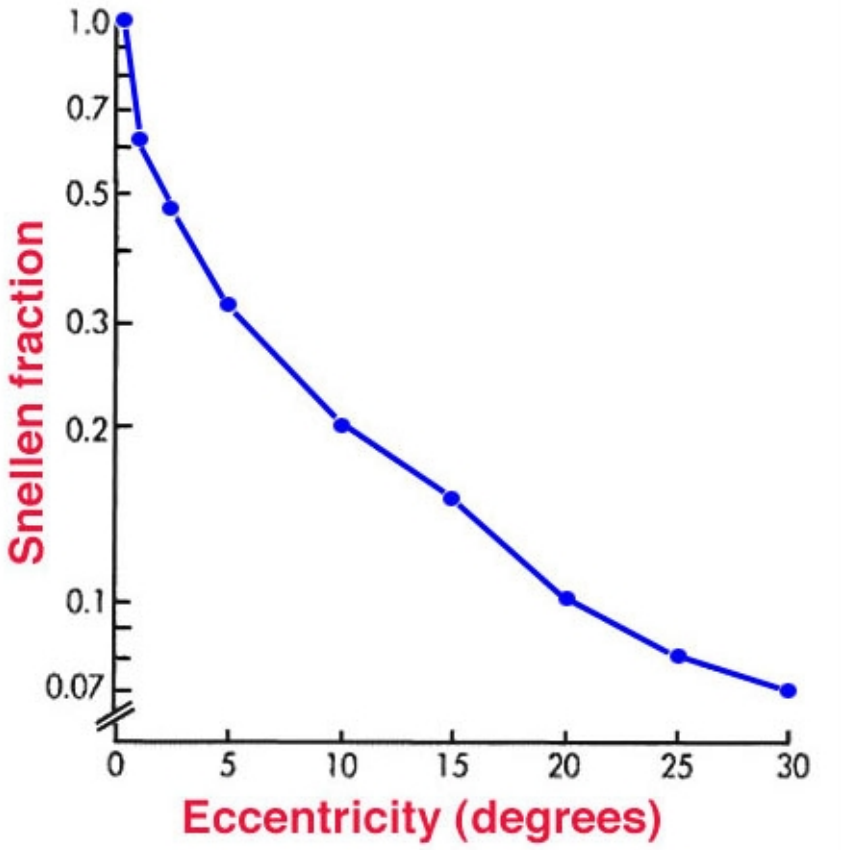

Figure 19. The effects of eccentricity on visual acuity (expressed in decimal notation). From Westheimer (22).

Contrast Sensitivity Function

Under photopic conditions, contrast sensitivity measurements reveal a band-pass function when using sinusoidal gratings (Fig. 23). The peak of the CSF function is in the mid-spatial range, and only under high contrast conditions is resolution at its maximal level.

The shape and critical parameters of the CSF depends on a number of factors including: the mean luminance of the grating, whether the luminance profiles of the gratings are sinusoidal or square waveforms; the level of defocus; and the clarity of the optics of the eye. At low light levels, maximum contrast sensitivity is approximately 8% and maximum resolution is approximately 6 cycles per degree. As mean light levels increase, the peak of the contrast sensitivity function is now close to 0.5% contrast, and the high spatial frequency cut off is at about 50 to 60 cycles per degree (~6/3 or 20/10). Also shown in Fig. 24, at photopic light levels, the peak contrast sensitivity is at approximately 5 to 10 cycles per degree (16).

The contrast sensitivity function provides a more thorough representation of the visual system. For example, the pivotal visual developmental study of Harwerth et al. (17) characterized the changes in the contrast sensitivity function after different periods of monocular deprivation in monkeys. The loss of sensitivity in the mid to high spatial frequencies was profound during abnormal visual development, with increased deprivation leading to further contrast losses. Not only will certain disease/disorders of the eye reduce visual acuity, contrast sensitivity will also be affected (18). For example, patients with multiple sclerosis will have mid to low contrast sensitivity losses (Fig. 25B), whereas patients with cataracts will have an overall reduction in contrast sensitivity (Fig. 25C). Mild refractive error or mild amblyopia will lead to a CSF similar to D in Fig. 25, with more severe refractive errors or severe amblyopia, resulting in a CSF similar to curve C.

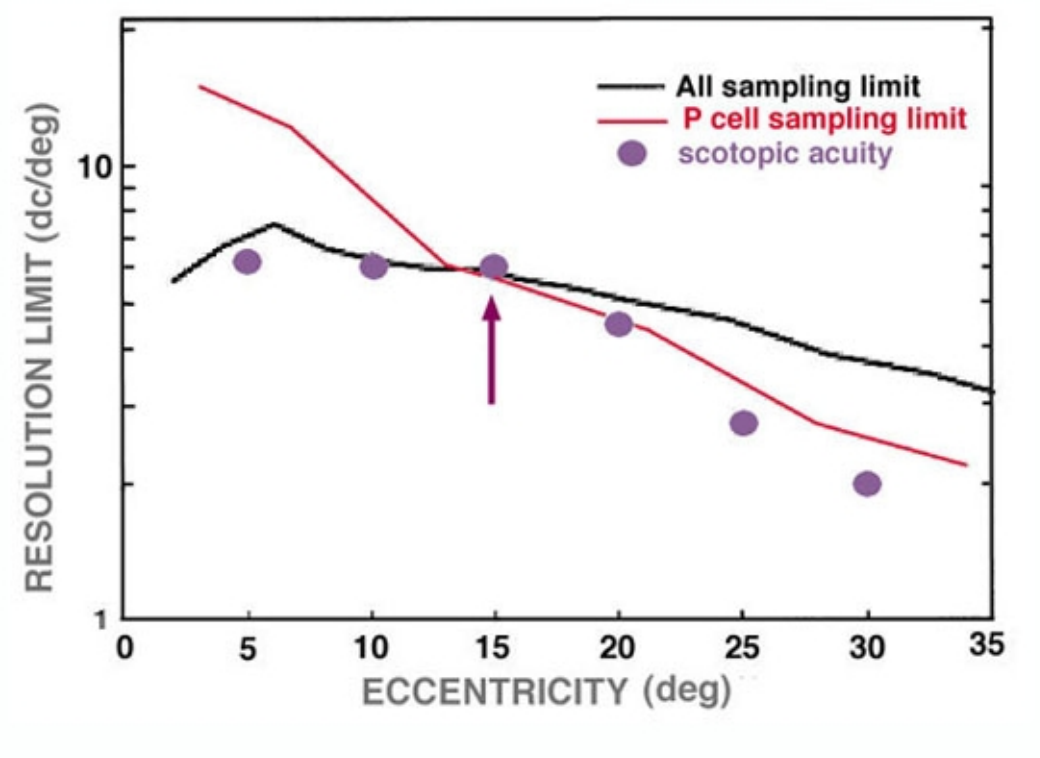

Figure 20. Scotopic acuity is limited by the AII amacrine cells at eccentricities less that 15° (open circles following the black line). After 15°, scotopic acuity is limited by P cells (open circles following the gray line). The arrow indicates the approximate location of maximum rod density. From Mills and Massey (15).

Spatial Summation

Spatial summation describes the eye's ability to summate or add up quanta over a certain area. This area over which spatial summation operates is called the critical diameter. According to Ricco's law, within this critical diameter, the threshold is reached when the total luminous energy reachs a constant value (k). Threshold is reached when the product of luminance (L) and stimulus area (A) equals or exceeds this constant value. In other words, when luminance is halved, a doubling in stimulus area is required to reach threshold. When luminance is doubled, the stimulus area can be halved and still reach threshold. Ricco's law is expressed as:

$$L \cdot A^{n} = k$$

where L is the luminance of the stimulus, A is the area of the stimulus, k is a constant value, and n describes whether spatial summation is complete ($n = 1$) or partial ($0 < n < 1$). No spatial summation occurs when $n = 0$. Critical area varies with eccentricity. Ricco's law holds for an area of 30 minutes of arc in the parafoveal area (4 to 7° eccentricity) and increasing to an area of about 2° at an eccentricity of 35° (19).

Spatial summation occurs because of the convergence of photoreceptors onto ganglion cells. This convergence of photoreceptors form a receptive field; thus, stimulating different photoreceptors within this receptive field would result in one signal. Receptive field sizes vary with eccentricity (Fig. 26) and helps explain the reason why critical area varies with eccentricity (20). Clearly, the size of spatial summation (functional receptive field) will limit resolution capabilities as outlined earlier.

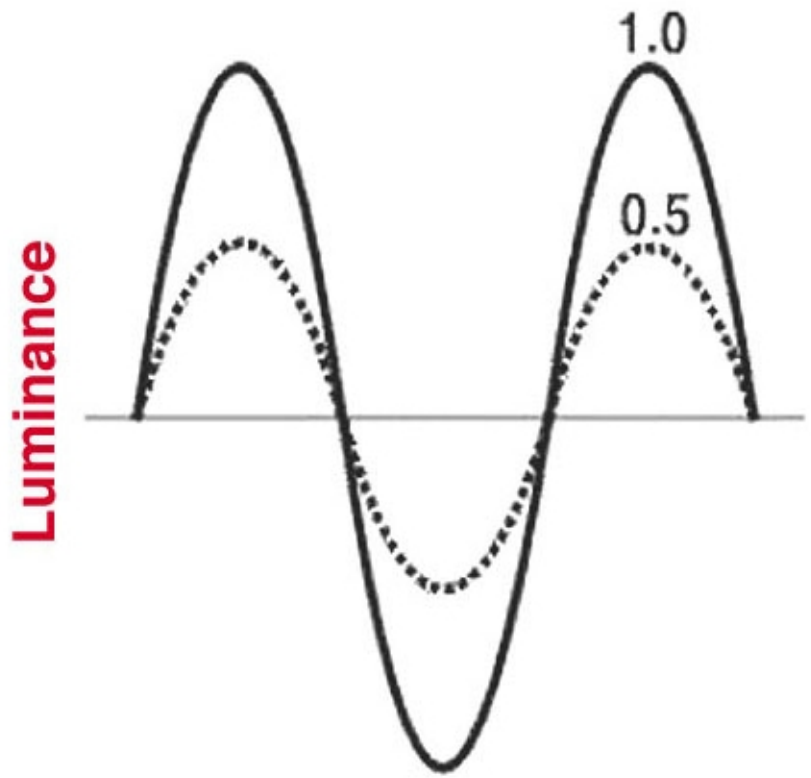

Figure 21. Luminance profile of sinusoidal gratings of contrast ratio of 1.0 and 0.5. For the contrast value of 1, the grating would have the maximum and minimum available luminances.

A schematic spatial summation graph is shown in Fig. 27. A simple logarithmic transform of $L \cdot A = k$ results in the log$L$ *versus* log$A$ plot having a straight line with a slope of −1 (complete spatial summation within Ricco's law). Outside the critical area, such a plot has a slope of 0, indicating that the size of the target does not affect the threshold.

Fig. 28 shows data on spatial summation where spots of light with different background luminances are presented 6.5° nasally from the fovea. Ricco's law of complete spatial summation holds when the gradient is −1 (solid line). Note that the critical area is larger for low luminance and smaller for high luminance. Such a change reflects the functional alteration of receptive field size with changes in adaptation level (20).

About the Authors

Michael Kalloniatis was born in Athens Greece in 1958. He received his optometry degree and Master's degree from the University of Melbourne. His PhD was awarded from the University of Houston, College of Optometry, for studies investigating colour vision processing in the monkey visual system. Post-doctoral training continued at the University of Texas in Houston with Dr Robert Marc. It was during this period that he developed a keen interest in retinal neurochemistry, but he also maintains an active research laboratory in visual psychophysics focussing on colour vision and visual adaptation. He was a faculty member of the Department of Optometry and Vision Sciences at the University of Melbourne until his recent move to New Zealand. Dr. Kalloniatis is now the Robert G. Leitl Professor of Optometry, Department of Optometry and Vision Science, University of Auckland. e-mail: m.kalloniatis@unsw.edu.au

Charles Luu was born in Can Tho, Vietnam in 1974. He was educated in Melbourne and received his optometry degree from the University of Melbourne in 1996 and proceeded to undertake a clinical residency within the Victorian College of Optometry. During this period, he completed post-graduate training and was awarded the post-graduate diploma in clinical optometry. His areas of expertise include low vision and contact lenses. During his tenure as a staff optometrist, he undertook teaching of optometry students as well as putting together the "Cyclopean Eye", in collaboration with Dr Michael Kalloniatis. The Cyclopean Eye is a Web based interactive unit used in undergraduate teaching of vision science to optometry students. He is currently in private optometric practice as well as a visiting clinician within the Department of Optometry and Vision Science, University of Melbourne.

Temporal Resolution

Michael Kalloniatis and Charles Luu.[1]

Created: May 1, 2005; Updated: June 5, 2007.

The eye can function over a large range of luminance levels; it must also be able to handle the different rates of change in luminance. Our eyes are constantly sampling information of images projected onto the retina in a periodic manner. Information is then integrated so objects around us appear to be stable or move smoothly. Because there is a finite amount of time required to collect and process information, there are limitations to the responsiveness of our visual system to rates of change. When intermittent stimuli are presented to the eye, they are perceived as separate if the rate at which they are presented is below a certain value. If the rate of presentation of the intermittent stimuli is slow, it appears to stay on but with changes in intensity, producing the sensation called flicker. Above a certain critical rate, the flicker ceases. This point is called the critical flicker frequency and is influenced by a number of factors. The first factor to be considered is the temporal summation property of the visual system.

Temporal Summation

Temporal Resolution and Temporal Summation

In the spatial domain, detection of two lights in space requires the appropriate detector array (Fig. 1). For us to discriminate the two lines, a response given by detector array C to F is required. All of these detector arrays provide a Yes-No-Yes response and thus allow the discrimination of the two lines.

In the temporal domain, the same principle applies, except now the stimulus is separated in time (Fig. 2). The separation between the two lines is in the temporal domain (two flashes are delivered) after a time interval *t*. The detector array now has different temporal integration times. For example, detector A integrates over time = *t*, whereas detector array B has an integration time of time = 0.5*t*, array C, time = 0.33*t*, and so on. Because of the shorter integration time for detector array C and beyond, such an array will be able to discriminate the two flashes that are separated by an interval of *t*.

To detect a flash of light one after the other, an appropriate integration time is required (Fig. 3). The period of integration is up to 0.1 seconds or 100 ms (for rods) and 10 to 15 ms for cones. The advantage of long integration time is that under limited light level conditions, a threshold will be reached, whereas when light levels are not limiting (cone or photopic vision), a short integration time is preferable to improve temporal resolution.

Temporal integration time is related to temporal summation. Temporal summation refers to the eye's ability to sum the effects of individual quanta of light over time. However, temporal summation only occurs within a certain period of time, called the critical duration or critical period. According to Bloch's law of vision, within this critical duration, the threshold is reached when the total luminous energy is reached. Bloch's law of temporal summation is analogous to Ricco's law of spatial summation. Bloch's law states that total luminous energy is a constant value (k), thus threshold is reached when the product of luminance (L) and stimulus duration (t) equals this constant. In other words, when luminance is halved, a doubling in stimulus duration is required to reach threshold. When luminance is doubled, the threshold can be reached in half the duration. Bloch's law is expressed as:

$$L \cdot t^{n} = k$$

Author Affiliation: 1 Department of Optometry and Vision Sciences University of Melbourne, Australia.

where L is the luminance of the stimulus, t is the duration of the stimulus, k is a constant value, and n describes whether temporal summation is complete ($n = 1$) or partial ($0 < n < 1$). No temporal summation occurs when $n = 0$ (Fig. 4).

Critical duration is shorter for stimulus of high luminance as threshold is reached faster and slower for stimulus of low luminance as a longer period of time is required to sum the quanta to reach threshold. Temporal summation ceases beyond the temporal integration time. Above this value, threshold is dependent only on luminance rather than the product of luminance and duration.

Temporal summation is also affected by other test variables, such as background luminance and the size of the stimulus. Critical duration is longer for brighter background and smaller test stimuli. When temporal summation data areplotted as log$L$ t *versus* log$t$ rather than log$L$ *versus* log$t$ (as in Fig. 4), the slope of zero identifies Bloch's law (Fig. 5).

The above plots show that temporal summation is longer for low light levels, indicating the larger temporal summation characteristics for scotopic vision. As light intensity is increased, e.g., 25,000 trolands, the critical duration is of the order of 20–30 msec. The interrelationship between temporal integration and spatial summation is shown on the right panel, where Bloch's law is measured for different sizes of test stimuli. Decreasing test size results in increased temporal summation, and hence poorer temporal discrimination. We will investigate this phenomenon further when we review flicker discrimination for different sized stimuli in the next section.

Broca-Sulzer Effect

In addition to basic discrimination characteristics of temporal resolution, there are several interesting perceptual phenomena. One of these phenomena is the Broca-Sulzer effect, which describes the apparent transient increase in brightness of a flash of short duration. Subjective flash brightness occurs with flash durations of 50 to 100 milliseconds. This phenomenon is associated with temporal summation and explains the leveling off of brightness to a plateau. When the light is turned on, time is required for temporal summation to reach threshold for light of low luminance. Light of high luminance reaches this threshold very quickly. As flash duration increases, brightness levels off to a plateau as temporal summation begins to breakdown, according to Bloch's law, after the critical duration. The apparent transient peak in brightness is probably attributable to an underlying neural mechanism (Fig. 6).

Critical Flicker Frequency

Critical flicker frequency (CFF) is the transition point of an intermittent light source where the flickering light ceases and appears as a continuous light. There are a multitude of factors that determine our perception of flicker that includes the intensity and size of the test stimulus.

Factors Affecting CFF

The **Ferry-Porter law** states that CFF is proportional to the logarithm of the luminance of flickering stimulus (L). It can be expressed as:

$$CFF = a \log L + b$$

where a and b are constants. With foveal observation, this relationship holds over a wide range (0.5 to 10,000 trolands) (Fig. 7). The above equation implies that when CFF is plotted as a function of log$L$, a straight line will identify the region where the Ferry-Porter law holds. As the intensity of the test stimulus is increased, our perception of flicker also increases. From a practical point of view, if a stimulus is flickering, such as computer monitor, decreasing the intensity level will eliminate the flicker.

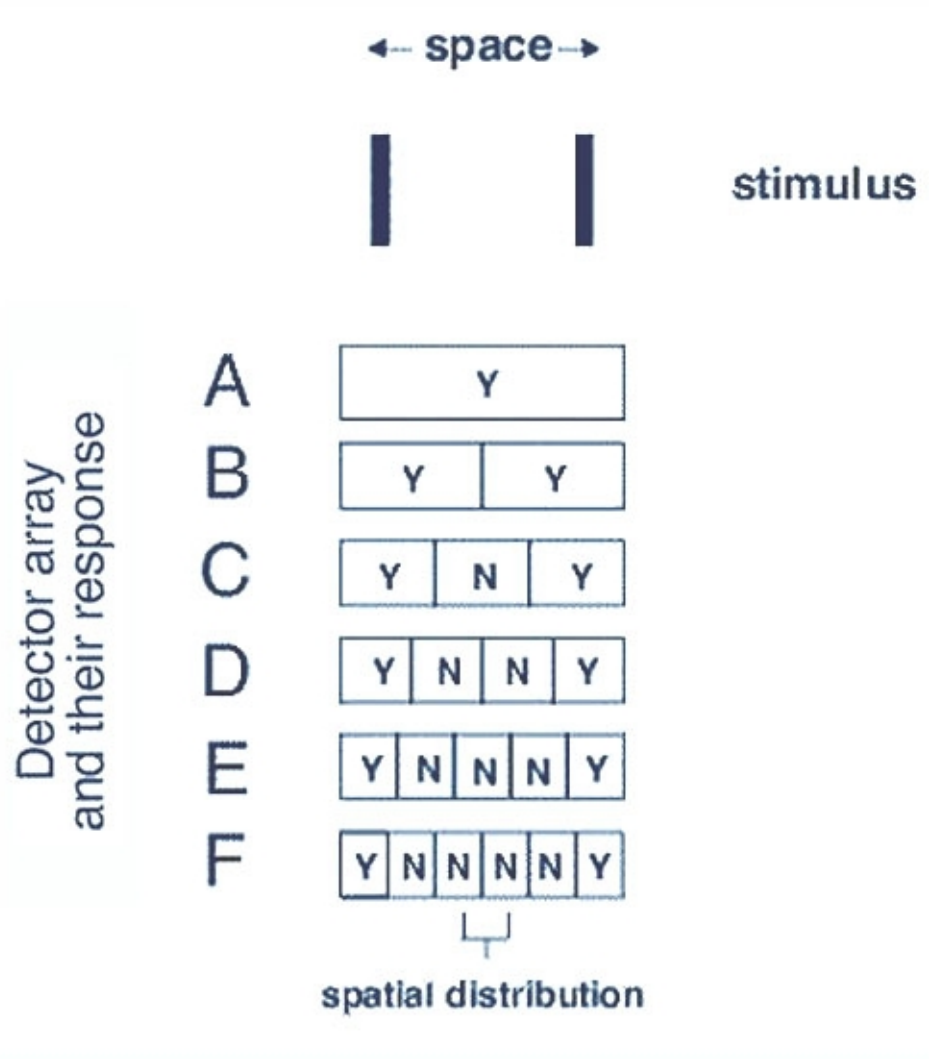

Figure 1. Detector array C and beyond allows the detection of the two lines.

Spectral Composition

Under photopic levels, lights of different wavelengths, when adjusted to match them for brightness, conforms to the Ferry-Porter law and follows the logarithmic function as brightness increases. However, under scotopic levels (rods functioning), the wavelengths fan out (Fig. 8). This is attributable to the different spectral sensitivities of the scotopic system to the photopic system. If plotted as scotopic photons, the bottom part of the curve would collapse into one and appear like the 19° curve in Fig. 10. Note that the temporal resolution to short wavelength test stimuli is different. However, in general terms, the plot below is correct, although the units chosen for the scotopic component (lower branches) give the misconception that temporal resolution is different for the rod system.

An important aspect of cone vision is that when the short-wavelength pathway is isolated (1), the temporal resolution is lower, close to 10–15 Hz, rather than the closer to 60 Hz for the longer wavelength pathways. This general phenomenon is characteristic of the short-wavelength pathway that is known to have larger spatial summation approximately 15' at about one degree eccentricity (the location of high S-cone density), whereas the longer wavelength pathways have a spatial summation of 4' (2). In the temporal domain, at high light levels, the S-cone pathways has a temporal summation time of approximately 100 ms, whereas the longer-wavelength cone pathway has a temporal integration of approximately 50 msec (3).

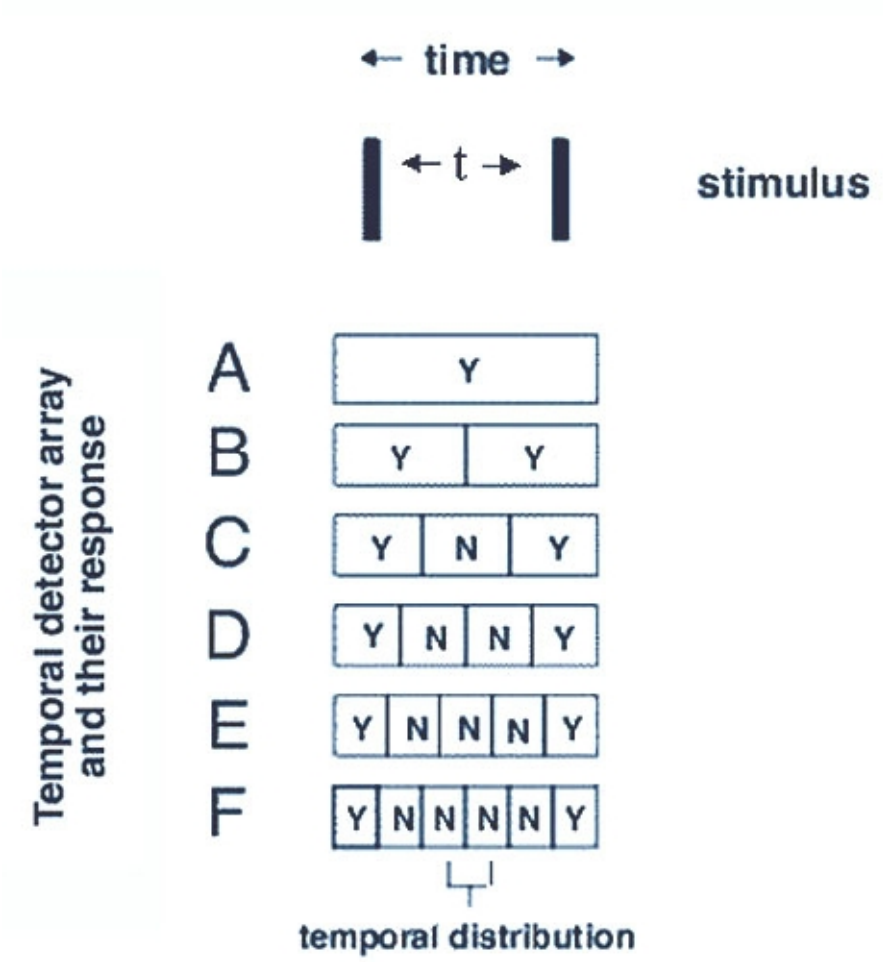

Figure 2. Speed of integration allows the detection of intermittent stimuli. Detector arrangement C and beyond allows discrimination of the stimuli over time.

Retinal Position

Because the CFF is different for rod and cones, the CFF for the test field will depend on the proportion of rods and cones being stimulated. Because the proportion of rod and cones changes with eccentricity, a foveal test stimulus will follow the Ferry-Porter law and show no kink (one branch only) in the curve because only cones are present at the fovea. An extrafoveal test stimulus will show a kink (two branches) in the CFF function because the rods determine the CFF at low retinal illuminances and the cones determining CFF at higher retinal illuminance. Note that the Ferry-Porter law applies over a decreasing range as the eccentricity increases, and that temporal resolution is poorer for eccentric locations (Fig. 9).

The Ferry-Porter law has been further examined for a single cone type, using conditions that eliminate detection of the flickering stimulus by rods. Under these conditions, the law has been found to hold, despite changes in stimulus size or modulation amplitude (4). However, the slope of the Ferry-Porter law changes with eccentricity, becoming steeper with eccentrically presented targets. This latter finding is consistent with previous work, suggesting that there is an increase in the speed of photopic retinal responses in the periphery, once stimuli have been appropriately scaled (5). This increase in speed has been hypothesized to relate to the change in cone photoreceptor outer-segment length that occurs in the periphery (5). Such scaling has not been performed to the classic data sets presented here.

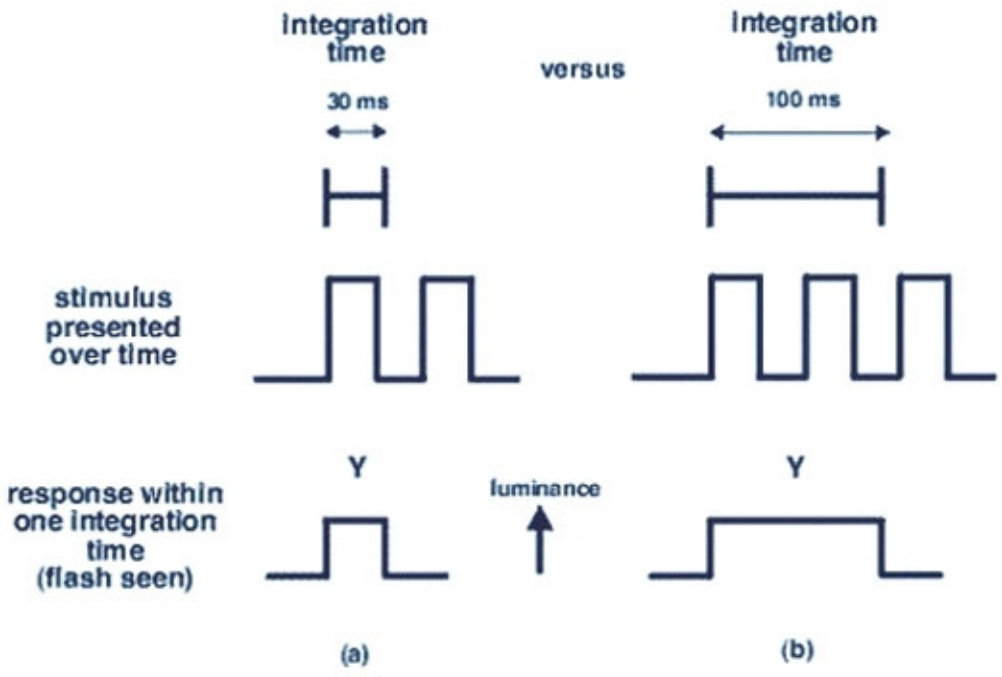

Figure 3. Flashes of light are presented to the eye. (a) With a short integration time, the flashes are detected. (b) No flashes are perceived (that is, the stimulus appeared as one bright flash) with a long integration time.

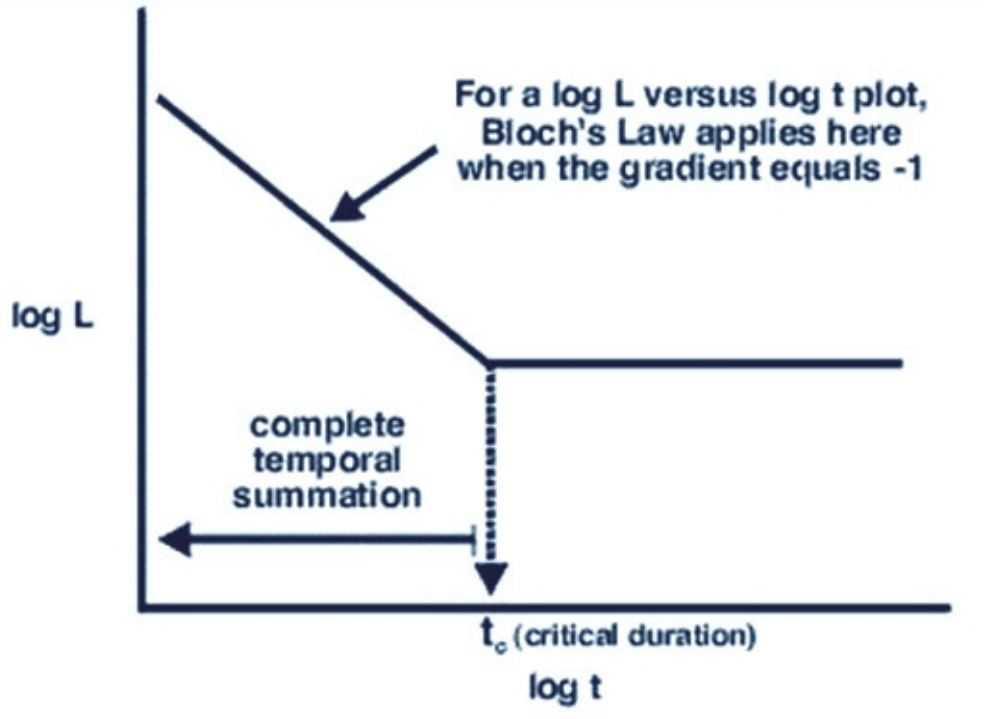

Figure 4. Temporal summation data plotted as log*L versus* log*t*, showing where Bloch's law applies.

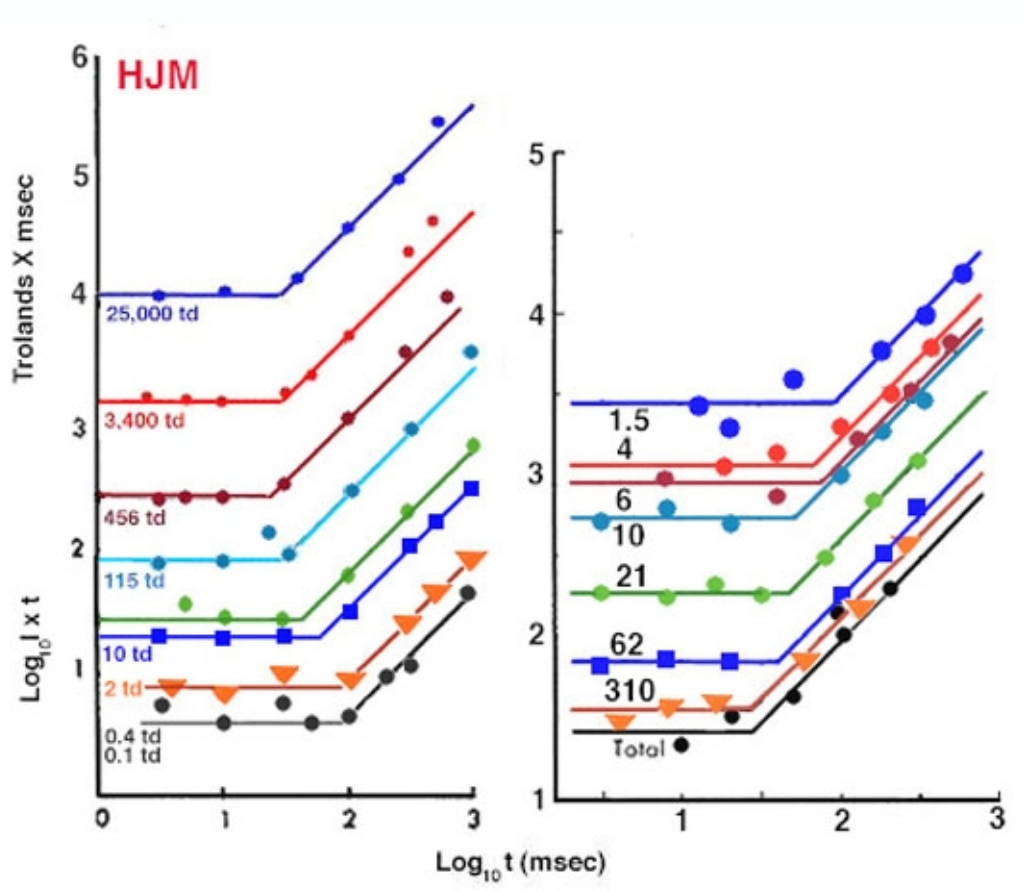

Figure 5. Luminance-duration *versus* time curves. Bloch's law holds when the gradient of the line is zero. Integration time (critical duration) can be determined from above. Beyond critical duration, Bloch's law breaks down (when the gradient is greater than zero). (a) 1° foveal test spot on different backgrounds. (b) Foveal test spots of different diameter (in minutes of arc) and for whole-eye stimulation (total). Kahneman and Norman's data from Hart (8).

Size of Test Field

Because of the different populations of rods and cones in the retina and different spatial summation properties, CFF will be dependent on the area of the retina being stimulated. Instead of varying retinal eccentricity as above, the size of the centrally fixated test field is varied (Fig. 10). As the test field increases, two branches begin to appear. The lower branch represents rod function. The maximum CFF, and hence maximum temporal resolution, is achieved by large test targets that have the shortest integration time noted earlier.

The **Talbot-Plateau law** describes the brightness of an intermittent light source that has a frequency above the CFF. This law states that above CFF, subjectively fused intermittent light and objectively steady light (of equal color and brightness) will have exactly the same luminance. In another words, brightness sensation from the intermittent light source is the same as if the light perceived during the various periods of stimulation had been uniformly distributed over the whole time. The Talbot-Plateau law applies only above the CFF.

The **Brücke-Bartley** (brightness enhancement) effect is a phenomenon related to the Broca-Sulzer effect. When the frequency is gradually lowered below the CFF, the effective brightness of the test field begins to rise. Not only does the brightness reach a value equal to that of the uninterrupted light, but the brightness even transcends it, reaching a maximum when the flash rate is about 8 to 10 Hz.

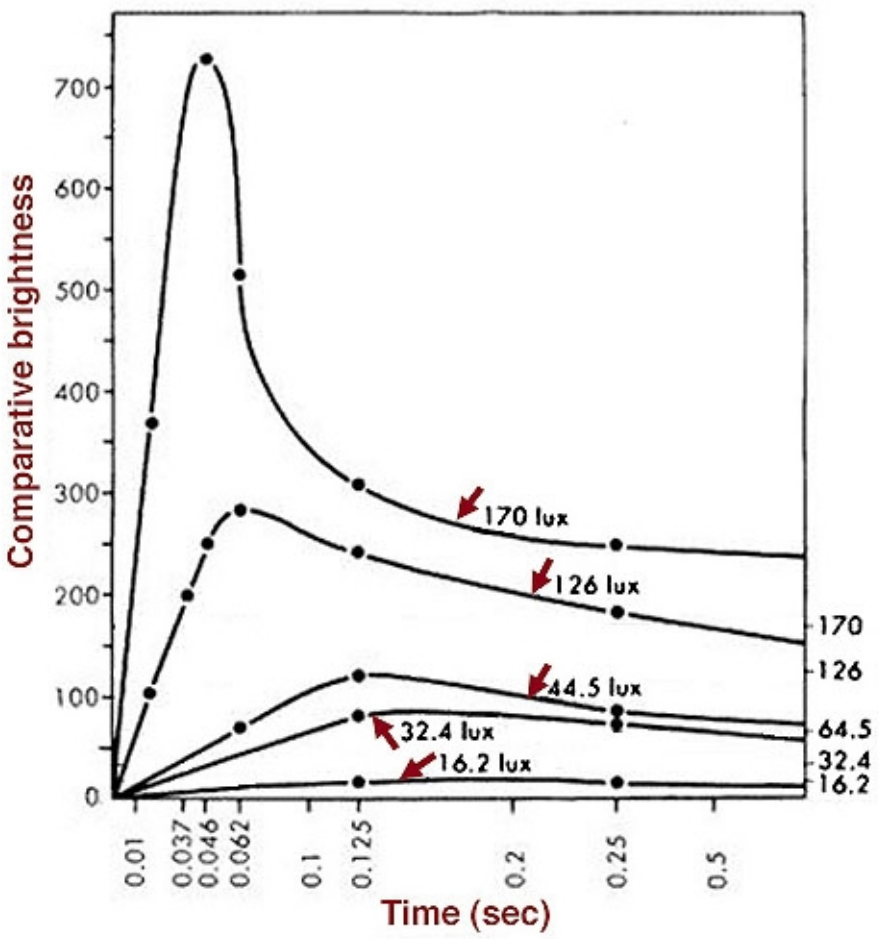

Figure 6. Apparent brightness of flashes with various luminances, as a function of flash duration. Broca and Sulzer data from Hart (8).

Temporal Contrast Sensitivity

In the spatial domain, spatial vision can be characterized by the contrast sensitivity function (CSF). To thoroughly investigate the visual system to flicker, a Temporal Contrast Sensitivity Function (TSF), or a de Lange function, can be plotted (6). A TSF is a plot of how flicker varies with contrast and *vice versa*. Above the curve represents no flicker, whereas flicker can be detected below the curve (Fig. 11). The eye appears to be most sensitive to a frequency of 15 to 20 Hz at high luminances (photopic vision). At photopic light levels, less than 1% contrast is required to detect the stimulus, and the high temporal frequency cut off is close to 60 Hz. At low light levels, the maximum contrast is about 20% and the high temporal frequency cut off is approximately 15 Hz. To detect flicker of high frequencies, maximum contrast is required. Temporal resolution is not as efficient at low luminances (scotopic vision).

Different sensitivity profiles exist for the different components of the visual system (opponent *versus* non-opponent) to discriminate motion. For the luminance system, detection, identification, and direction discrimination provide equivalent thresholds. However, at all eccentricities tested, the chromatic system required approximately 0.3 log units higher contrast levels to signal direction of motion (Fig. 12) (7). Overall, these results imply that both luminance (non-opponent) and chromatic (opponent) visual channels are involved in motion discrimination.

Light and Dark Adaptation

Michael Kalloniatis and Charles Luu.[1]

Created: May 1, 2005; Updated: July 9, 2007.

Dark Adaptation

The eye operates over a large range of light levels. The sensitivity of our eye can be measured by determining the absolute intensity threshold, that is, the minimum luminance of a test spot required to produce a visual sensation. This can be measured by placing a subject in a dark room and increasing the luminance of the test spot until the subject reports its presence. Consequently, dark adaptation refers to how the eye recovers its sensitivity in the dark after exposure to bright lights. Aubert (1) in 1865 was the first to estimate the threshold stimulus of the eye in the dark by measuring the electrical current required to render the glow on a platinum wire just visible. He found that the sensitivity had increased 35 times after time in the dark, and he also introduced the term "adaptation".

Dark adaptation forms the basis of the Duplicity Theory, which states that above a certain luminance level (about 0.03 cd/m^2), the cone mechanism is involved in mediating vision: photopic vision. Below this level, the rod mechanism comes into play, providing scotopic (night) vision. The range where two mechanisms are working together is called the mesopic range, as there is not an abrupt transition between the two mechanisms.

The dark adaptation curve shown in Fig. 1 depicts this duplex nature of our visual system. The first curve reflects the cone mechanism. The sensitivity of the rod pathway improves considerably after 5-10 minutes in the dark and is reflected by the second part of the dark adaptation curve. One way to demonstrate that the rod mechanism takes over at low luminance levels is to observe the color of the stimuli. When the rod mechanism takes over, colored test spots appear colorless, as only the cone pathways encode color. This duplex nature of vision will affect the dark adaptation curve in different ways and is discussed below.

To produce a dark adaptation curve, subjects gaze at a pre-adapting light for about 5 minutes, and then the absolute threshold is measured over time (Fig. 1). Pre-adaptation is important for normalization and to ensure that a biphasic curve is obtained.

From the above curve, it can be seen that initially there is a rapid decrease in threshold, then it declines slowly. After 5 to 8 minutes, a second mechanism of vision comes into play, where there is another rapid decrease in threshold, then an even slower decline. The curve asymptotes to a minimum (absolute threshold) at about 10^{-5} cd/m^2 after about 40 minutes in the dark.

Factors Affecting Dark Adaptation

There are four factors that affect dark adaptation, which will be discussed below:

1. intensity and duration of the pre-adapting light
2. size and position of the retina are used in measuring dark adaptation
3. wavelength distribution of the light used
4. rhodopsin regeneration

Intensity and Duration of Pre-adapting Light

Different intensities and duration of the pre-adapting light will affect the dark adaptation curve in a number of areas. With increasing levels of pre-adapting luminances, the cone branch becomes longer while the rod branch

Author Affiliation: 1 Department of Optometry and Vision Sciences University of Melbourne, Australia.

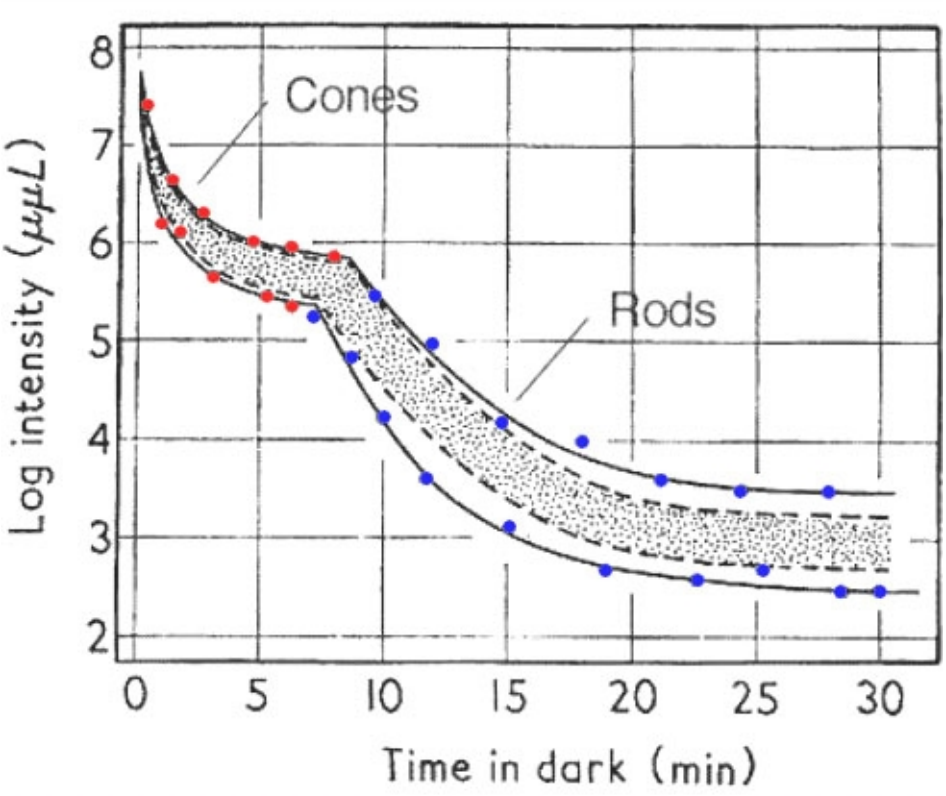

Figure 1. Dark adaptation curve. The shaded area represents 80% of the group of subjects. Hecht and Mandelbaum's data are from Pirenne (9).

becomes more delayed. The absolute threshold also takes longer to reach. At low levels of pre-adapting luminances, rod threshold drops quickly to reach absolute threshold (Fig. 2).

The shorter the duration of the pre-adapting light, the more rapid the decrease in dark adaptation (Fig. 3). For extremely short pre-adaptation periods, a single rod curve is obtained. It is only after long pre-adaptation that a biphasic cone and rod branches are obtained.

Size and Location of the Retina Used

The retinal location used to register the test spot during dark adaptation will affect the dark adaptation curve because of the distribution of the rod and cones in the retina (Fig. 4).

When a small test spot is located at the fovea (eccentricity of 0°), only one branch is seen with a higher threshold compared with the rod branch. When the same size test spot is used in the peripheral retina during dark adaptation, the typical break appears in the curve representing the cone branch and the rod branch (Fig. 5).

A similar principle applies when different sizes of the test spot is used. When a small test spot is used during dark adaptation, a single branch is found because only cones are present at the fovea. When a larger test spot is used during dark adaptation, a rod-cone break would be present because the test spot stimulates both cones and rods. As the test spot becomes even larger, incorporating more rods, the sensitivity of the eye in the dark is even greater (Fig. 6), reflecting the larger spatial summation characteristics of the rod pathway.

Wavelength of the Threshold Light

When stimuli of different wavelengths are used, the dark adaptation curve is affected. In Fig. 7, a rod-cone break is not seen when using light of long wavelengths, such as extreme red. This occurs because of rods and cones

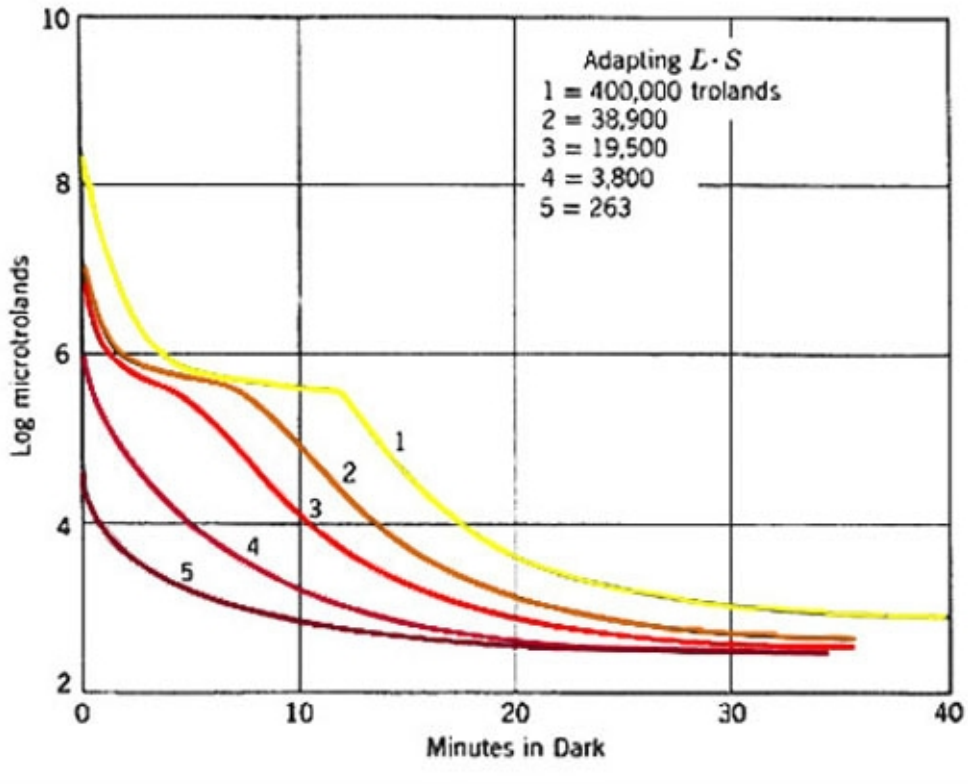

Figure 2. Dark adaptation curves following different levels of pre-adapting luminances. Hecht, Haig and Chase's data are from Bartlett (10).

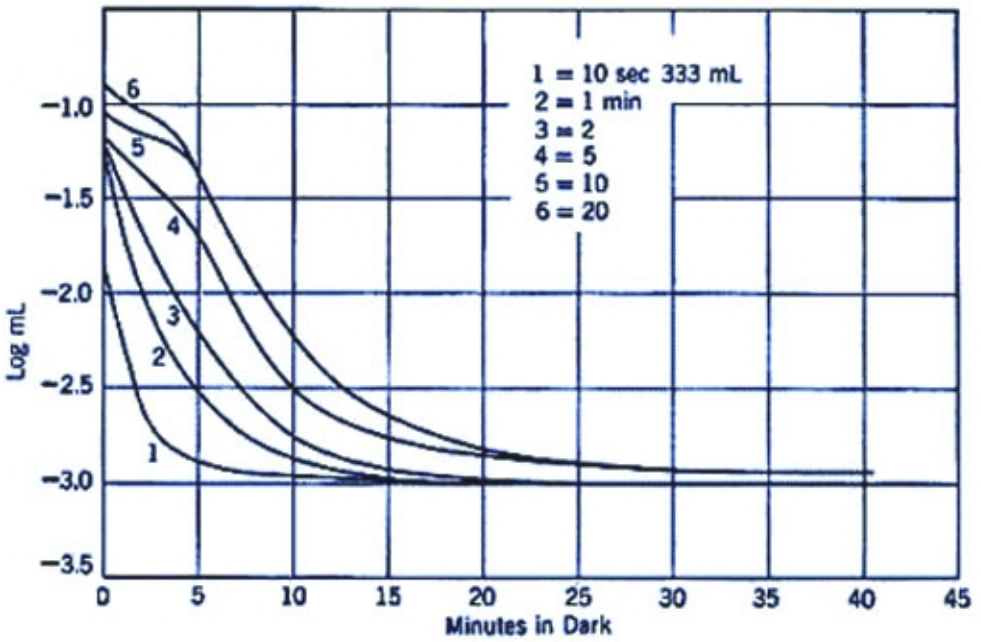

Figure 3. Dark adaptation curves following different durations of a pre-adapting luminance. Wald and Clark's data are from Bartlett (10).

having similar sensitivities to light of long wavelengths (Fig. 8). Fig. 8 depicts the photopic and scotopic spectral sensitivity functions to illustrate the point that the rod and cone sensitivity difference is dependent upon test

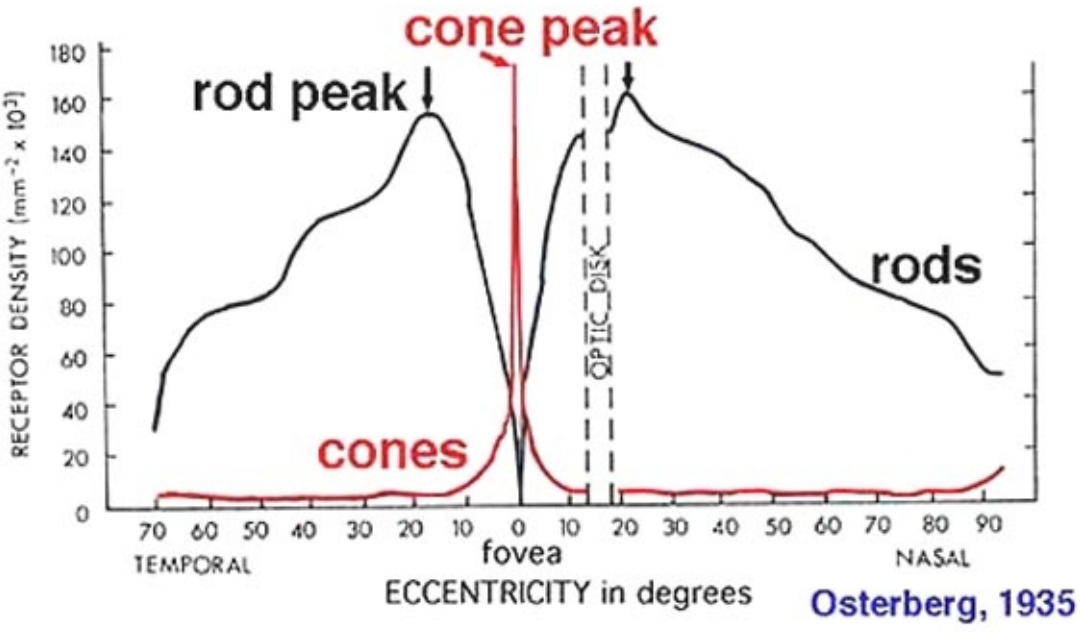

Figure 4. Graph to show rod and cone densities along the horizontal meridian. From Osterberg (11).

wavelength (although normalization of spatial, temporal, and equivalent adaptation level for the rod and cones is not present in this figure). On the other hand, when light of short wavelength is used, the rod-cone break is most

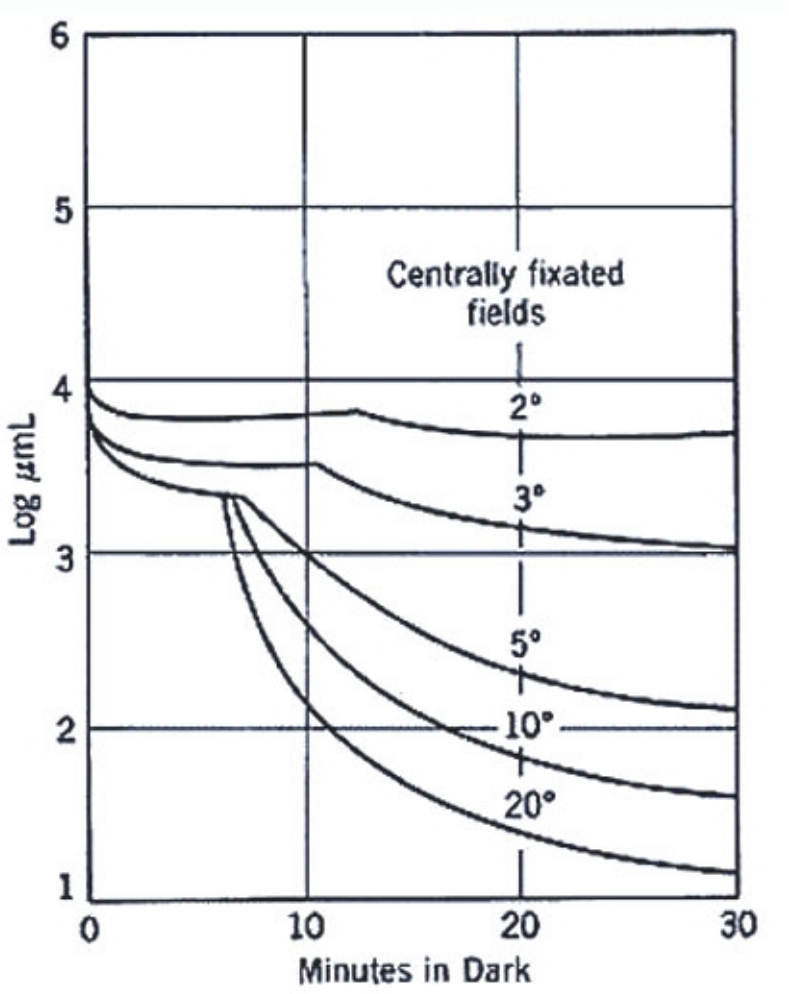

Figure 6. Dark adaptation measured using different size test spots. Hecht, Haig, and Wald's data are from Bartlett (10).

prominent because the rods are much more sensitive than the cones to short wavelengths once the rods have dark adapted.

Rhodopsin Regeneration

Dark adaptation also depends upon photopigment bleaching. Retinal (or reflection) densitometry, which is a procedure based on measuring the light reflected from the fundus of the eye, can be used to determine the amount of photopigment bleached. Using retinal densitometry, it was found that the time course for dark adaptation and rhodopsin regeneration was the same. However, this does not fully explain the large increase in sensitivity with time. Bleaching rhodopsin by 1% raises the threshold by 10 (decreases sensitivity by 10). In Fig. 9, it can be seen that bleaching 50% of rhodopsin in rods raises the threshold by 10 log units, whereas bleaching 50% of cone photopigment raises the threshold by about 1.5 log units. Therefore, rod sensitivity is not fully accounted for at the receptor level and may be explained by further retinal processing. The important thing to note is that bleaching of cone photopigment has a smaller effect on cone thresholds.

Light Adaptation

With dark adaptation, we noticed that there is progressive decrease in threshold (increase in sensitivity) with time in the dark. With light adaptation, the eye has to quickly adapt to the background illumination to be able to

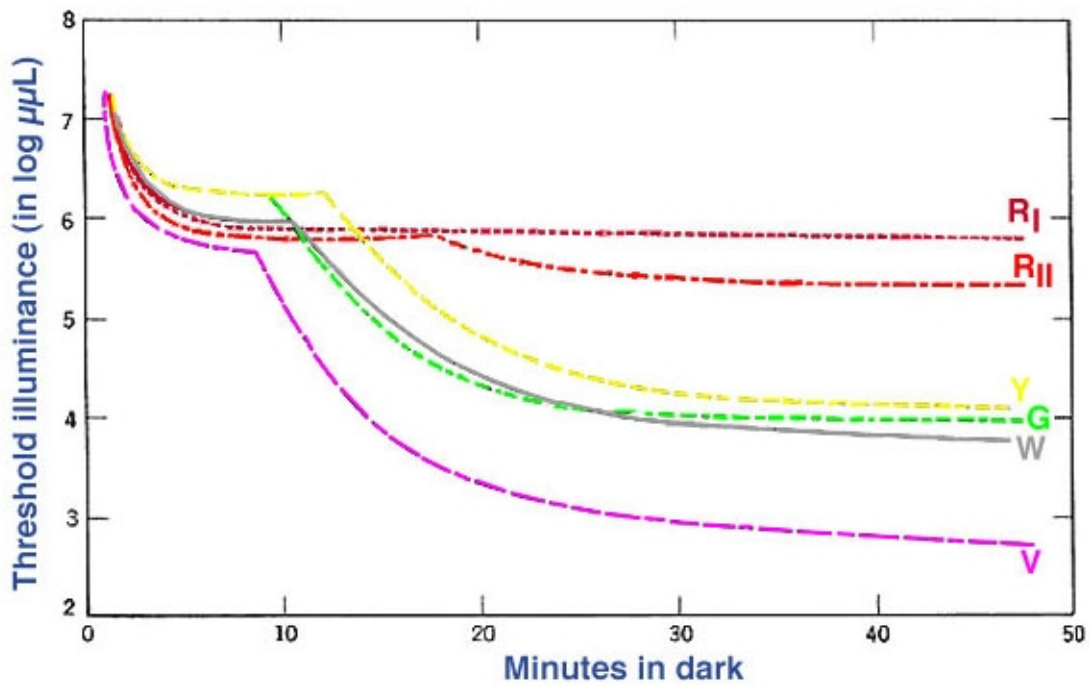

Figure 7. Dark adaptation curve using different test stimuli of different wavelengths. Subjects were pre-adapted to 2,000 mL for 5 minutes. A 3° test stimulus was presented 7° on the nasal retina. The colors were: RI (extreme red), 680 nm; RII (red), 635 nm; Y (yellow), 573 nm; G (green), 520 nm; V (violet), 485 nm; W (white). Chapanis' data are from Bartlett (10).

distinguish objects in this background. Light adaptation can be explored by determining **increment thresholds**. In an increment threshold experiment, a test stimulus is presented on a background of a certain luminance. The stimulus is increased in luminance until the detection threshold is reached against the background (Fig. 10). Therefore, the independent variable is the luminance of the background, and the dependent variable is the threshold intensity or luminance of the incremental test required for detection. Such an approach is used when visual fields are measured in clinical practice.

The experimental conditions shown in Fig. 10 can be repeated by changing the background field luminance. Depending upon the choice of test and background wavelength, the test size, and retinal eccentricity, a monophasic or biphasic threshold *versus* intensity (tvi) curve is obtained. Fig. 11 illustrates such a curve for parafoveal presentation of a yellow test field on a green background. This stimulus choice leads to two branches. A lower branch belongs to the rod system. As the background light level increases, visual function shifts from the rod system to the cone system. A dual-branched curve reflects the duplex nature of vision, similar to the biphasic response in the dark adaptation curve.

When a single system (e.g., the rod system) is isolated under certain experimental conditions, four sections of the curve are apparent. These experimental conditions involve using a red background to suppress the cone photoreceptors and a green test spot to stimulate the rod photoreceptors (2). The curve in Fig. 12 can also be obtained by performing increment threshold experiments on rod monochromats that lack cone photoreceptors. When the rod system is isolated using the conditions of Aguilar and Stiles (2), four sections are obtained:

1. dark light
2. Square Root Law (de Vries-Rose Law)
3. Weber's Law
4. saturation

The threshold in the **linear portion** of the tvi curve is determined by the dark/light level. As background luminance is increased, the curve remains constant (and equal to the absolute threshold). Sensitivity in this section is limited by neural (internal) noise, the so-called "dark light". The background field is relatively low and does not significantly affect threshold. This neural noise is internal to the retina, and examples of these include thermal isomerisations of photopigment, spontaneous opening of photoreceptor membrane channels, and spontaneous neurotransmitter release.

The second part of the tvi curve is called the **Square Root Law** or (**de Vries-Rose Law**) region. This part of the curve is limited by quantal fluctuation in the background. Rose (3) proposed that the visual threshold would be quantal limited. The visual system is usually compared with a theoretical construct, an **ideal light detector**. An ideal detector can detect and encode each absorbed quantum of light and is limited only by the noise due to quantal fluctuations in the source. To detect the stimulus, the stimulus must be sufficiently exceed the fluctuations of the background (noise).

Because the variability in quanta increases with the number of quanta absorbed, threshold would increase with background luminance. In fact, the increase in threshold should be proportional to the square root of the background luminance, hence, the slope of 0.5 in a log-log plot. For the rod pathway, a slope of 0.6 is often found (4). Barlow (5) explored the conditions that influenced the transition from the Square Root Law to **Weber's Law** (see below). He concluded that for brief, small test spots, increment thresholds rise as the square root of the background over the entire photopic range. Spots of large areas and long durations have slopes close to Weber's Law. Other spatio-temporal configurations result in different proportions of each region.

When plotted using log ΔL versus log L coordinates, the Weber law section ideally has a slope 1. For the rod pathway, a slope 0.8 or less is found, implying that the rod pathway does operate under true Weber conditions. This section of the curve demonstrates an important aspect of our visual system. Our visual system is designed to distinguish objects from its background. In the real world, objects have contrast, which is constant and independent of ambient luminance. Therefore, the principle of Weber's law can be applied to contrast that remains constant regardless of illumination changes. This is called contrast constancy or contrast invariance, with this contrast level defined as Weber's constant. Contrast constancy can be mathematically expressed as $\Delta L / L$ = constant. ΔL is the increment threshold on a background L. The constant is also known as the Weber constant or Weber fraction. The Weber constant for the rod and cone is 0.14 (6) and 0.02 to 0.03 (7), respectively. Within the cone pathways, the S-cone pathway again has different characteristics to those of the longer-wavelength pathway with a Weber constant of around 0.09 (8).

Section 4 of the curve (Fig. 12) shows rod **saturation** at high background luminance. The slope begins to increase rapidly, and the rod system starts to become unable to detect the stimulus. This section of the curve occurs for the cone mechanism under high background light levels.

The Perception of Color

Michael Kalloniatis and Charles Luu.[1]

Created: May 1, 2005; Updated: July 9, 2007.

Overview

Color vision processing in the primate visual system is initiated by absorption of light by three different spectral classes of cones. Consequently, color vision is described as being trivariant or trichromatic, and initial psychophysical studies demonstrated that colors could be matched by the use of three different primaries. In 1802, Thomas Young (1) proposed a model that perception of color can be coded by three principal color receptors rather than thousands of color receptors coding for individual colors.

Spectral sensitivity of cones can be determined through several methods. Two of these methods include isolating receptoral responses (2) using calculations from color matching function of normals and dichromats (a dichromat is a subject whose retina has one cone photopigment missing) (3), microspectrometry (4), or reflection densitometry (5, 6). The microspectrometer technique involves isolating a single cone and passing light through it. The change in transmission of different wavelengths can be used to calculate the spectral absorption of the cone or determine the change in electrical response. Reflection densitometry involves directing light in the retina and determining the change in absorption as a function of wavelength. These results are subsequently used to calculate spectral absorption.

Three classes of cones in the human retina have been isolated from the above techniques. These three classes of cones are the short-wavelength-sensitive (S-cones), middle-wavelength-sensitive (M-cones), and long-wavelength-sensitive (L-cones), and all have different but overlapping spectral sensitivities. The spectral sensitivity of S-cones peaks at approximately 440 nm, M-cones peak at 545 nm, and L-cones peak at 565 nm after correction for pre-retinal light loss, although the various measuring techniques result in slightly different maximum sensitivity values (Fig. 1).

Color Matches

The trichromatic nature of color vision will enable almost any color to be matched by a mixture of three colors. This trichromacy of vision is also linear. This means that colorimetric equations have properties of an ordinary equation.

The color matches of quantity C_s of a stimulus S can be expressed as:

$$Cs(S) = C1(l1) + C2(l2) + C3(l3)$$

where *li* are the three primary colors (not necessarily monochromatic spectral colors) and *Ci* are tristimulus values.

Tristimulus values represent the quantities of each of the three primaries necessary to achieve a match for color and luminosity (Fig. 2). They can be expressed in units of luminous flux or radiant flux, or even an arbitrary scale provided that the arbitrary scale conveys the relative proportions of the three quantities.

From Moses and Hart (26).

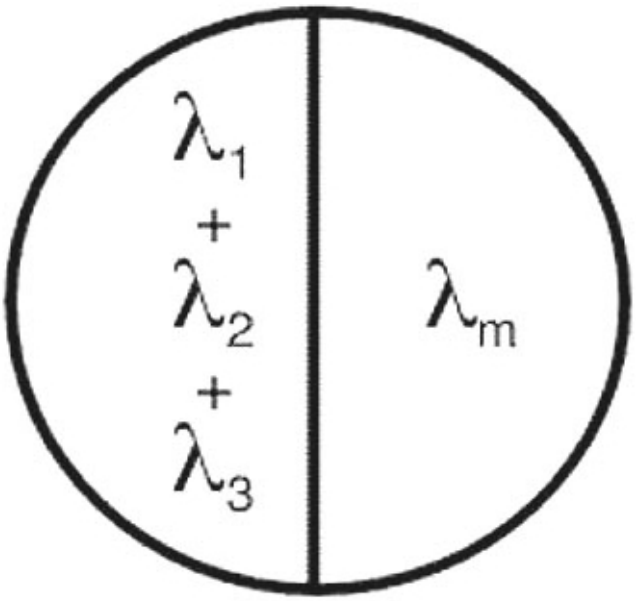

Figure 2. Subjects are asked to adjust three colors on the left-hand side of the bipartite field to match a standard color presented on the right-hand side of the bipartite field.

Additive and Subtractive Color Mixtures

Two or more colors can be added together to produce a new color composed of the mixture of the initial colors used. This can be demonstrated on a white screen with three colors: blue, green, and red. Cyan, magenta, yellow, and white are formed from the mixture of these colors (Fig. 3). One of the requirements in choosing colors to be used in color mixing experiments is that two of them cannot be mixed to produce the third.

Subtractive color mixtures involve the selective absorption of wavelengths. Cyan, magenta, and yellow are subtractive primaries. If white light was shone through a yellow filter, the yellow filter will absorb blue and transmit red and green (which makes yellow). Therefore, yellow can be considered as a -B filter. A magenta filter subtracts or absorbs green (-G filter) from white light, and cyan subtracts or absorbs red (-R filter) from white light (Fig. 4).

Grassmann's Laws provide a quantitative description of color matching data (7). They hold up well within a prescribed set of conditions (with respect to brightness, adaptation of the observer, size of the field, etc). Grassmann's Laws are useful in quantifying color matching data, but as a rule, color matching data are affected by the following:

- macular pigment (xanthophyll) variations in subject's central 4-5 degrees of vision
- chromatic aberrations
- rod intrusion, especially when large fields and low photopic light levels are involved
- failure of Abney's Law of luminance additivity including the Helmholtz-Kohlrausch effect
- Bezold-Brücke hue shift at bright intensities

Color Specification

The Munsell Color System

All colors can be fully specified in terms of their hue, lightness, and saturation. The Munsell system has three dimensions: hue, value, and chroma. These three dimensions correspond to the three perceptual attributes of human color vision.

The three dimensions of the Munsell color system are:

1. Hue: Related to wavelength or dominant wavelength. Hue is denoted by a combination of letters and numbers making up a 100-step scale (Fig. 5). There are 10 letter categories used to denote hue, with each of these further subdivided (by the use of numerals 1 to 10) into 10 subgroups. If the numeral denoting the hue subgroup is 5, then it can be omitted (e.g., 5R is the same hue as R).
2. Value: Specified on a numerical scale from 1 (black) to 10 (white), and this attribute is related to reflectance and luminosity (or lightness).
3. Chroma: The Munsell term corresponding to saturation. It is indicated numerically on a scale of 0 to the various maxima, dependent on the saturation obtainable with available pigments.

For example, a color may have a notation 2GY 6/10. This means it is a green/yellow that is quite close to being a yellow; it has a value of 6 (i.e., almost midway in the black/white scale) and a chroma of 10 (i.e., it is saturated).

The scaling used in the Munsell system is designed to be perceptually uniform. In other words, the color samples are arranged in equal, visual steps. For example, the perceived difference between a chroma of 3 and a chroma of 4 is (nominally) the same as the perceived difference between chroma 4 and 5. This scaling is the same for all three dimensions, although step sizes along different dimensions are *not* comparable (that is, a single step difference in hue does not have the same perceptual difference as a single step in saturation).

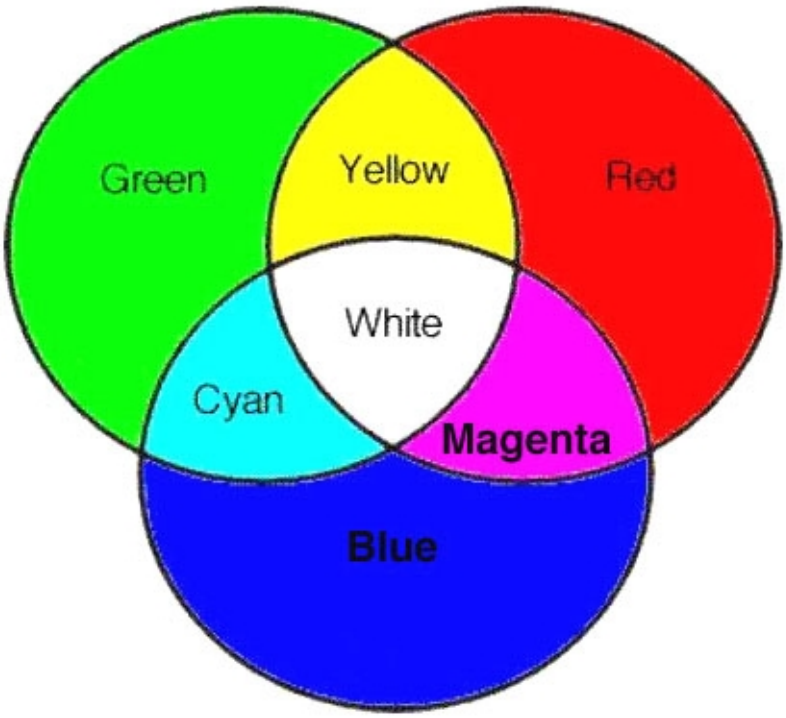

Figure 3. Additive color mixtures of blue, green, and red to produce cyan, magenta, yellow, and white.

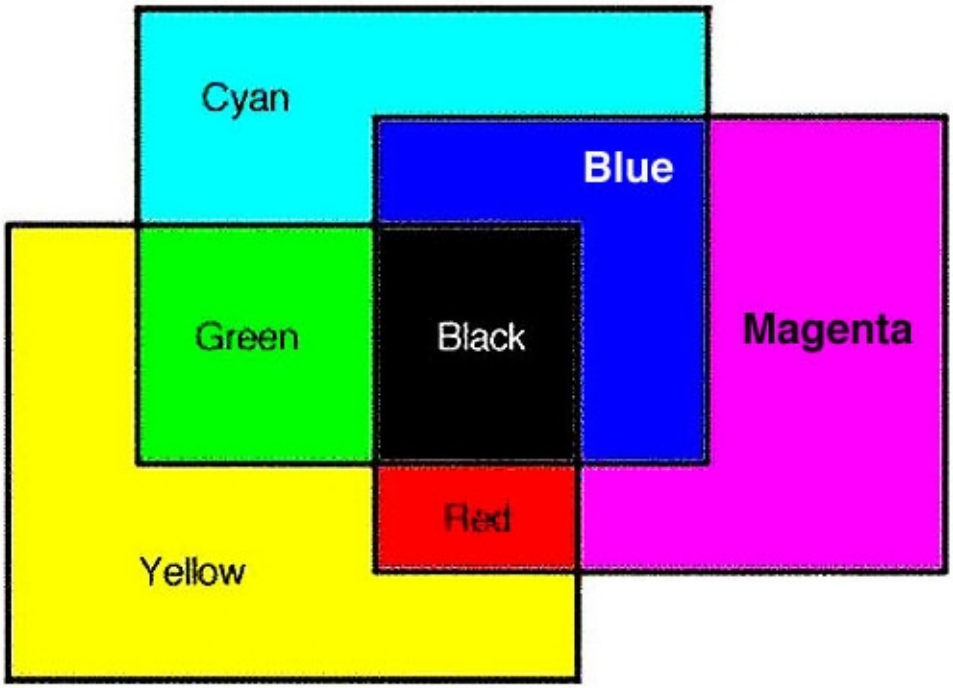

Figure 4. Subtractive color mixtures of cyan, magenta, and yellow to produce blue, green, and red.

A schematic representation of the Munsell system is shown in Fig. 6. The value scale is on the vertical axis, the hue scale is on the perimeter of the cylinder, and chroma is on a radial scale. The Munsell top, shown in Fig. 5, is a more precise representation of this concept.

1931 Commision Internationale d'Elairage (CIE) Chromaticity System

Trichromatic color matches using three colors can be illustrated on Newton's color circle (Fig. 7). Newton's color circle consists of the following components:

- a circle representing the spectral colors (although not shown here, mixtures of blue and red (purple locus) are not spectral colors, and hence, a straight line between R and B is more appropriate)
- a triangle whose vertices represent the three primary colors used to make color matches (R, G, and B)
- the center of the circle representing white (W)

Newton's color circle provides a qualitative description of color matches and can be used to explain why two colors may not be sufficient to make color matches and to also explain the use of "negative" colors. For example, if 500 nm is required to be matched (spectral color located on the circle), blue and green will be required. However, blue and green primaries alone will produce a desaturated 500 nm. Therefore, red must be added to the spectral color to desaturate it and make the match (Fig. 8). When the third primary is added to desaturate the color mixture, negative tristimulus values result (Fig. 5). This can be demonstrated by the following equation:

$$500\ \text{nm}\ (\text{S}) + \text{R} \equiv \text{G} + \text{B}$$

or

$$500\ \text{nm}\ (\text{S}) \equiv \text{G} + \text{B} - \mathbf{R}$$

To deal with the "negative" colors, the CIE devised the XYZ system that uses unreal (imaginary) primaries to describe color space. The 1931 CIE chromaticity system chose three imaginary primaries (reference stimuli) X, Y, and Z, so that all spectral loci lying inside this triangle will be positive. The alychne are locus of colors with no luminosity, and this was chosen to lie along the X to Z on the XYZ chromaticity system. All luminosity is expressed in Y. The reference loci of Y was chosen to just enclose the domain of real colors. Equi-energy white was chosen to have equal chromaticity co-ordinates, that is, 0.33, 0.33 (Fig. 9 and Fig. 10). Chromaticity co-ordinates represents the relative contribution of the three primaries, and the sum of the co-ordinates equals 1.0. Therefore, z can be calculated, by knowing the co-ordinates x and y because $x + y + z = 1$.

Dominant wavelength, complementary wavelength, and excitation purity can be easily located for a sample. The dominant wavelength represents the principle wavelength of the color. The complementary wavelength is the wavelength that produces white when mixed in appropriate portions with the dominant wavelength. Spectral complementaries can be found when a line joined by a line passes through the achromatic point shown as C (Fig. 11). The dominant wavelength of A is given by the spectral wavelength at DA, and the complementary is given by the wavelength at CA (Fig. 11). Point C identifies the location of the white point and B identifies another wavelength that, when mixed at the appropriate proportions, will produce white.

The achromatic point varies, depending upon the standard illuminant that is used (Fig. 12). A shift in the *x* and *y* co-ordinates occurs as color temperature increases. For standard illuminant C, there is no complimentary wavelengths for green (between wavelengths 492 nm to 567 nm). However, white light can be formed with a suitably chosen purple light (Fig. 12).

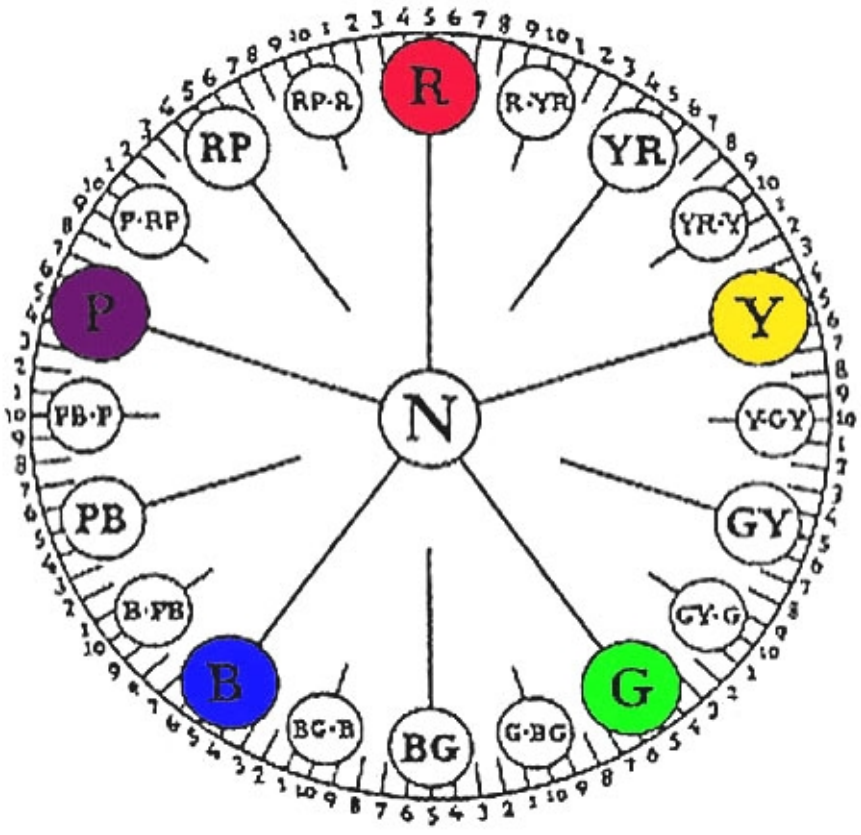

Figure 5. The Munsell top showing the location of the different colors.

Color Discrimination Functions

The three variables in color vision—hue, saturation, and brightness—all depend on wavelength. Color discrimination experiments allow us to know how much change in wavelength is required to detect a difference in hue, saturation, and brightness.

Hue discrimination describes the amount of change in wavelength (l + Δl) that is required to be able detect a change in hue. For blue and red light, a large change in wavelength is required to detect a change in hue, whereas a less than 2-nm change in wavelength is needed for most of the spectrum for a person with normal color vision (Fig. 13).

Saturation discrimination describes the degree of paleness of the color. Saturation is related to colorimetric purity (P), which is also defined as:

$$P = L/(Lw+L)$$

where *L* is the luminance of the spectral color and *Lw* is the luminance of the white that is mixed with the spectral color. The colorimetric purity of a color quantifies the amount of white mixed with the spectral color. If the spectral color is pure (no white added), then the colorimetric purity is 1.

In saturation discrimination experiments, the luminance is kept constant. A bipartate field is used with white (*Lw*) on one side and white mixed with the spectral color on the other side (Lw + ΔL). It can be seen in Fig. 14

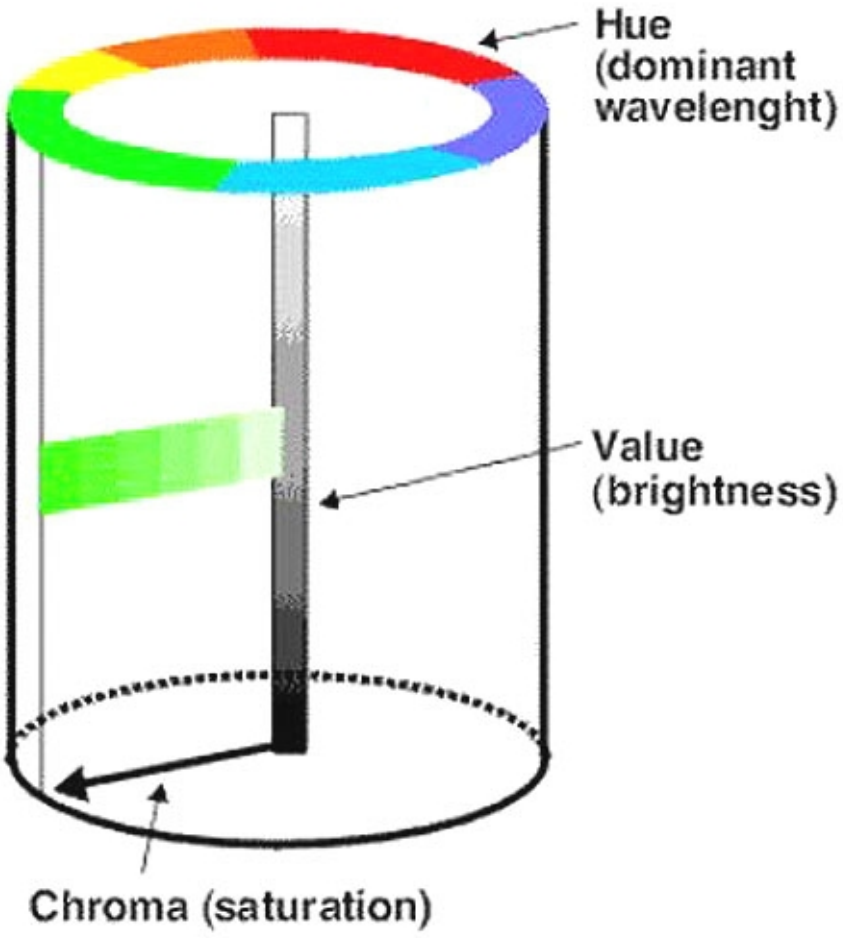

Figure 6. Munsell color system, illustrating hue, value, and chroma.

that more 570-nm color is required to make the white patch appear colored. Therefore, yellow has low saturating power, whereas blue and red have high saturation power.

The V(λ) function closely matches the sensation of brightness and hence is commonly considered to reflect **brightness discrimination**. The wavelength 555 nm is perceived as the brightest in the color spectrum (see the earlier section on the photopic and scotopic luminosity function).

Theories of Color Vision

Any theory of color vision must predict all the perceptual attributes noted earlier. We present here a simplistic view of the trichromatic and color opponent theories. See the Color Vision chapter by Peter Gouras for a discussion on the physiological correlate of color opponency.

The **trichromatic theory** was first proposed by Thomas Young in 1802 (1) and was explored further by Helmholtz (8) in 1866. This theory is primarily based on color mixing experiments and suggests that a combination of three channels explain color discrimination functions.

Evidence for the trichromatic theory includes:

- identification of the spectral sensitivities of two cone pigments by Rushton's retinal densitometry (5)
- identification of three cone pigments by microspectrometry (9)

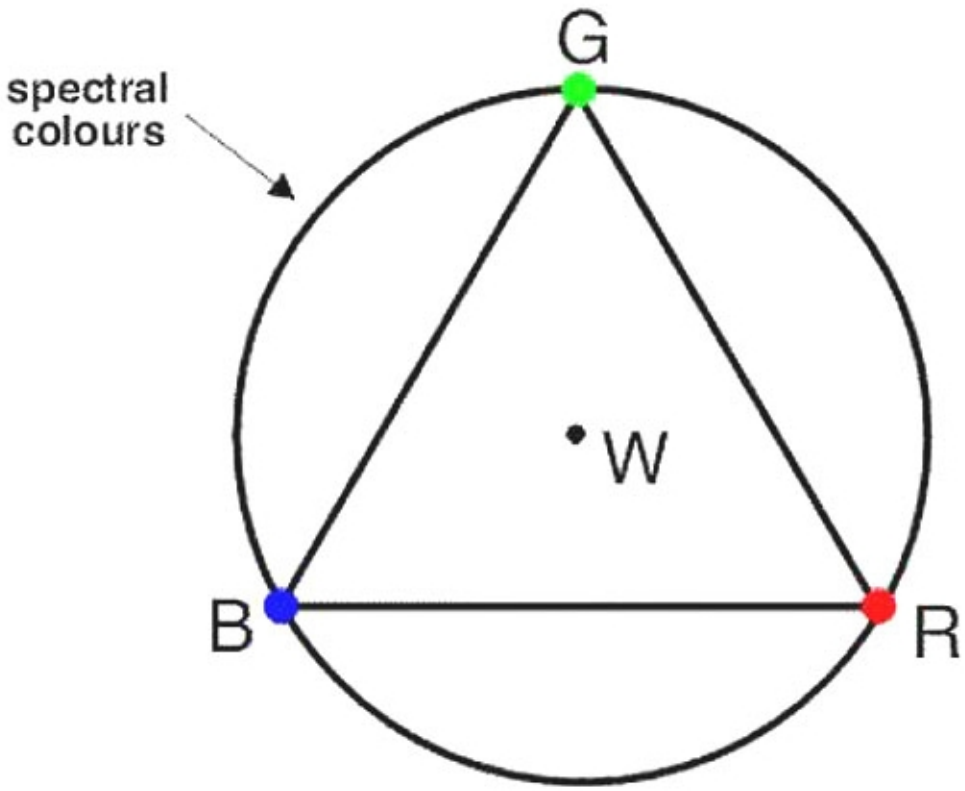

Figure 7. Newton's color circle.

- identification of the genetic code for L, M, and S cones (10, 11)
- color matching functions
- isolating photoreceptors and measuring their physiological responses as a function of wavelength (2)
- Spectral sensitivity measurements (Wald-Marre spectral sensitivity functions and Stiles' π-mechanisms)

However, the trichomatic theory fails to account for the four unique colors—red, green, yellow and blue—and also fails to explain why dichromats can perceive white and yellow. It also fails to fully explain color discrimination functions and opponent color percepts.

The **opponent color theory** was first proposed by Hering (12) in 1872. At the time, this theory rivaled the well-accepted trichromatic theory, which explains the trichromasy of vision and predicts color matches. Hering's opponent color theory suggests that there are three channels, red-green, blue-yellow, and black-white, with each responding in an antagonist way. That is, either red or green is perceived and never greenish-red. Hering, however, never challenged the initial stages of processing expressed by the trichromatic theory. He simply argued that any color vision theory should explain our perception, that is, color opponency as revealed by colored after images.

Hurvich and Jameson (13) provided quantitative data for color opponency. Using hue cancellation paradigms, the psychophysical color opponent channels were isolated. The Vλ function was used for brightness discrimination to describe the perception of blackness and whiteness. Therefore, by adjusting the amount of blue or yellow AND red or green, any sample wavelength can be matched (Fig. 15). Complementary wavelengths can be used to cancel each other for all wavelengths except the four unique hues (blue, green, yellow, and red).

Other evidence supporting the opponent color theory include:

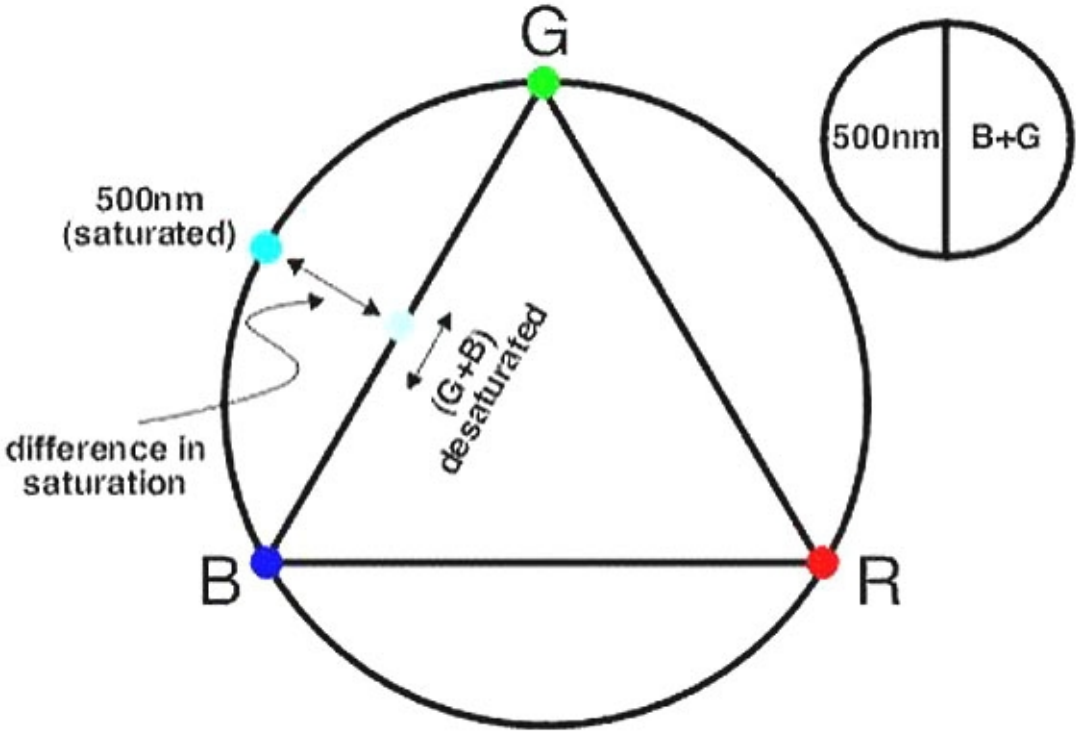

Figure 8. The use of Newton's color circle to illustrate matching a spectral color of 500 nm using the three primaries.

- Electrical recordings of horizontal cells from fish retina show blue-yellow opponent process and red-green opponent (14).
- Electrical recordings from the lateral geniculate nucleus show opponent color processes (15).
- Electrical recordings of ganglion cells from primate retinas show opponent color processes (16-18).

Stage Theory

This has led to the modern model of normal color vision, which incorporates both the trichromatic theory and the opponent color theory into two stages (Fig. 16). The first stage can be considered as the receptor stage, which consists of the three photopigments (blue, green, and red cones). The second is the neural processing stage, where the color opponency occurs. The second stage is at a post-receptoral level and occurs as early as the horizontal cell level.

Color Vision Deficiencies

Color vision deficiencies (CVDs) can be congenital or acquired. Congenital CVD means that the CVD is present at birth and is inherited, whereas acquired CVD occurs secondary to eye disease. Congenital CVD affects ~8% of males and ~0.5% of females.

CVDs are classified into three groups. These are monochromasy, dichromasy, and anomalous trichromasy. People with normal color vision are called trichromats. Monochromats are typically totally color blind and may have one cone pathway in addition to the rod pathway. Dichromats have a cone photopigment missing; therefore, they only have two cone channels. Anomalous trichromats have all three cone photopigments;

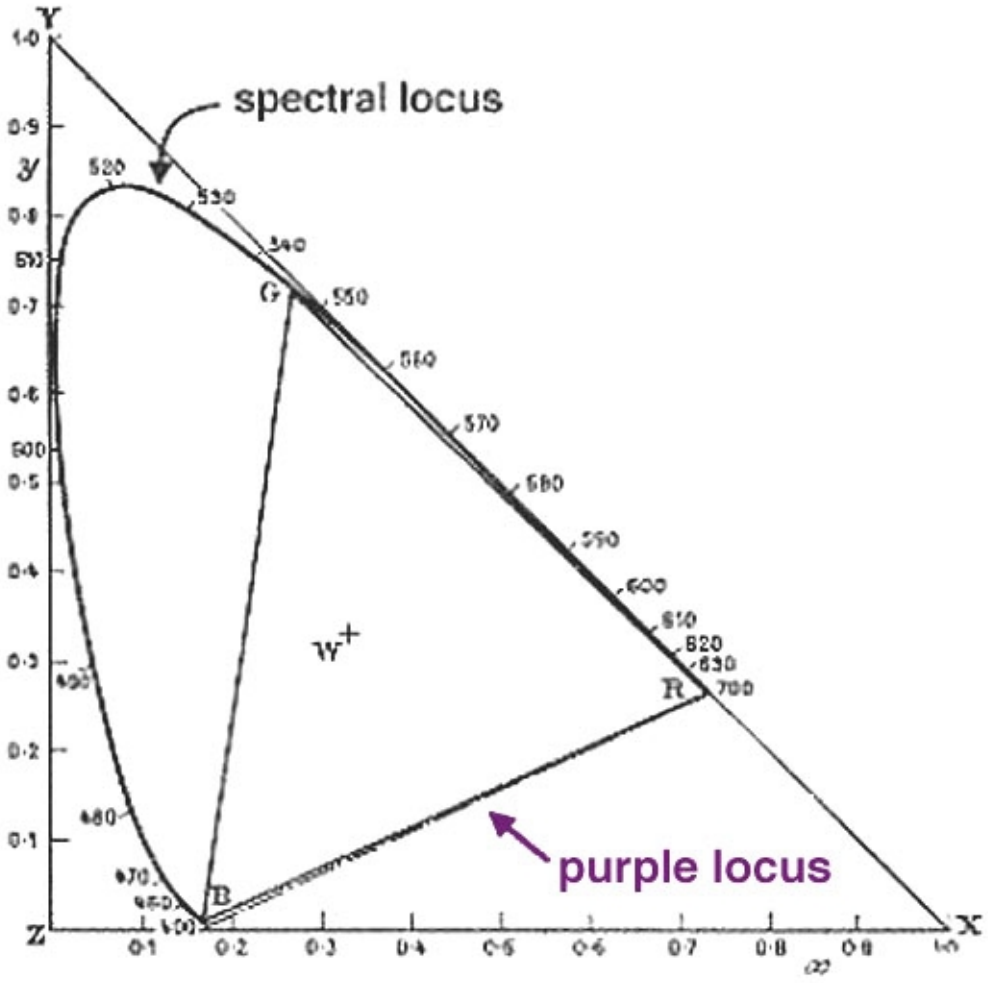

Figure 9. 1931 CIE chromaticity diagram. The triangle represents the three primaries used in the RGB system. From Le Grand (27).

however, one cone photopigment is anomalous, having a shifted peak sensitivity The types and prevalence of CVDs are listed in Table 1.

Dichromasy and anomalous trichromasy can be classified according to the affected cone photopigment. Three terms that are used also used to describe CVD are protan, deutan, and tritan (from the Greek protos, first; deuteros, second; and tritos, third; the order that the CVDs were described). A protan has the longer wavelength cone photopigment missing or anomalous, a deutan has the middle wavelength cone photopigment missing or anomalous, and the tritan has the shorter wavelength cone photopigment missing or anomalous (Fig. 17).

The pattern of inheritance for deutan (red-green) CVD is sex-linked recessive, whereas a tritan CVD has an autosomal dominant inheritance. The genetics of CVDs is particularly important in the clinic because patients are often keen to understand why they are CVD and whether they will pass their CVD to their children. For some time, it was thought that congenital inherited tritanopia did not exist because so few cases had been reported. Also, tritan-like CVDs are associated with disease, making it essential to discriminate between acquired and congenital tritan defects. The existence of congenital inherited tritanopia was originally established by family studies (19-21) and subsequently confirmed by molecular genetics (10, 11).

Table 1. **Prevalence of congenital color deficiencies.**

Types of color vision deficiency	Males	Females
Overall	~8%	~0.5%
Anomalous trichromasy		
Protanomaly	1%	0.01%
Deutanomaly	5%	0.4%
Tritanomaly	Rare	Rare
Dichromasy		
Protanopia	1%	0.01%
Deuteranopia	1.5%	0.01%
Tritanopia*	0.008%	0.008%
Monochromasy		
Rod monochromasy	Rare	Rare
Cone monochromasy	Rare	Rare
Atypical monochromasy	Very rare	Very rare

*Modified after Cole (33), Pease (22), and estimates from Wright (34).

Using the CIE Diagram to Develop Diagnostic Color Vision Tests

Discrimination of color by dichromats is limited due to one photopigment being absent. Therefore, when it comes to color matching, certain colors are confused with another. Confusion lines are lines joining points on the chromaticity diagram that appear the same in color for dichromats. The number of confusion lines also provide information about the amount of change in wavelength (Δl) before another color is discriminated (when the next confusion line is met). All confusion lines converge to a point called the copuntal point (Fig. 18).

Fig. 19 shows the confusion lines for a protanope and a deuteranope. There are 17 confusion lines for a protanope and 27 confusion lines for a deuteranope. Therefore, deuteranopes can discriminate more colors because smaller changes in wavelength (Δl steps) can be discerned. Fig. 20 shows the confusion lines for the tritanope.

Color Vision Tests

Confusion lines form the basis of many color vision tests such as the Farnsworth Panel D-15 and Ishihara Pseudoisochromatic plates. Pseudoisochromatic plate tests are also commonly used in the clinic to screen for color vision deficiency. Colors are carefully chosen based on the confusion lines. The most commonly used pseudoisochromatic plate in the clinic would be the Ishihara Isochromatic plates (for screening red-green color vision deficiency) and the Tritan (F-2) plate.

Pseudoisochromatic plates are designed in four ways:

1. Transformation plates: where a person with normal color vision sees one figure and a CVD person sees another (Fig. 21a).
2. Vanishing plates: where a person with normal color vision sees the figure whereas a CVD person will not (Fig. 21b).

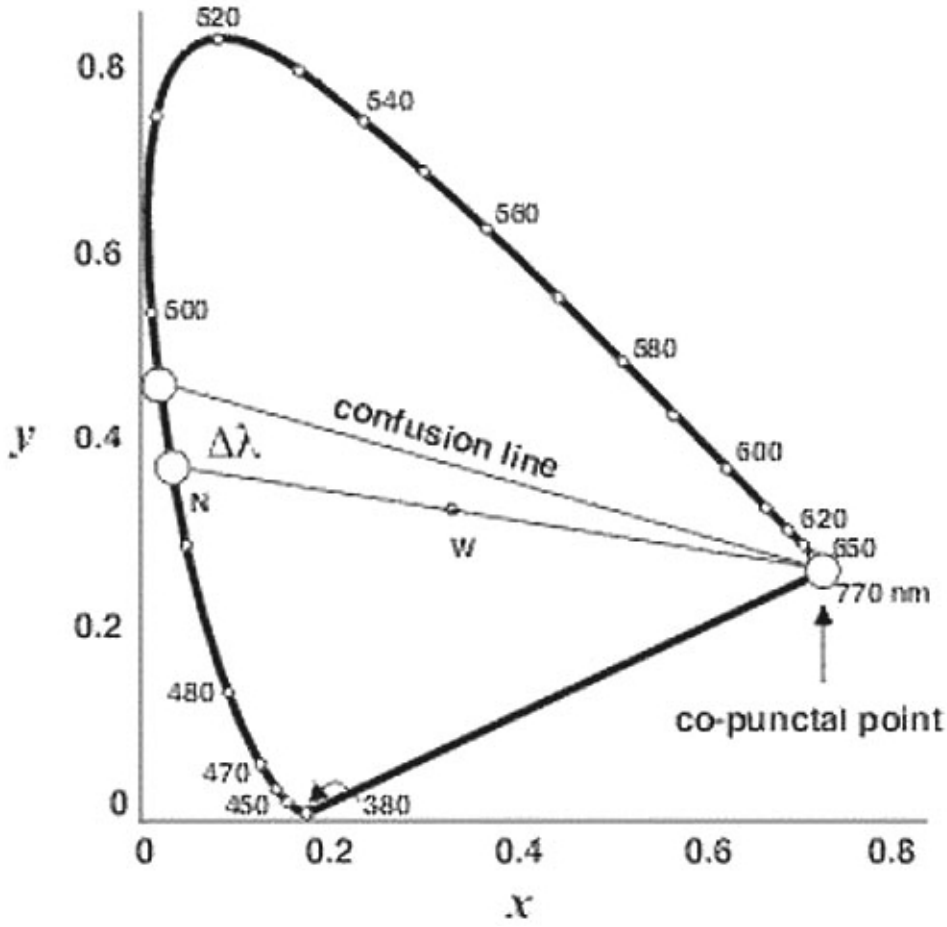

Figure 18. Schematic of two confusion lines showing the copunctal point and Δλ for a protanope.

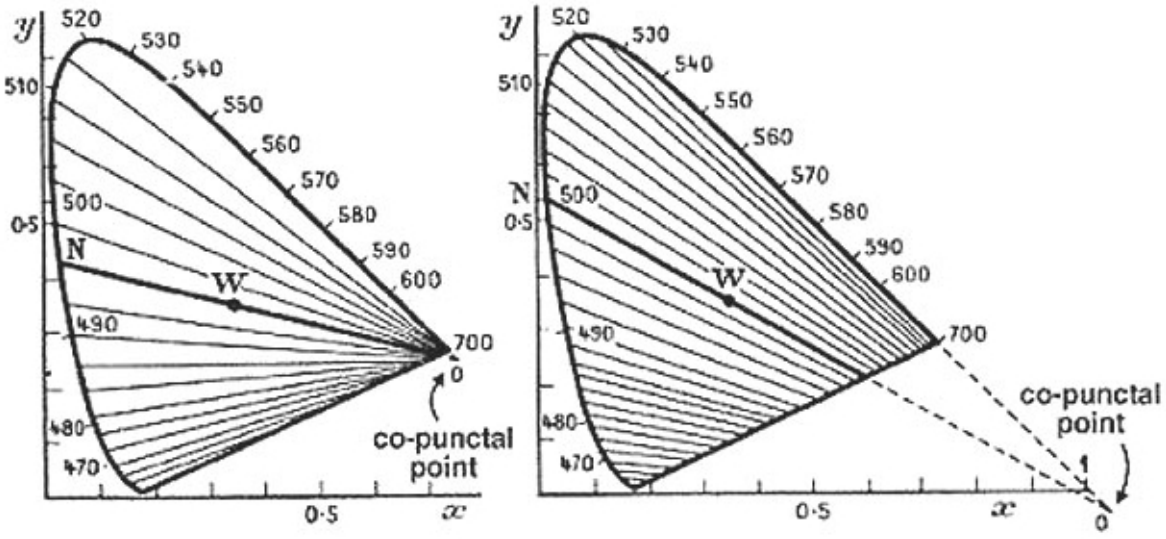

Figure 19. Confusion lines for a protanope (a) and a deuteranope (b). Pitts' data in 1935 from Le Grand (27).

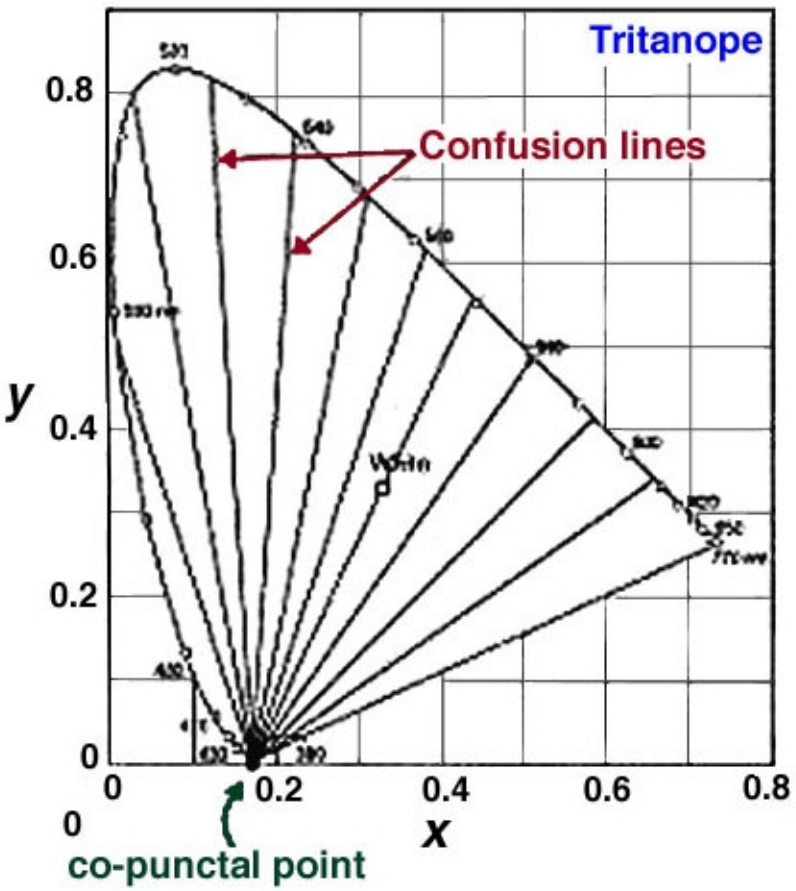

Figure 20. Confusion lines for a tritanope. From Benjamin (28).

3. Hidden-digit plates: where a person with normal color vision does not see a figure whereas a CVD will see the figure (Fig. 22a).
4. Diagnostic plates: designed to be seen by normal subjects and persons with CVDs see one number more easily than another (Fig. 22b).

The Ishihara color vision test is a screening test, and the fail criterion for the Ishihara is typically four or more plates. Further color vision testing will be required to confidently diagnose the type of color vision defect. Another useful screening plate test is the Farnsworth F-2 plate (22). There are many color vision tests available for screening and for diagnosis, of which only a few will be discussed here. The colors of the Panel D-15 are also carefully chosen from the CIE diagram so that they are all isoluminant (that is, have the same value), as seen in Fig. 23.

Patients are asked to arrange 15 colored caps in sequential order based on the similarity from the pilot color cap (Fig. 24). The type of color vision defect can be detected from their arrangement of the caps. These color caps are arranged in a particular fashion because of the confusion of colors that lie on the confusion lines (Fig. 25). The criterion for failure in the Panel D-15 test is two or more major crossings (i.e., greater than a two-cap error). Deutan, protan, and tritan will produce characteristic errors (crossings) according to their confusion lines. Rod monochromats are color blind, and their Vl peaks at about 507 nm. They arrange the D-15 caps according to the scotopic reflectance of the D-15 caps.

Other arrangement color tests include the L'Anthony's Desaturated Panel D-15, saturated H-16, and the Farnsworth 100-Hue Test. The desaturated panel D-15 is particularly useful in the early diagnosis of acquired diseases and mild congenital deficiencies. The sequence of test administration includes screening for CVDs with a pseudo-isochromatic plate test such as the Ishihara and F-2 plate. Failure of either of these tests implies proceeding to the panel D-15. A patient who fails the Panel D-15 is said to be a moderate to severe anomalous dichromat, or a dichromat. A patient who then fails the H-16 is a dichromat or very severe anomalous trichromat, whereas a moderate anomalous trichromat will pass the H-16. A subject who passes the D-15 can proceed to the desaturated D-15, which can pick up the mild anomalous trichomats. The very mild anomalous trichromats who may or may not fail pseudoisochromatic plates can be diagnosed with the Nagel anomaloscope.

The Farnsworth 100-Hue is another arrangement test (Fig. 26). Unlike the tests mentioned above where the colors are specifically chosen to lie close to the confusion lines, the Farnsworth100-Hue is a discrimination test. Fig. 27 shows where the colors of the 100-Hue lie on the chromaticity diagram. The colors are chosen to have the same Munsell value and chroma. Originally, there were 100 hues, but Farnsworth removed 15 to make the series more uniform. Performance on the Farnsworth 100-Hue is rated by calculating the total error score.

Lantern tests have been used since the19th century as a means of assessing color vision, especially for occupational reasons. Lantern tests simulate colored signal lights. They usually present pairs of red, white, and green lights, because these are the signal colors used at sea and in air navigation, and the subject is required to name the colors. There are a great number of different lantern tests that vary quite widely in the level of difficulty they present. The level of difficulty depends on the size of the stimulus and its intensity (see Cole and Vingrys (23, 24) for a review). The lanterns in current use are the Farnsworth lantern, now superseded by the Optec 900, the Holmes Wright Type A and B lanterns, and the Beyne lantern (Fig. 28).

Lantern tests are usually failed by dichromats and anomalous trichromats whose defect is severe enough to cause them to fail the Farnsworth D15 test, but the ability to recognize small colored signal lights can vary quite widely among those with mild anomalous trichromasy. A pass at the D15 test or a small range at the anomaloscope does not necessarily mean that signal light colors can be recognized (25).

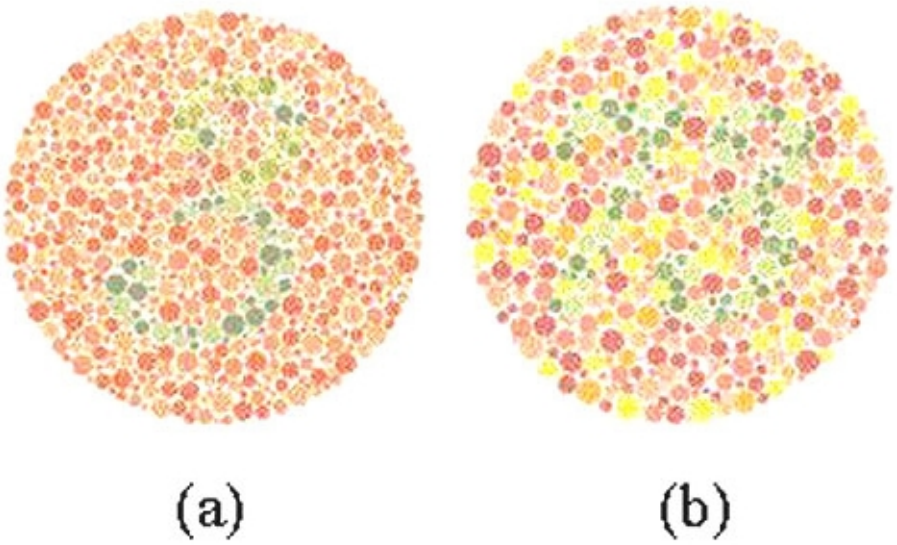

Figure 21. a, the transformation plate of the Ishihara. Normal should see 3, whereas a CVD person should see 5. b, the vanishing plate of the Ishihara. Normal should see 73, whereas a CVD person will not read the figures correctly.

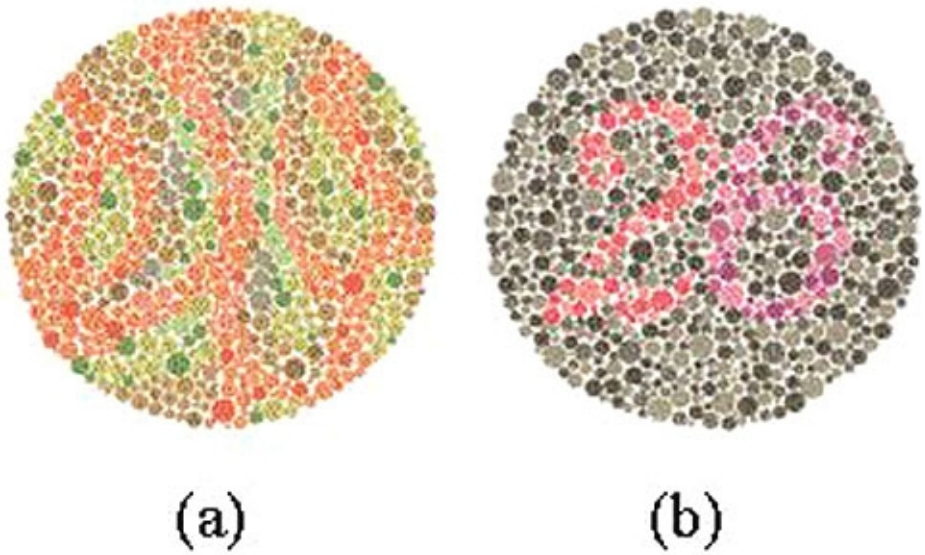

Figure 22. a, the hidden-digit plate of the Ishihara. Normal should not see anything, whereas a CVD person should see 5. b, the diagnostic plate of the Ishihara. Normal should see both the 2 and the 6. Deutan-type CVD should see 2 more easily, whereas a protan-type CVD should see the 6 more easily.

About the Authors

Michael Kalloniatis was born in Athens Greece in 1958. He received his optometry degree and Master's degree from the University of Melbourne. His PhD was awarded from the University of Houston, College of Optometry, for studies investigating colour vision processing in the monkey visual system. Post-doctoral training continued at the University of Texas in Houston with Dr Robert Marc. It was during this period that he developed a keen interest in retinal neurochemistry, but he also maintains an active research laboratory in visual psychophysics focussing on colour vision and visual adaptation. He was a faculty member of the Department of Optometry and Vision Sciences at the University of Melbourne until his recent move to New Zealand. Dr. Kalloniatis is now the Robert G. Leitl Professor of Optometry, Department of Optometry and Vision Science, University of Auckland. e-mail: m.kalloniatis@unsw.edu.au

Charles Luu was born in Can Tho, Vietnam in 1974. He was educated in Melbourne and received his optometry degree from the University of Melbourne in 1996 and proceeded to undertake a clinical residency within the Victorian College of Optometry. During this period, he completed post-graduate training and was awarded the post-graduate diploma in clinical optometry. His areas of expertise include low vision and contact lenses. During

his tenure as a staff optometrist, he undertook teaching of optometry students as well as putting together the "Cyclopean Eye", in collaboration with Dr Michael Kalloniatis. The Cyclopean Eye is a Web based interactive unit used in undergraduate teaching of vision science to optometry students. He is currently in private optometric practice as well as a visiting clinician within the Department of Optometry and Vision Science, University of Melbourne.

The Perception of Space

Michael Kalloniatis and Charles Luu.[1]

Created: May 1, 2005; Updated: June 6, 2007.

Retinal Disparity

When we look at an object with two eyes, we perceive it as singular, like we do other parts of the visual scene stimulating points on our retina that share a common visual direction. These points are termed "retinal corresponding points" and fall on an area called the "horopter". Points outside the horopter fall on slightly different retinal areas and so do not have the identical visual direction and lead to "retinal disparity", the basis of our depth discrimination. This retinal image disparity occurs due to the lateral displacement of the eyes. The region in visual space over which we perceive single vision is known as "Panum's fusional area", with objects in front and behind this area being in physiological diplopia (i.e., double vision). Our visual system suppresses this diplopia, and hence we do not perceive double vision under normal viewing conditions. To understand the discussion on the horopter and Panum's fusional space, the sense of direction will be introduced. Two terms describing direction sense are oculocentric and egocentric visual direction.

Oculocentric Visual Direction

The visual direction of an object can be represented by a line that joins the object and the fovea called the Principal Visual Direction or visual axis. On the basis of the principal visual direction, the direction of all other objects in the subject's visual field is determined. This is the called oculocentric visual direction. Therefore, each point of the retina can be considered to have it own sense of direction. For example, when we look at an object, the object is imaged on the fovea. Other objects imaged above the fovea are seen as "below", and those imaged below the fovea are seen as "above". Visual sense of direction is organized about the fovea. For a given position of the eye, objects having superimposed retinal images will be seen as being in alignment in the visual field, but at a different distance from the eye (Fig. 1).

Egocentric Visual Direction

Egocentric visual direction refers to the direction of an object in space relative to one self, rather than the eyes. Egocentric direction is determined by retinal position, proprioceptive information about the eye, head and body position, and the vestibular apparatus. All this information allows us to determine whether a change in retinal position is due to object movement or due to eye or head movement. In Fig. 2a, a stationary object is imaged on the fovea with the head and the body stationary. When the eye moves, the stationary object is then imaged on a new retinal position. Therefore, oculocentric direction has changed, but the egocentric direction has not changed as the object has remained stationary. In another example, the eye tracks a moving object (Fig. 2b). As the object is imaged on the fovea at all times, the oculocentric direction is the same, but the egocentric direction is changing.

In binocular vision, the idea of corresponding retinal points has been used to describe the principle visual direction. Corresponding retinal points are points stimulated on the retina that give rise to the same visual direction. When objects stimulate non-corresponding points, this gives rise to different visual directions. These retinal points are called disparate points. Therefore, corresponding points have the same principle visual direction, and non-corresponding points have different visual directions (Fig. 3).

As we see the world single and not double, binocular vision can be represented by a single eye, the cyclopean eye. The cyclopean eye is an imaginary eye situated midway between the two eyes (Fig. 4). Disparate points give rise

Author Affiliation: 1 Department of Optometry and Vision Sciences University of Melbourne, Australia.

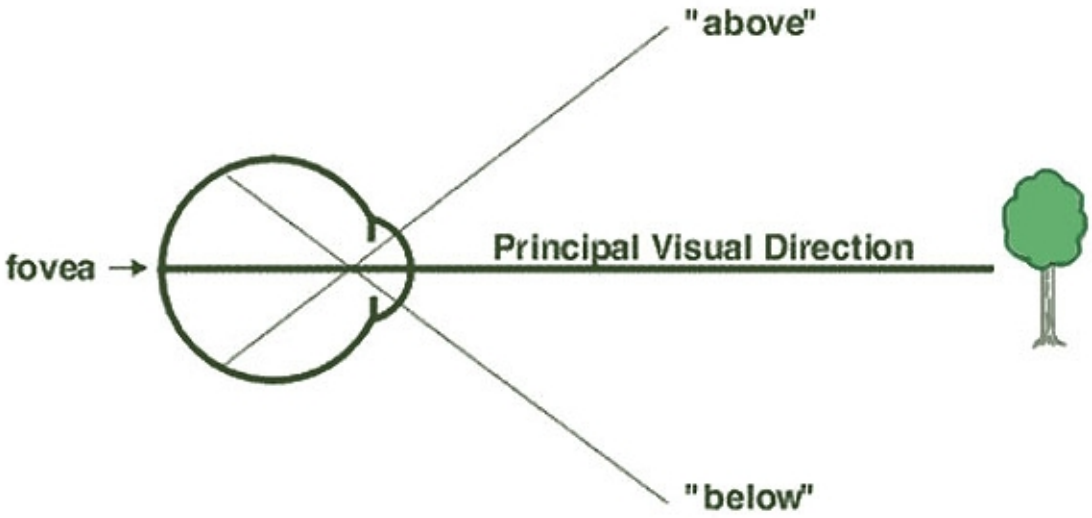

Figure 1. Oculocentric visual direction.

to physiological diplopia (double vision). In Fig. 5, it can be seen that point A stimulates disparate points (non-corresponding retinal points).

Using the cyclopean eye, crossed and uncrossed diplopia can be explored. For an object closer than the fixation point such as point B in Fig. 6a, crossed diplopia occurs as the point B is imaged on the temporal retina of both eyes. This is termed crossed diplopia because the image in the left eye is seen on the right side. For an object located further than the fixation point, the image of the object falls on the nasal retina of both eyes, producing uncrossed diplopia. This is termed uncrossed diplopia because the image in the left eye is seen on the left side (Fig. 6b).

The principle of the cyclopean eye can be applied to patients with strabismus (a turned eye). Patients with strabismus are usually classified according to the direction of the eye turn. Two common types of strabismus are patients with an esotropia, their eye(s) turned in, and patients with exotropia, their eye(s) turned out. Patients with an exotropia will have crossed diplopia, whereas patients with an esotropia will have uncrossed diplopia (Fig. 7).

The Horopter

Our visual world is composed of multiple points, hence the need to develop concepts to deal with the whole visual space. This concept is called the horopter. The horopter is the locus of points in space that stimulates corresponding points, that is, a multitude of points in visual space that lead to single vision.

The Vieth-Muller Circle

The Vieth-Muller circle is a theoretical horopter. All points on this circle should stimulate corresponding points on the retina and lead to single vision, provided that the fixation point lies on the center of the circle and the eyes rotate about its nodal point (instead of their center of rotation). The Vieth-Muller circle assumes there is angular symmetry of the corresponding points (Fig. 8).

Measuring the Horopter

The horopter can be measured through several methods. These methods include:

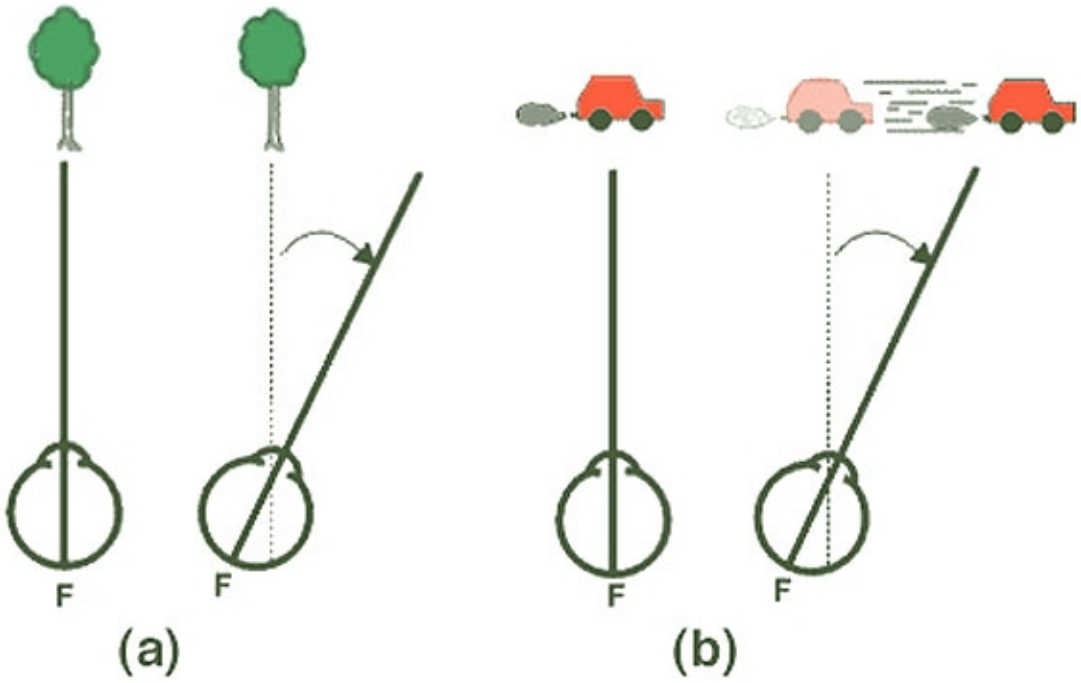

Figure 2. (a) Different oculocentric direction but the same egocentric direction as the object is stationary. (b) Same oculocentric direction but egocentric direction is changing because the object is moving.

- Haplopic method
- Nonius method
- Apparent front-parallel plane (AFPP) method

The Nonius and AFPP methods directly determine the longitudinal horopter, whereas the haplopic method does not. Instead, the haplopic method determines the inner and outer boundaries of single binocular vision, and the horopter is taken as the midline.

Haplopic Method

The haplopic method (method of the region of singular binocular vision) is based on the primary definition of corresponding points; retinal points that correspond give rise to identical visual directions and, as a consequence, single vision. Thus, if diplopia is observed, disparate points are being stimulated. Therefore, the method involves determining the boundaries of single binocular vision (Fig. 9).

Nonius Method

Because corresponding points give rise to identical visual directions, the position of an object that stimulates a pair of corresponding points can be located if each eye sees a different part of the object. If the two parts are seen in the same direction, then the objects are in that position where they stimulate corresponding points. This is the basis of the Nonius method (method of equating visual directions) (Fig. 10).

The Apparent Fronto-Parallel Plane (AFPP) Method

The theory of stereopsis holds that stimulation of disparate points is necessary for the perception of relative depth by stereopsis. If there is no depth difference between an object and the fixation point, then they stimulate corresponding points. Thus, if the subject is asked to arrange a series of objects so that they appear to be in a fronto-parallel plane (i.e., no depth difference between them), then they will lie on the horopter. This is the apparent fronto-parallel plane method (Fig. 11). Note the change in shape of the horopter at different distances.

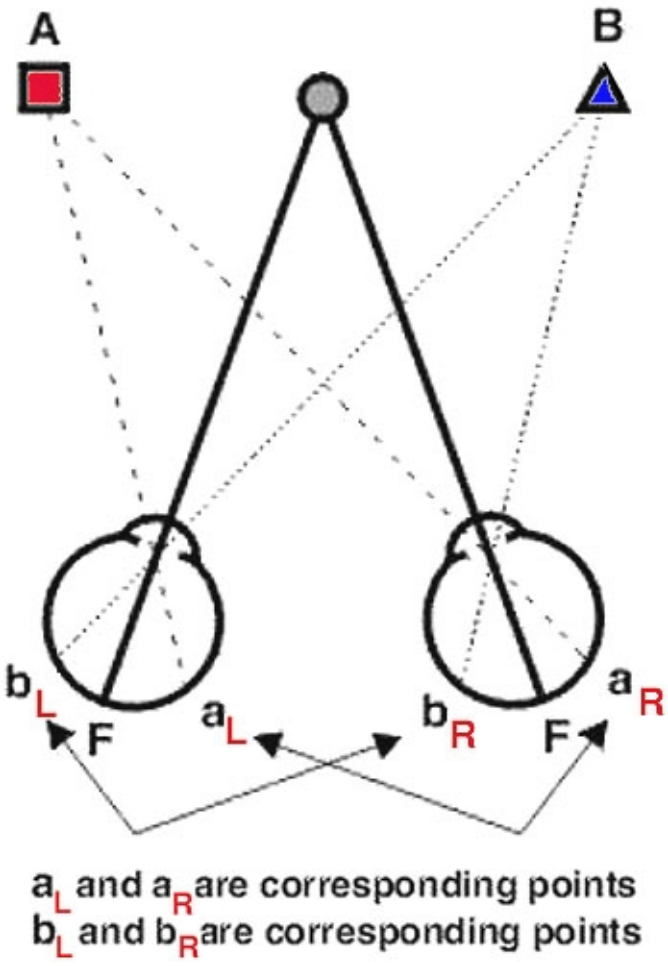

Figure 3. Corresponding points of the two eyes.

Relationship of the Horopter to Panum's Fusional Area

The haplopic method demonstrates the existence of Panum's fusional area. This concept allows for single binocular vision about the point of fixation, even when corresponding retinal points are not being stimulated. An image on the retina of one eye can be fused (and seen as single) with a similar image on the retina of the other eye, although disparity in the retinal image exists. Panum's fusional area is needed for stereopsis; if images do not fall in Panum's area, then diplopia results—and so Panum's fusional area defines the zone of stereovision.

Aniseikonia

Aniseikonia describes a subject's spatial perception when there is a difference in retinal image size of the same object between the two eyes. Anisekonia can be investigated by placing an aniseikonic lens placed in front of one eye (to magnify the retinal image in one eye) while plotting the horopter using the AFPP method. When this is performed, the apparent fronto-parallel plane becomes skewed about the fixation point, with the horopter being nearer on the side of the eye having the increased magnification (Fig. 12). Note that magnification cannot be too large, otherwise, diplopia would result because the two retinal images would fall outside Panum's fusional area. Aniseikonia identifies reshaping of visual space within Panum's fusional area.

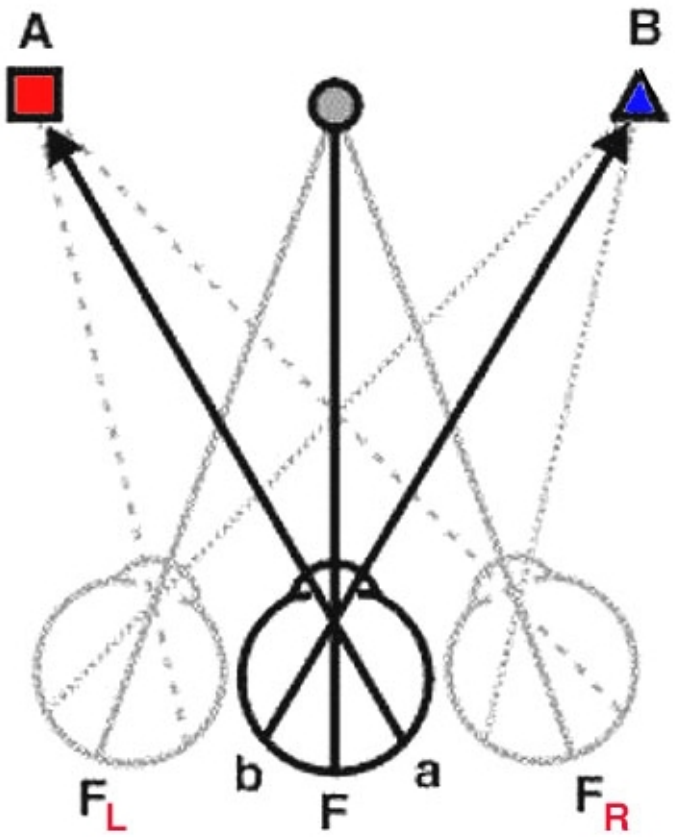

Figure 4. The cyclopean eye is used to determine the direction of point A and point B. Point A stimulating the temporal retina of right eye and the nasal retina of the left eye, that is, stimulates a retinal point to the right of the fovea.

The importance of these plots with the aniseikonic lens is to demonstrate stable corresponding retinal points. As long as the magnification difference between the two eyes is not too large, fusion will be maintained, although spatial distortions will occur. Once the magnification difference exceeds Panum's fusional space, diplopia will result. Aniseikonic symptoms are a common complaint of patients with unequal refractive errors or large astigmatic corrections. The magical 2-week rule applies, i.e., the time taken for sensory adaptation. If symptoms persist, reducing the magnification difference or reducing the correction are two clinical options.

About the Authors

Michael Kalloniatis was born in Athens Greece in 1958. He received his optometry degree and Master's degree from the University of Melbourne. His PhD was awarded from the University of Houston, College of Optometry, for studies investigating colour vision processing in the monkey visual system. Post-doctoral training continued at the University of Texas in Houston with Dr Robert Marc. It was during this period that he developed a keen

interest in retinal neurochemistry, but he also maintains an active research laboratory in visual psychophysics focussing on colour vision and visual adaptation. He was a faculty member of the Department of Optometry and Vision Sciences at the University of Melbourne until his recent move to New Zealand. Dr. Kalloniatis is now the Robert G. Leitl Professor of Optometry, Department of Optometry and Vision Science, University of Auckland. e-mail: m.kalloniatis@unsw.edu.au

Charles Luu was born in Can Tho, Vietnam in 1974. He was educated in Melbourne and received his optometry degree from the University of Melbourne in 1996 and proceeded to undertake a clinical residency within the Victorian College of Optometry. During this period, he completed post-graduate training and was awarded the post-graduate diploma in clinical optometry. His areas of expertise include low vision and contact lenses. During his tenure as a staff optometrist, he undertook teaching of optometry students as well as putting together the "Cyclopean Eye", in collaboration with Dr Michael Kalloniatis. The Cyclopean Eye is a Web based interactive unit used in undergraduate teaching of vision science to optometry students. He is currently in private optometric practice as well as a visiting clinician within the Department of Optometry and Vision Science, University of Melbourne.

The Perception of Depth

Michael Kalloniatis and Charles Luu.[1]

Created: May 1, 2005; Updated: June 6, 2007.

Stereopsis

Stereopsis refers to our ability to appreciate depth, that is, the ability to distinguish the relative distance of objects with an apparent physical displacement between the objects. It is possible to appreciate the relative location of objects using one eye (monocular cues). However, it is the lateral displacement of the eyes that provides two slightly different views of the same object (disparate images) and allows acute stereoscopic depth discrimination.

Monocular Cues

Several strong monocular cues allow relative distance and depth to be judged. These monocular cues include:

- relative size
- interposition
- linear perspective
- aerial perspective
- light and shade
- monocular movement parallax

Relative Size

Retinal image size allow us to judge distance based on our past and present experience and familiarity with similar objects. As the car drives away, the retinal image becomes smaller and smaller. We interpret this as the car getting further and further away. This is referred to as size constancy. A retinal image of a small car is also interpreted as a distant car (Fig. 1).

Interposition

Interposition cues occur when there is overlapping of objects. The overlapped object is considered further away (Fig. 2).

Linear Perspective

When objects of known distance subtend a smaller and smaller angle, it is interpreted as being further away. Parallel lines converge with increasing distance such as roads, railway lines, electric wires, etc. (Fig. 3).

Aerial Perspective

Relative color of objects gives us some clues to their distance. Because of the scattering of blue light in the atmosphere, creating a "wall" of blue light, distance objects appear more blue (Fig. 4). Thus, distant mountains appear blue. Contrast of objects also provide clues to their distance. When the scattering of light blurs the outlines of objects, the object is perceived as distant. Mountains are perceived to be closer when the atmosphere is clear.

Figure 1. Relative size. A retinal image of a small car is considered to be distant.

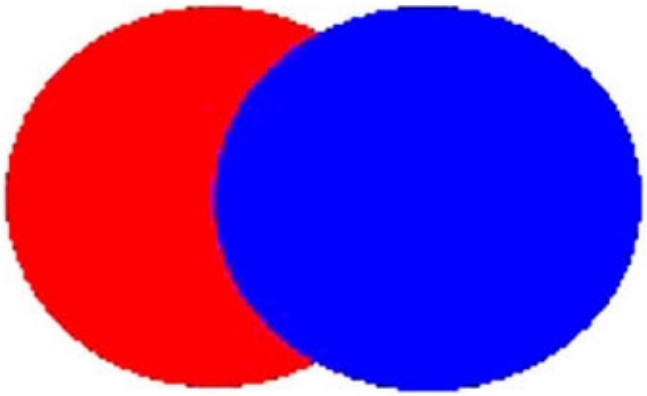

Figure 2. Interposition. The blue circle is reported to be closer because it overlaps the red circle.

Light and Shade

Highlights and shadows can provide information about an object's dimensions and depth (Fig. 5). Because our visual system assumes that the light comes from above, a totally different perception is obtained if the image is viewed upside down.

Monocular Movement Parallax

When our heads move from side to side, objects at different distances move at a different relative velocity. Closer objects move "against" the direction of head movement and farther objects move "with" the direction of head movement.

Figure 3. Linear perspective. Parallel lines, such as railway lines, converge with increasing distance.

Figure 4. Aerial perspective. Mountains in the distance appear more blue.

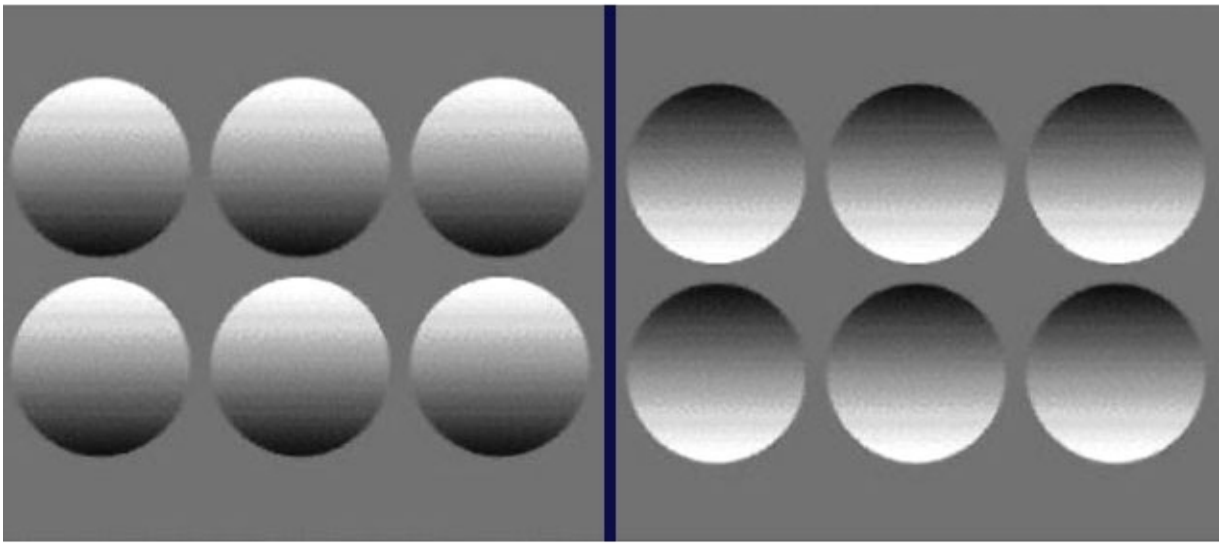

Figure 5. Highlights and shadows provide information about depth.

Binocular Cues

Stereopsis is an important binocular cue to depth perception. Stereopsis cannot occur monocularly and is due to binocular retinal disparity within Panum's fusional space. Stereopsis is the perception of depth produced by binocular retinal disparity. Therefore, two objects stimulate disparate (non-corresponding) retinal points within Panum's fusional area.

Fusion describes the neural process that brings the retinal images in the two eyes to form one single image. Fusion occurs to allow single binocular vision. Fusion takes place when the objects are the same. When the objects are different, suppression, superimposition, or binocular ("retinal") rivalry may occur. Suppression occurs to eliminate one image to prevent confusion. Superimposition results in one image presented on top of the other image. Binocular rivalry describes alternating suppression of the two eyes, resulting in alternating perception of the two images. This usually occurs when lines that are presented to the two eyes differ in orientation, length, or thickness. An example of binocular rivalry occurs when one eye is presented with a horizontal line and the other eye is presented with a vertical line. Binocular rivalry occurs at the intersection of the lines, and some suppression also exists (Fig. 6).

Panum's fusional area is the region of binocular single vision. Outside Panum's fusional area, physiological diplopia occurs. Using the haplopic method of determining the horopter, Panum's area can be determined (Fig. 7).

Retinal Disparity

Retinal disparate points are retinal points that give rise to different principal visual direction and diplopia. However, retinal disparity within Panum's fusional area (zone of single binocular vision) can be fused, resulting in single vision. Retinal disparity is essential for stereoscopic depth perception because stereoscopic depth perception results from fusion of slightly dissimilar images. Because of the lateral displacement of our eyes, slightly dissimilar retinal images result from the different perception of the same object from each eye.

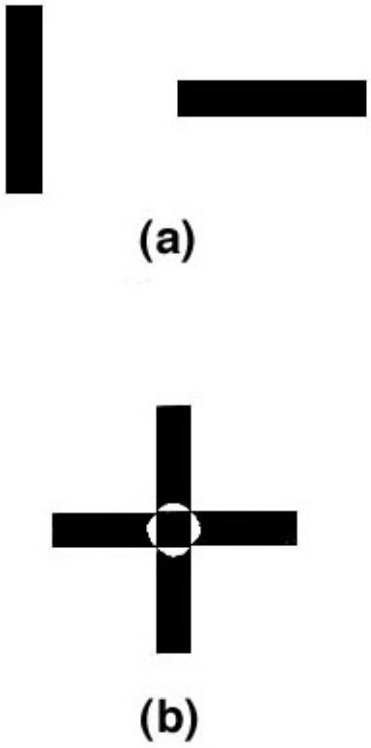

Figure 6. (a) Binocular rivalry can be demonstrated by placing a pen between yourself and the screen. Keep your eye on the tip of the pen, and notice the two bars merge. You may need to slowly move the pen from the screen toward you. (b) Result of (a).

Clinical Tests Used to Measure Stereopsis

There are two groups of clinical tests used to measure stereopsis. These are the contour stereotests and the random-dot stereotest. Random-dot stereograms were first used by Julesz (1) to eliminate monocular cues. As there are no contours, depth perception (stereopsis) can only be appreciated when binocular fusion occurs. Two process of stereopsis are used, and these are local and global stereopsis. Local stereopsis exists to evaluate the two horizontally disparate stimuli. This process is sufficient for contour stereotests. Global stereopsis is required in random-dot stereogram when the evaluation and correlation of corresponding points and disparate points are needed over a large retinal area.

An example of a contour stereotest used in the clinic is the Titmus Fly Stereotest. In the Titmus Fly Stereotest, horizontal disparity is presented via the vectographic technique (2). When tested at 40 cm, the fly has a disparity of 3,600 sec of arc; the disparities of the animals range from 400 to 100 sec of arc, and the disparities of the Wirt rings range from 800 to 40 sec of arc (Fig. 8).

Examples of random-dot stereotests used in the clinic are the Frisby Stereotest, the Randot Stereotest, the Random-dot E Stereotest, and the Lang Stereotest. The Frisby Stereotest (Fig. 9) uses real depth to determine stereoacuity. Three perspex of different thicknesses are used. Four squares of geometric shapes are painted on one side of the perspex. In one of the squares, a circle of these geometric shapes is painted on the other side of the perspex. Both the Randot (Fig. 10) and the Random-dot E uses crossed polarized filters. Disparity is also constructed vectographically. The Randot Stereotest uses modified animals and ring designs with random dot backgrounds to eliminate monocular cues. The Lang Stereotest uses a panographic technique (2) to present

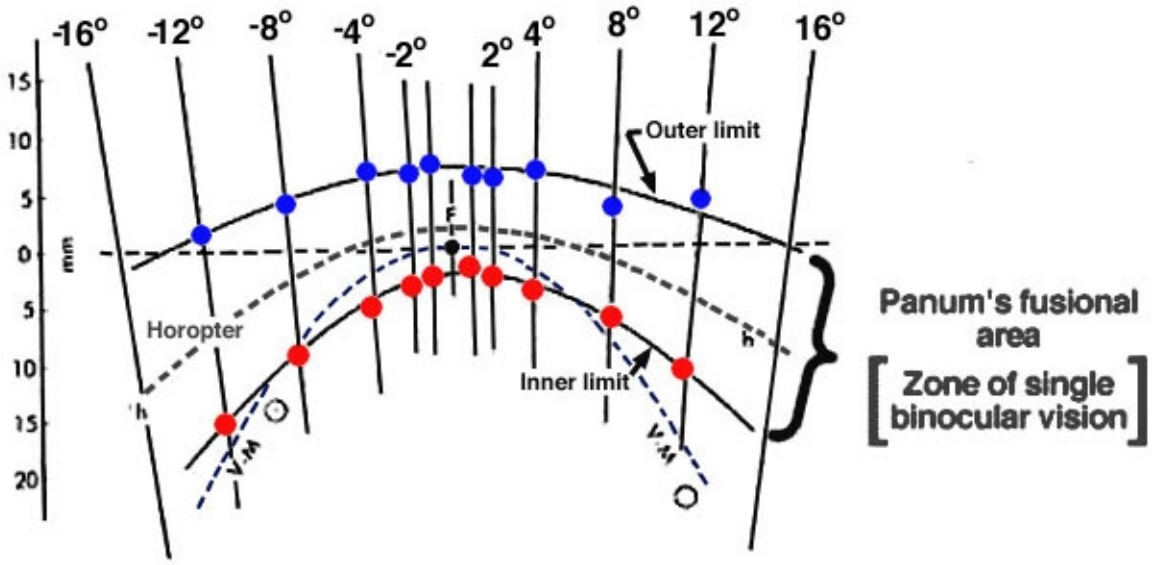

Figure 7. Haplopic method of determining the horopter involves locating the region of single binocular vision at a distance of 40 cm. Panum's fusional area lies between the outer and inner limits of the region of single binocular vision.

disparity; therefore, no filters are required. Patients are required to identify pictures on the Lang Stereotest. The Lang II Stereotest has a monocularly visible shape on it (Fig. 11).

All of the tests provide a measure of stereoacuity by asking the patient to identify the correct target that has stereoscoptic depth (target with disparity). The working distance and interpupillary distance will need to be taken into consideration when calculating stereoacuity. Patients with disturbed binocular vision or different refractive error in one eye will perform poorly on depth discrimination tests.

Brain Visual Areas

The Primary Visual Cortex

Matthew Schmolesky

Created: May 1, 2005; Updated: June 14, 2007.

Introduction

The human visual system can detect and discriminate between an incredibly diverse assortment of stimuli that may be chromatic or achromatic, in motion or not, patterned or unpatterned, two-dimensional or three. Remarkably, the neural end-product of visual stimuli impacting upon the retina is, in one sense, always the same. After the complexities of phototransduction, lateral interactions provided by horizontal and amacrine cells, and integration of signals by ganglion cell dendrites, only the constantly changing stream of action potentials propogating along ganglion cell axons is left to inform our visual perception. These seemingly identical signals must somehow be processed in the subcortex and cortex to create the full range of visual percepts we experience. How this is achieved is a puzzle that currently occupies the professional lives of thousands of researchers, and the basic framework of a solution has only begun to unfold in the last several decades.

To achieve an understanding of cortical and subcortical processing, we can ask two basic questions about the signals leaving the retina:

- What are the discrete anatomical pathways that carry the signal?
- What information do the signals actually carry?

The answers to these questions do not exist. That is, the answers we have thus far are incomplete and, in many cases, conflicting. I point this out first because the reader should be aware that vision research is a burgeoning field, where new articles published every week bring additional details about how the brain copes with its monumental task. To complicate matters, the animals most commonly studied to understand visual processing (monkey, cat, ferret, rat, mouse, hamster, zebrafish, goldfish, etc.) do not conveniently carry small, medium, large, and extra-large copies of the same brain within their craniums. Although evolution has settled upon many visual system designs that are shared by these species, substantial differences also exist. For the purpose of this review, I will focus almost entirely upon the macaque monkey visual system for the reason that it is one of the most understood and best models that we have for human vision to date. I will begin with a historical perspective on visual system research and continue by attempting to answer the two basic questions posed above in relation to the primary visual cortex, or V1.

Historical Perspective

The relationship between vision and the eye must have been correctly understood from the earliest times of human existence. Surpassing this most basic understanding, however, required careful dissection of the eye, optical fibers, and brain structures of animals and/or humans. One view holds that the religious and social doctrines of the Pre-Classical civilizations (e.g., Egyptians, Sumerians, Assyrians, Babylonians, Hindus, Chinese, Indians, etc.) did not permit such dissections. The more primitive herdsman and farmers surrounding the Mediterranean Sea did not have such inhibitions and are believed to have studied basic anatomy, albeit nonsystematically, during sacrificial rituals. These herdsman and farmers evolved a terminology for the anatomical structures that they discovered.

Polyak (1) maintains that this terminology was quickly adopted by the Greeks of 600–400 B.C. when the study of anatomical organization was rigorously pursued. During this time, physicians such as Hippocrates (460–380 B.C.), Alkmaeon (520 B.C.), and Anaxagoras (500 B.C.) carried out dissections of animal and human bodies and brains and held opinions of some accuracy concerning brain function, such as movement, sensation, and thinking.

The height of Greek medical scientific knowledge was reached during the Hellenistic or Alexandrian period from 323 to 212 B.C. The most prolific of medical scientists was the "Prince of Physicians" Galen (129–201 A.D.) of Pergamon (present day Turkey). As noted by Polyak (1), Galen's contributions to the understanding of human anatomy and physiology under normal and pathological conditions were vast and provided a foundation for medicine in the Arab period and, subsequently, the Revival in Europe during the late Middle Ages and Modern Times. Fig. 1 shows the Arab adaptation of Galen[1]s ideas on the pathways of the visual sytem from eyes to forebrain.

Although Galen accurately described much of the visual system gross anatomy, he did not recognize the decussation of fibers at the optic chiasm, nor did he trace the fibers to the dorsal lateral geniculate nucleus (LGNd) of the thalamus (Fig. 1). Instead, he suggested that they were connected to the lateral ventricles (which he named the "thalami"). This belief was consistent with the prevailing view on nerves in general at the time, namely that they were hollow channels carrying various "spirits", such as the visual spirit. Over 1,000 years later, the beliefs of humanist scientists such as Leonardo Da Vinci (who pictorally described the same optic fiber to the lateral ventricle pathway) (Fig. 2) and Des Cartes (who promoted the view of nerves carrying animal spirits) echoed Galen's teachings and demonstrate how little progress had been made in such a long time.

Following the Hellenistic period, the ethics supported during the first several centuries of the Christian Era denied medical practitioners and scientists the right to dissect human corpses. This stricture was expanded in the Dark Ages to include the dissection of animals, and from this point until the 1600s, healers were forced to rely almost entirely upon what little information they could glean from the Classical period (Fig. 3, Fig. 4).

Between 1600 and 1860 A.D., the most basic understanding of central visual system anatomy and function was obtained. The partial decussation of optical fibers at the chiasm was deduced. The projection of these fibers into the LGNd and the optic radiations to the cortex were described. Accidental and experimentally induced cortical lesions were correlated to symptomologies found in the patients and experimental animals, respectively, leading to the notion of localized cortical function. Cortical dissections were carefully performed, and the line of Gennari (the dense, myelinated fiber bundle running through V1 layer 4B, named for its discoverer) in the primary visual cortex was described (Fig. 5).

This striation gave rise to the term "striate cortex" to describe V1. Unstained sections of cortex were examined on slides revealing the six cortical layers to Baillarger. The notion of retinotopic organization in central structures gained wide acceptance.

In the late 1800s and early 1900s, several advances in histological preparation led to a boom in cellular studies of the visual cortex. Better chemical treatments were found for hardening the brain prior to cutting thin slices; gross neuronal and fiber staining dye protocols were developed (e.g., those of Weigert (2) and Nissl (3)); and the Golgi technique for labeling individual cells, complete with their extensive axonal and dendritic arborizations, was established (Fig. 6).

For the first time, researchers could view the intricacies of neuronal morphology and the details of laminar differences. No single researcher contributed more in this regard than Santiago Ramón y Cajal (1852–1934). Ramón y Cajal (4) gave a detailed account of the cellular morphologies throughout the cortex (visual and otherwise) using the Golgi method and his own modified silver staining method. The incredible detail afforded by these techniques allowed Ramón y Cajal to suggest certain neural pathways and circuits and theorize on the functional significance of the cortical constituents. The advent of electron microscopy permitted researchers to describe the details of synaptic connections. The development of "tracer" dyes that are taken up by distal fibers and transported toward the cell body (retrograde tracers) or taken up by the cell/dendrites and transported along the fibers to the distal terminals (anterograde tracers) greatly enhanced the search for feedforward and feedback pathways in the visual system. (Specific transsynaptic degeneration following lesions in nuclei and/or fiber bundles was used previously, but with far less success.)

All of the progress described above is anatomical in nature. What about the function of the visual pathways? How were researchers approaching this issue in the late 1800s and early 1900s? Clinical cases described over the centuries already pointed to the functional specialization of discrete cortical areas. Experimental lesions within the cortex confirmed this notion. Electrical stimulation of the cortex (e.g., Fritsch and Hitzig (5) on dog and monkey motor cortex) provided the *coup de grace* to the doctrine of functional equivalence and established the theory of functional cerebral localization in its place. Surgeons such as Penfield (6) were mechanically stimulating the brains of conscious patients during operations and recording the sensations evoked (Fig. 7). The critical step in obtaining a functional map of the visual system, however, came when researchers moved from electrical stimulation to electrical recording.

Scalp recordings of visual evoked potentials (VEPs) were used to map visually responsive cortical areas and examine retinotopic organization and binocularity in rabbit, cat, and monkey (7-9). Simultaneously, microelectrodes were being used to study single cells/fibers (or small groups) in the retina/optic tract (10, 11) and somatosensory cortex (12, 13). Hubel and Wiesel first applied the single unit recording technique to the visual cortex of cats (14, 15) and monkeys (16-18) with stunning results. With this incredible series of experiments (for which David Hubel (19) and Torston Wiesel later won the Nobel Prize in 1982), the modern era of visual cortex research was ushered in.

With this historical perspective in mind, we should turn our attention to the current understanding of the primary visual cortex and its place in the visual pathways.

Which Anatomical Pathways Carry the Visual Signal?

Basic Anatomy

The macaque primary visual cortex, like that of all mammals studied, resides in the posterior pole of the occipital cortex (Fig. 8). V1 extends rostrally almost to the lunate sulcus and posterolaterally almost to the inferior occipital sulcus; the V1/V2 border is met before either sulci. Much of V1 is found within the calcarine sulci, and the limits of V1 within these folds can be marked by the distinct appearance of V1 layer 4 (Fig. 9).

The anatomy of the primate primary visual cortex has been worked out in great detail. The three basic organizing principles of primate V1 are the: 1) laminar and 2) columnar arrangement of excitatory and inhibitory neurons (an arrangement shared with other neocortical areas) and 3) the regular spacing of anatomical/functional compartments revealed by cytochrome oxidase (CO) labeling.

Several simple facts and rules of thumb can be stated before addressing the details of these anatomical features:

- The six cortical layers introduced by Brodmann (layer 1 most dorsal, layer 6 most ventral) have been subdivided time and again as additional aspects of the neurons and their connections have been revealed.
- Layer 1 is nearly aneuronal, composed predominantly of dendritic and axonal connections. In 1 mm^3 of V1 tissue, one could expect to find approximately 4,700 neurons, 2,900 microglia, 3,400 oligodendrocytes and 49,000 astrocytes (20). Of the neurons present, over 80% are GABAergic (21).
- Approximately 20% of the neurons in layers 2–6 are inhibitory interneurons (GABAergic) that make major contributions to the function of V1 circuits but do not project axons outside of this area.
- Layers 2/3 (the "supergranular" layers) contain many excitatory projection neurons that send axons to extrastriate cortical regions (e.g., V2, V3, V4, MT, etc.).
- Layer 4 (the "granular" layer) is divided into four horizontal sublayers: 4A, 4B, 4Cα, and 4Cβ. Layers 4Cα and 4Cβ are the major recipients of LGNd innervation. The LGNd magnocellular (M) and parvocellular (P) layers project to 4Cα and the 4Cβ, respectively. Thus, the M and P streams remain segregated at this stage (but see qualification below).

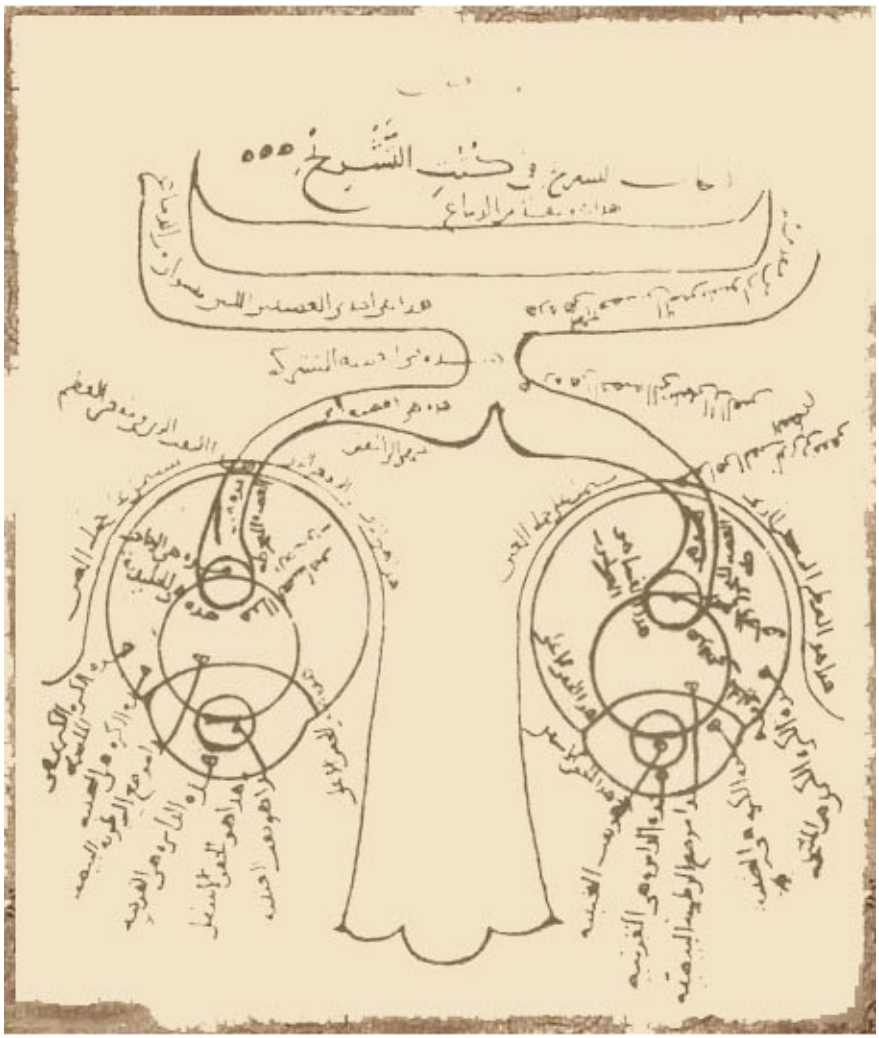

Figure 1. Diagrammatic representation of the visual system from the oldest existing copy of the "Book of Optics" by Ibn Al-Haitham, an Arab physicist written in the 11 century A.D. From Polyak (1).

- Layers 5/6 (the "infragranular" layers) contain many excitatory projection neurons that innervate the LGNd to provide feedback to this relay area.
- Labeling of V1 and V2 for CO content has revealed CO-rich and -poor regions termed "blobs" (or puff, spots, or patches) and "interblobs" in V1 and the thick, thin, and pale stripes in V2. The relevance of these compartments is still a matter of some debate.
- CO blobs do not extend uniformly from the surface of layer 1 to the base of layer 6. Instead, they concentrate in layers 3B, 4B, and 4C (Fig. 10).
- Projections to and from the CO blobs and interblobs are relatively distinct as follows (Fig. 11):
    - Pβ (for primate P or midget ganglion cells) project to the LGNd parvocellular layers (see the chapter on midget pathways of the retina), which project to V1 layer 4C and then project to the interblobs of V1 layers 2/3; and finally these layers project to the pale stripes of the V2 geniculate.
    - The blue-yellow ganglion cells (see the chapters on S-cone pathways and color vision) project to the intercalated layers and S/K (K for "koniocellular") layers of the LGNd, which project to the blobs of V1 layers 2/3, which project to the thin stripes of V2.
    - Pα (M cells or parasol ganglion cells) project to the LGNd magnocellular layers and thence to layer 4C of V1. This layer projects to the blobs of V1 layers 2/3 and also to layer 4B of V1. Layer 4B, in turn, projects to the mediotemporal area (MT) and to the thick stripes of V2.
- Layers 1 and 2 receive feedback inputs from extrastriate cortex.

Figure 2. Drawing by Leonardo DaVinci of the projection of the eyes to the ventricles of the brain. From Polyak (1).

- The neuroglia in the young adult macaque V1 account for 20-35% of all cells (not including pericytes). The neuroglia can be divided into oligodendrocytes (~7-10% of cells), astrocytes (~11-20% of cells), and microglial cells (~1.5-3% of cells) (20, 22).

Neuronal Constituents

There are three basic types of neurons in the primate V1 (Fig. 12):

- spiny pyramidal cells (excitatory)
- spiny stellate cells (excitatory)
- smooth or sparsely spinous interneurons (almost all are GABAergic)

The pyramidal cells, as you might guess, have cell bodies that appear like pyramids, have apical dendrites (that is, extending toward the white matter), and their dendrites are covered with spines. Spiny stellate cells are generally smaller, and their cell bodies more resemble a star shape. They also have spiny dendrites (Fig. 12A). The interneurons have more rounded cell bodies and have little or no spines on their dendrites. Over the years, anatomists have given more or less descriptive appelations to a number of unique subtypes, which are briefly described below.

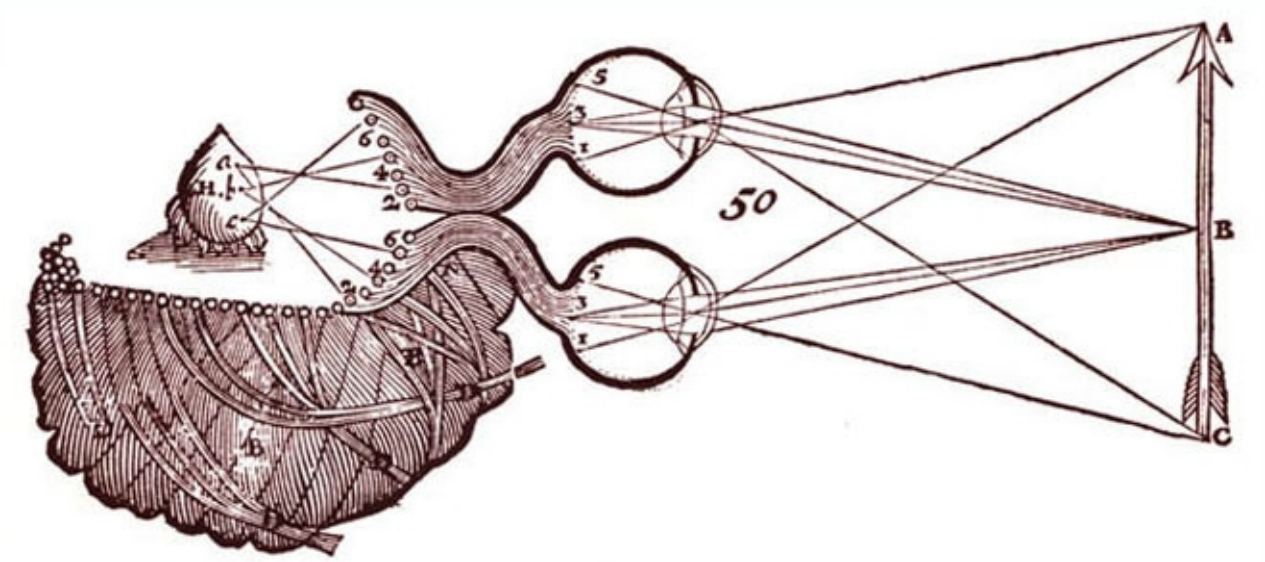

Figure 3. Binocular stereoscopic visual system as imagined by Des Cartes. The two retinal images of the arrow are accurately, point for point, projected upon the surface of the cerebral ventricles and thence to the centrally located pineal gland, H, the supposed "seat of imagination and common sense". From Polyak (1).

- Chandelier cell – inhibitory; axons show characteristic branching into vertical sections resembling candlesticks (Fig. 12E).
- Neurogliaform cells – inhibitory; resembling glial cells but definitively neurons; axon and dendrites branch but remain in the locale of the soma, giving rise to a dense spherical region of fibers (Fig. 12G).
- Double bouquet cell – inhibitory; axon collaterals and bitufted dendrites extend vertically in a tight bundle (Fig. 12C). Antibodies to calbindin specifically mark these cells, and by using this strategy, researchers have found that these cells are regularly spaced in layer 3, thereby forming yet another columnar unit. There are approximately 7 to 15 double bouquet cells per 10,000 μm^2 (23).
- Basket cells (24, 25) – inhibitory; relatively large cell bodies extend myelinated axonal branch laterally for a great distance. The axonal branches terminate on pyramidal cell bodies and dendrites in a manner resembling a basket. Dendrites extend vertically (Fig. 12, D and H).
- Cajal-Retzius cells – inhibitory; Cajal and Retzius found this cell type independently in layer 1 of neonatal animals and humans, respectively. They may or may not exist in the adult.
- Meynert cell – excitatory; large pyramidal cell first described by Meynert; the "outer" Meynert cell bodies are found in 4B and are regularly distributed relative to pyramidal cell cones (22) (see below). These cells project to area MT. The "inner" Meynert cell bodies are regularly spaced at the layer 5/6 border, lying below CO interblobs. These cells are also found in layer 6. These cells typically have asymmetric, lateral dendritic arborizations, are highly direction selective, and are also known to project to area MT.

The cell types described above represent only a few of the more unique varieties. Jennifer Lund and colleagues (26-29) have rigorously studied the presumptive interneurons of the macaque V1 using the Golgi impregnation staining method. On the basis of a range of morphological criteria (the laminar position of somata, axonal arborization, dendritic arborization, pattern and extent of branching), they have described over 40 types of interneurons alone.

Additional low-density interneurons might remain unidentified. The classes that have been described might be further divided based on chemical content and/or physiological response properties (Fig. 12). Alternatively, it should be noted that many of the anatomically distinct types may be physiologically indistinguishable from one another.

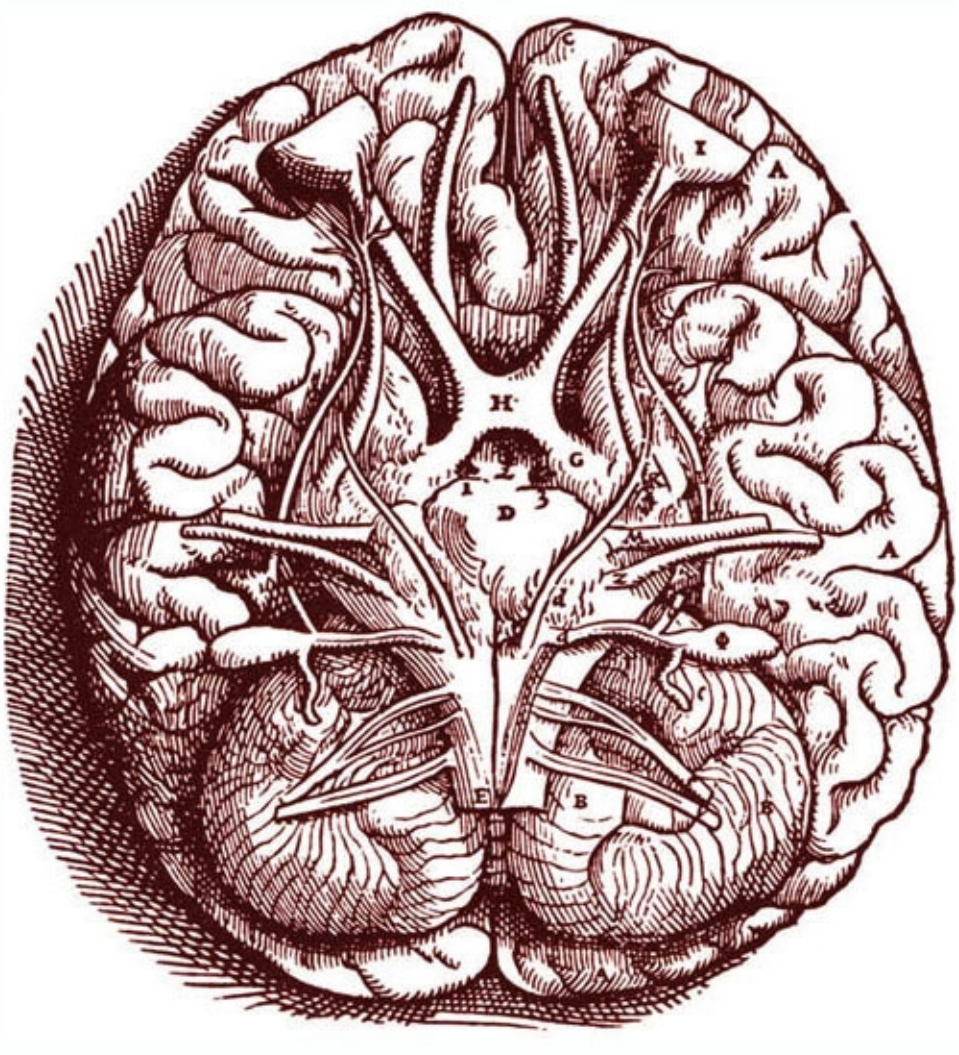

Figure 4. Woodcut from the "Fabrica" (1555) by Vesalius showing the basal aspect of the human brain with the origins of the cranial nerves and the brain stem. From Polyak (1).

The Cortical Layers

Many numbering schemes exist for the neocortical layers in general and the layers of V1 in particular. I have adopted the basic scheme of Brodmann, who defined the cortical layers based on careful histology. I have also adopted the refinements suggested by the work of Lund and colleagues (see below) (Fig. 13).

Layer 1 is composed of a dense network of synapses formed between the apical dendrites of layer 2–5B pyramidal cells (29) and the collected inputs from LGNd K layers (30, 31), the pulvinar, feedback pathways from extrastriate areas, nonspecific thalamic nuclei, and other subcortical regions. Thus, although layer 1 contains few neurons, it is a networking layer that has a direct, concerted affect on the firing properties of pyramidal cells in deeper layers.

The supragranular layers (2, 3A, and 3B) contain many somata and dendrites of pyramidal cells. Layers 2 and 3A receive little thalamic inputs (the K layer projection to V1 blobs is focused mainly in 3B). They do not receive direct inputs from layer 4C, in contrast to layer 3B that receives a massive 4C input. Layers 2 and 3A do contain many axons and dendrites of neurons found in all other cortical layers.

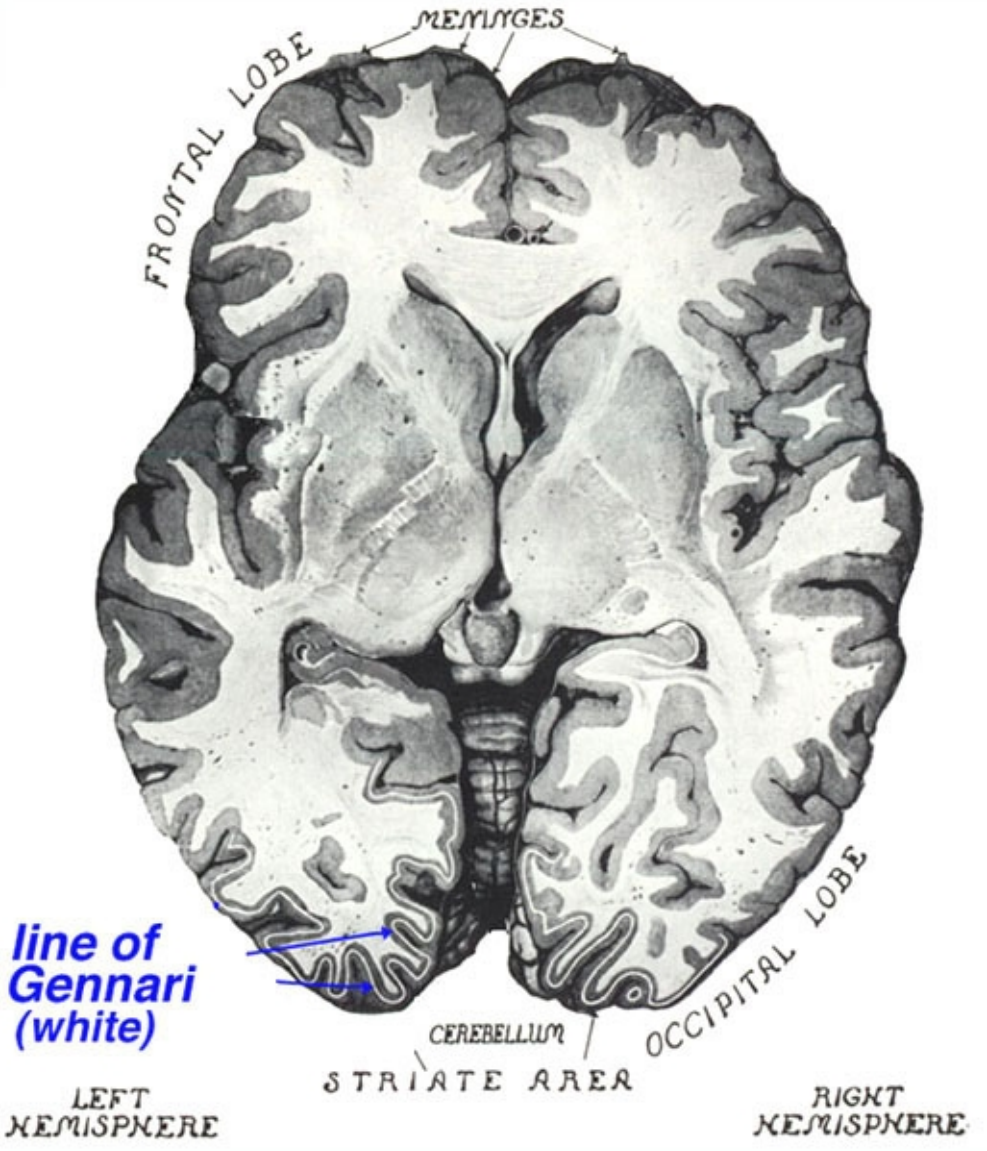

Figure 5. Horizontal section of the brain showing the line of Gennari in the striate cortex. From Polyak (1).

Layer 4A shows up in the Nissl stain as a dark band of small, granule-like cells. This and the lack of pyramidal cells set this layer apart from layer 3B.

Layer 4B is a cell-poor layer that contains a low density arrangement of pyramidal cells—the large outer Meynert cells. This layer receives a strong input from the underlying 4Cα, and the Meynert cells are known to project directly to area MT as well as the superior colliculus (SC) (32). Cells in layer 4B also project to the thick CO stripes of V2, which in turn project to MT. Thus, this layer plays a substantial role in conveying information in the M pathway/dorsal stream.

Layer 4C is distinguished from 4B in part due to the great density of stellate cell packing in this layer. Polyak (1) divided 4C into the α and β divisions, based solely on histology; upper 4C neurons are more dispersed. Differences in geniculate innervation patterns (i.e., the M layers of LGNd to 4Cα and the P layers to 4Cβ) (33, 34), the projection patterns of the 4C cells (35) and physiological properties (36) have overwhelmingly supported this division. Additional evidence has suggested that the upper and lower divisions of 4Cα may be distinct as well (26, 33, 37, 38).

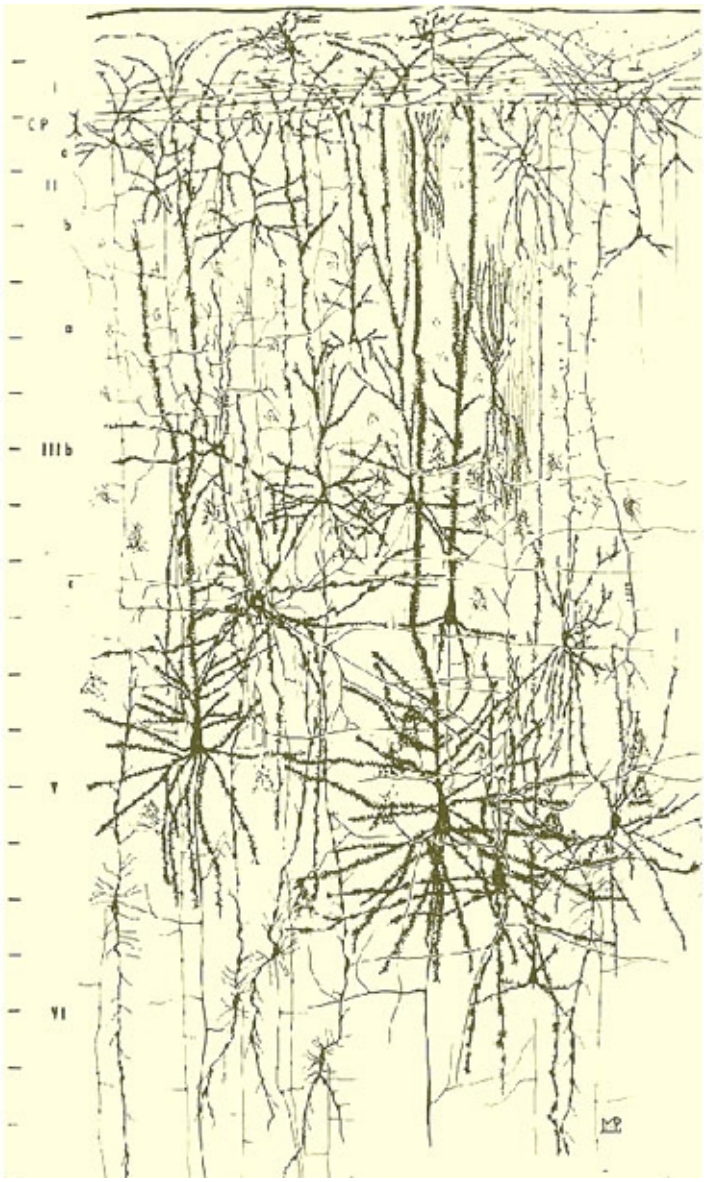

Figure 6. Composite figure of a mosaic of camera lucida drawings showing the morphological features (size, location, and distribution) of the principal neuronal types of the human cortex. From rapid-Golgi preparations. Scale: 100 μm.

4Cβ spiny stellate neurons provide a dense innervation of layers 4A and 3B and sparse innervation in 4C, 5, and maybe 6 (35). No direct projections from 4Cβ to 3A, 4B, or 5B have been found (26). In contrast, as already noted, 4Cα projects heavily to 4B.

Local layer 5A neurons do not project to 4B and only weakly innervate 4Cβ. They innervate all other layers. 5A neurons appear to project primarily to 3B and 1 (26). Pyramidal neurons in 5B send recurrent axons to layer 3A (39). Meynert cells at the 5/6 border and within layer 6 project to both MT and SC (40).

Layer 6: It is known that neurons in layer 6 send recurrent axons into 4Cβ (39). Other neurons (or possibly even the same ones) project axons back to the LGNd (41). Layer 6 also receives a direct input from the LGNd (42), thereby forming a neural loop.

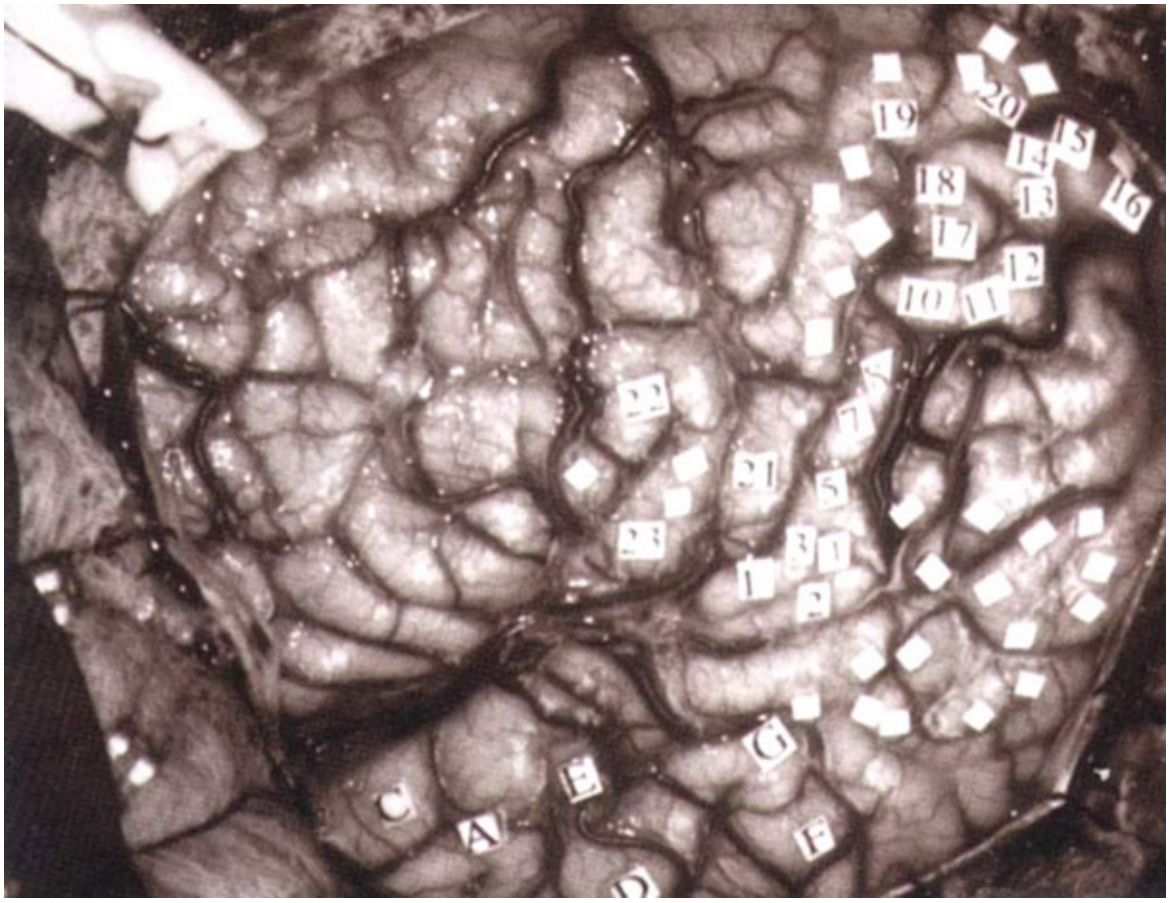

Figure 7. Human brain labeled as to cortical areas during neurosurgery. From Penfield and Boldrey (6).

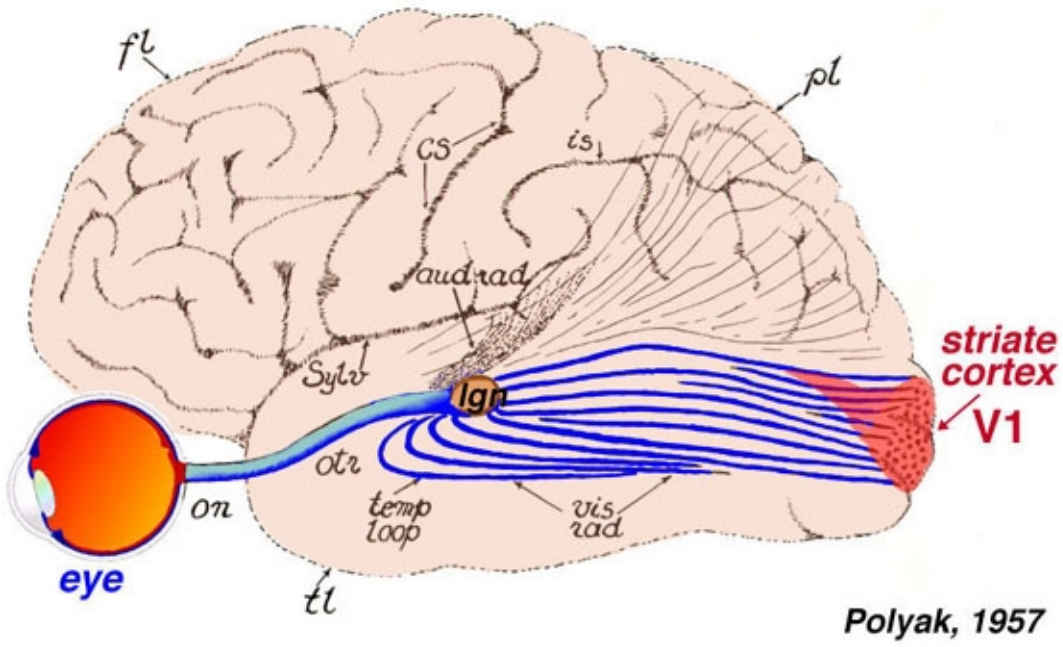

Figure 8. Visual input to the brain goes from eye to LGN and then to primary visual cortex, or area V1, which is located in the posterior of the occipital lobe. Adapted from Polyak (1).

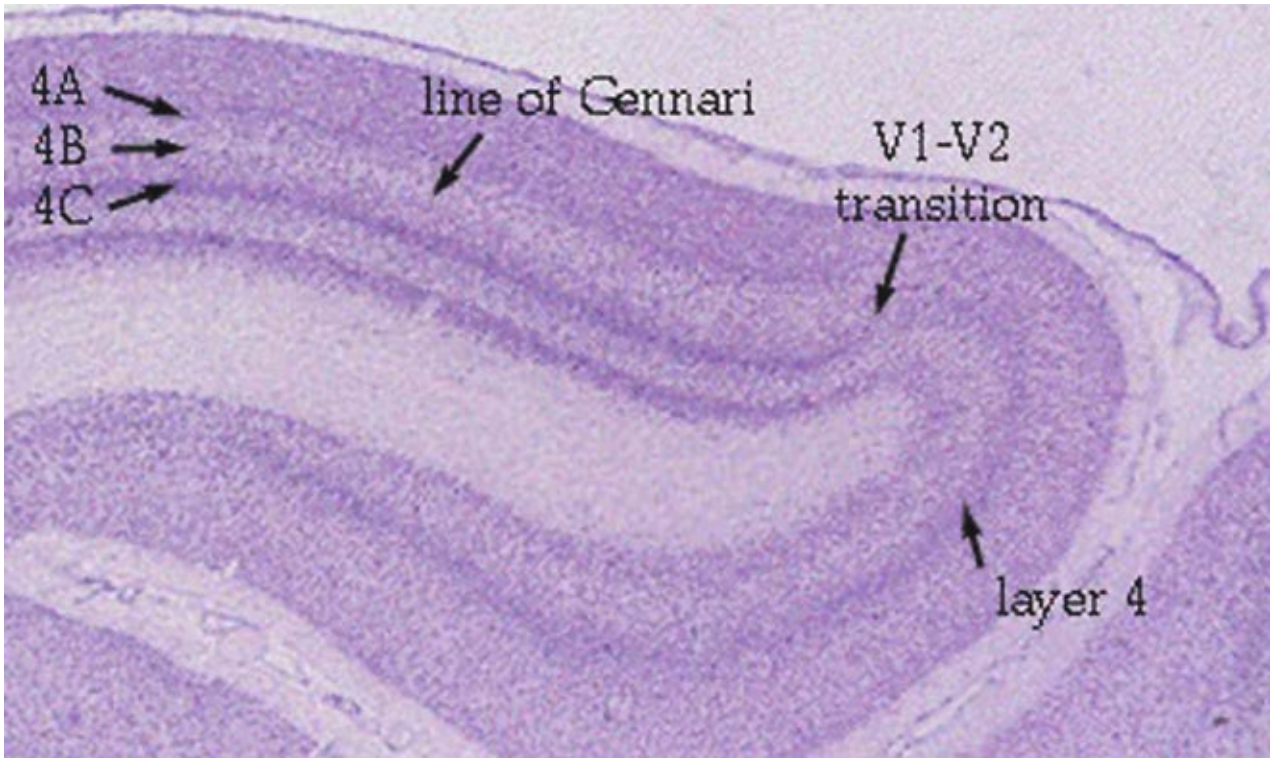

Figure 9. Nissl-stained section to show the border between area 17 (V1) and area 18 (V2).

V1 Cortical Columns

The term "cortical column" refers to the notion that cells arranged vertically from the surface of the cortex to the white matter might compose functional or anatomical units. Thus, a cortical column can be defined on the basis of anatomical features (e.g., stereotyped patterns of pyramidal cell apical dendrite bundles), functional features (e.g., columns of cortical cells, all responding to the same stimulus orientation), or both.

Many types of columns have been proposed including ocular dominance, orientation, spatial frequency, and color columns. The details of these columnar arrangements will be described in later sections dealing with the physiology of V1. However, I will here briefly describe the ocular dominance columns to provide an example of columnar arrangement in the primary visual cortex.

Ocular Dominance Columns

Visual signals from the two eyes remain segregated in the LGNd (Fig. 11) and in the geniculorecipient layers of area V1 (Fig. 14). One can observe this segregation by measuring the electrophysiological responses of the units in layer 4C. As the recording electrode is moved within layer 4C, there is an abrupt shift as to which eye drives the unit. In layer 4C, the shift from one eye to the other takes place over a distance of less than 50 μm. Signals from these bands converge on individual neurons in the superficial layers of the cortex, thereby forming columns dominated by one eye or the other in an alternating fashion (Fig. 15).

Cytochrome Oxidase Labeling

CO is an integral transmembrane protein that is found in the inner mitochondrial membrane. Because it acts to catalyze the generation of adenosine triphosphate (ATP), which is itself an energy molecule used in an enormous range of cellular processes; the amount of CO in a cell or nucleus can be used as an indicator of cellular activity. In 1978, Margaret Wong-Riley discovered that, quite apart from its use as an activity indicator,

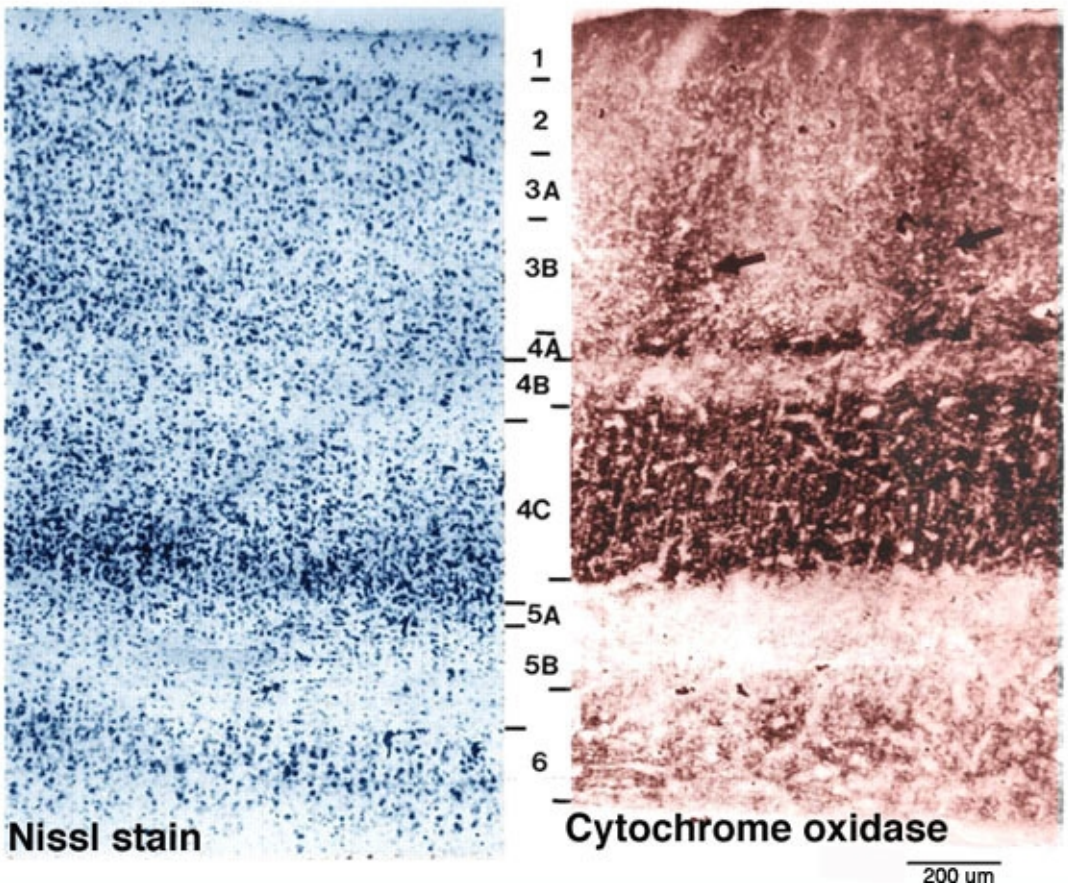

Figure 10. Nissl (left) and cytochrome oxidase (right) labeled cross sections of the visual cortex of a macaque monkey, showing the individual layers.

CO labeling in the primary visual cortex reveals a striking array of CO-rich and -deficient regions (i.e., blobs and interblobs) (Fig. 16).

Presumably, these regions reflect stable differences in energy consumption in two populations of neurons that were previously undistinguished. Assuming this were true, what other differences might exist between blobs and interblobs? It should be noted that dense CO staining does not exist throughout the entire cortical depth. Instead, CO blobs are most visible in layers 3B, 4A, and 4C. Be that as it may, if these dense regions were in fact different from their CO-deficient neighbors in some way, the cells directly above and below rich and poor regions might also show differences in connectivity and functional characteristics, correlating with the cells above and below them.

For instance, blobs in layer 3B have been shown to correspond to specific geniculate innervation in macaques (43, 44). Boyd and Casagrande (45) found recently that V1 cells projecting to MT in bush babies and owl monkeys were more numerous below the CO blobs of layer 3B than below the interblobs. Similar data in macaque monkeys also shows clustering of MT projecting cells in periodical steps through the lateral extent of V1 (46-48) but did not find a correlation between these clusters and the CO (Fig. 17 and Fig. 18).

Feedforward and Feedback Pathways

The signals from the two retinas are communicated to area V1 via the LGN. In the macaque monkey, after the signals are processed in V1 they are communicated via multiple pathways to the 30+ visually responsive, extrastriate cortical areas (Fig. 19).

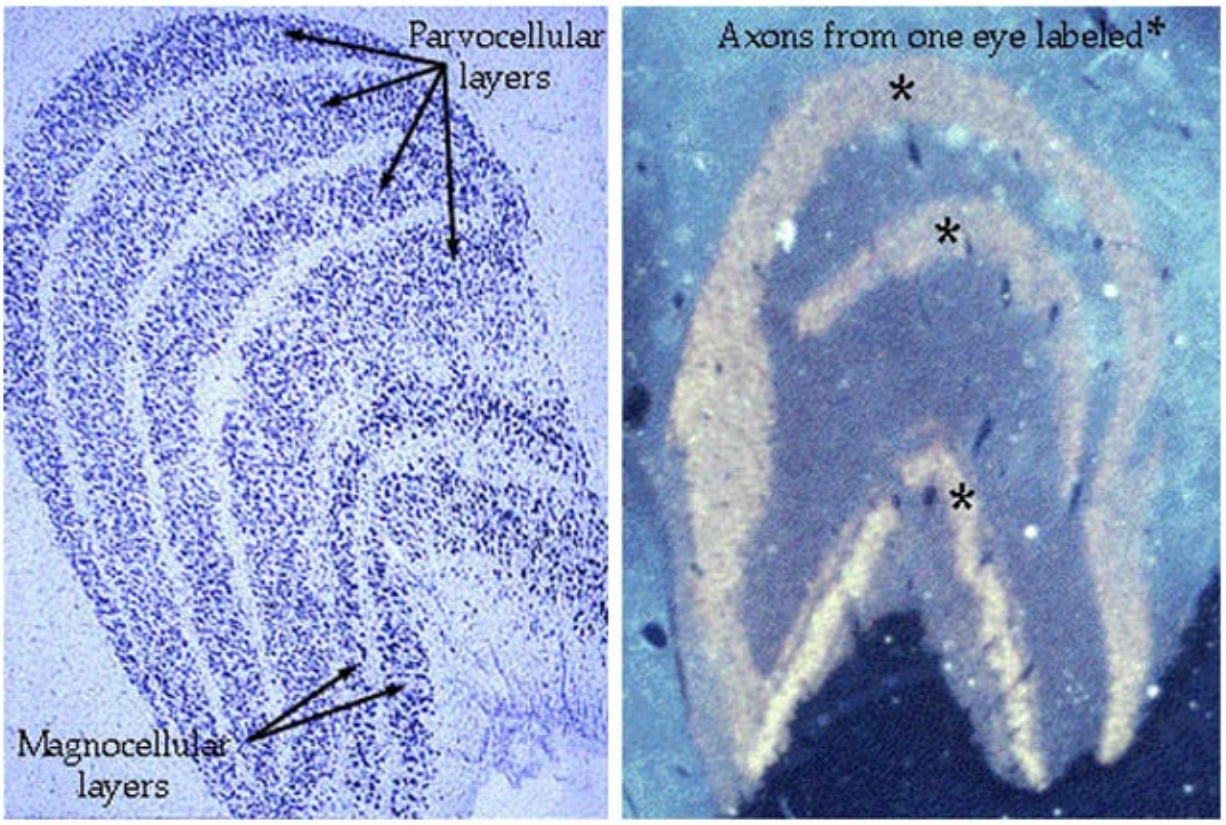

Figure 11. The projections of the small (P cells) and large (M cells) ganglion cells from the two eyes to parvocellular and magnocellular layers of the LGN, respectively.

Anatomical hierarchical models place the visual cortical areas into a multi-level processing model based upon the pattern of feedforward, lateral, and feedback pathways found in each area. In general, feedforward pathways are considered to be those that project from the supragranular layers of one area and terminate in layer 4 of the target area. In contrast, feedback projections are those that arise from the infragranular layers of one area and terminate outside of layer 4 in the target area (49-51).

In the previous sections, I have described the anatomical borders of V1, the cells that exist in this area, the arrangement of those cells in layers, columns, and CO compartments, and I have hinted at the visual pathways that course into and out of V1. It is true that visual information is passed from the retina to the LGNd to V1 to the higher cortical areas and that the higher areas project back to V1 and V1 to the LGNd (there are no efferent projections to the primate retina). However, although this view of visual processing is accurate, it does not capture the wealth of upstream and downstream connections found in V1.

Direct feedforward projections to V1 originate from the pulvinar, LGNd, claustrum, nucleus paracentralis, raphe system, locus coeruleus, and the nucleus basalis of Meynert (31, 33, 43, 52-57).

Direct feedforward projections from V1 extend to V2, V3, V5 or MT, MST, and FEF (41, 46-48, 58-63).

Direct feedback projections to V1 originate from V2, V3, V4, V5 or MT, MST, FEF, LIP, and inferotemporal cortex (47-49, 57, 61, 62, 64, 65).

Direct feedback projections from V1 extend to SC, LGNd, pulvinar, and pons (32, 41, 54, 66, 67).

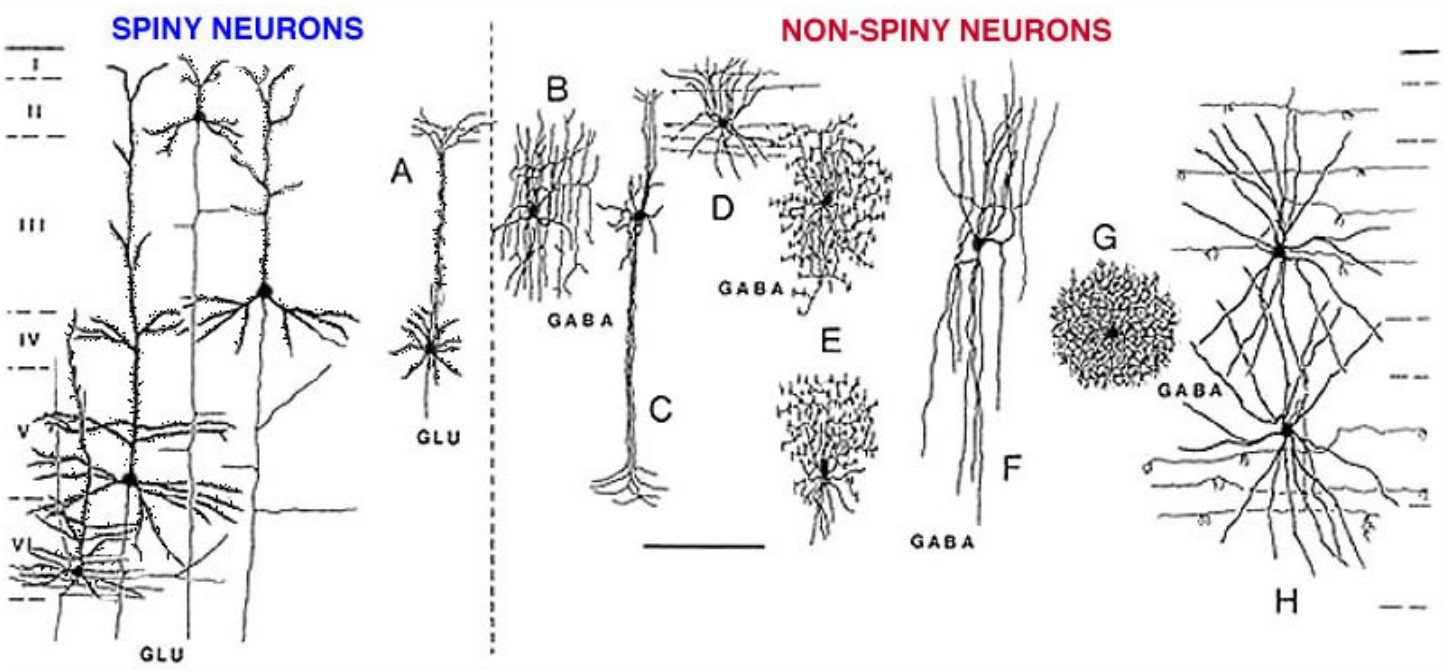

Figure 12. Basic cell types in the monkey cerebral cortex. Left: spiny neurons that include pyramidal cells and stellate cells (A). Spiny neurons use the neurotransmitter glutamate (Glu). Right: smooth cells that use the neurotransmitter GABA. B, cell with local axon arcades; C, double bouquet cell; D and H, basket cells; E, chandelier cells; F, bitufted, usually peptide-containing cell; G, neurogliaform cell.

The connections listed above represent only a subset of the direct and indirect projections that carry signals into and out of the primary visual cortex and do not even begin to describe the extensive lateral connections within V1 itself.

What Information Does the Visual Signal Carry?

We now know the arrangement of neurons, dendrites, and axons in the layers, columns, and CO compartments of V1. We know many of the pathways extending into and out of V1 involving the retina, subcortex, and extrastriate cortex. We can imagine light impinging upon the eye and, from this origin point, a cascade of action potentials streaming from neuron to neuron, area to area— forward, lateral, and back again. In the abstract, we know that it is these signals that are responsible for our vision of the external world. But how do these millions of patterned spikes resolve themselves into an actual percept? A partial answer is to consider that every image can itself be broken down into components (e.g., lines, colors, textures, shades, and motion, etc.) and that visual cortical neurons are specialized to detect only a subset of these components.

Receptive Field Properties

Each cell in the visual cortex has a receptive field (RF), a discrete area in space relative to the fovea where the presentation or removal of a visual stimulus will cause cellular activation. By definition, stimuli presented outside of this receptive field will neither increase nor decrease the ongoing activity of that individual cell. The location and size of a RF can be considered among the most basic of RF properties.

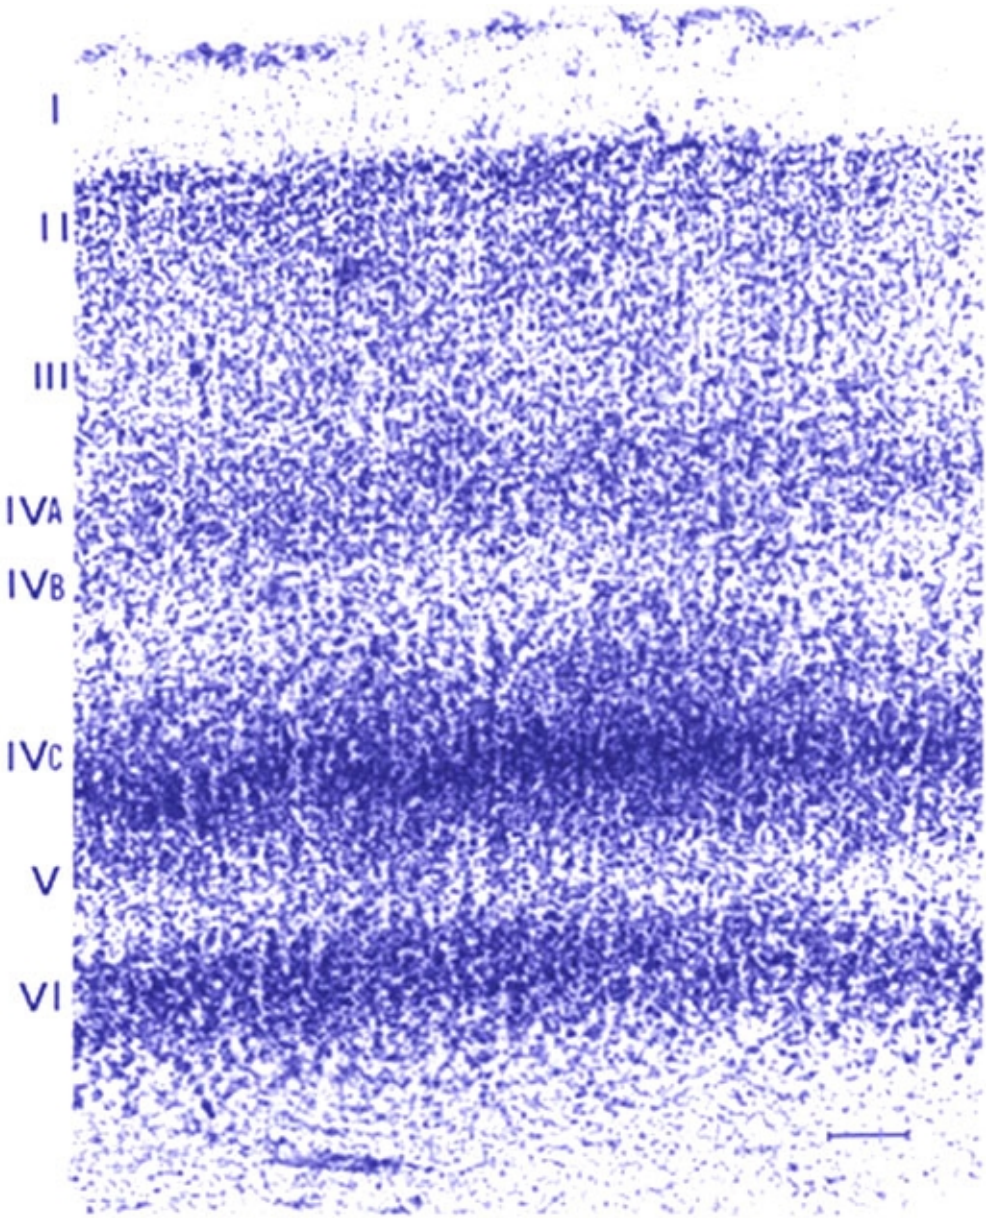

Figure 13. Nissl stain of the visual cortex reveals the different layers quite clearly.

Retinotopic Maps in V1

The spatial position of the ganglion cells within the retina is preserved by the spatial organization of the neurons within the LGN layers. The posterior LGN contains neurons whose RF are near the fovea. Progressing from posterior to anterior, the RF locations become increasingly peripheral in the retina (68). This spatial layout is called retinotopic organization because the topological organization of the RFs in the LGN parallels the organization of the retina.

The signals in area V1 are also retinotopically arranged. From electrophysiology in monkeys, one can measure the location of RFs with an electrode that penetrates tangentially through layer 4C, transversing through the ocular dominance columns. The RF centers of neurons along this path correspond systematically to locations from the fovea to the periphery. This trend is interrupted locally by small, abrupt jumps at the ocular dominance borders. Thus, the striate cortex retains the retinotopic map of the contralateral visual field that is developed in the LGN.

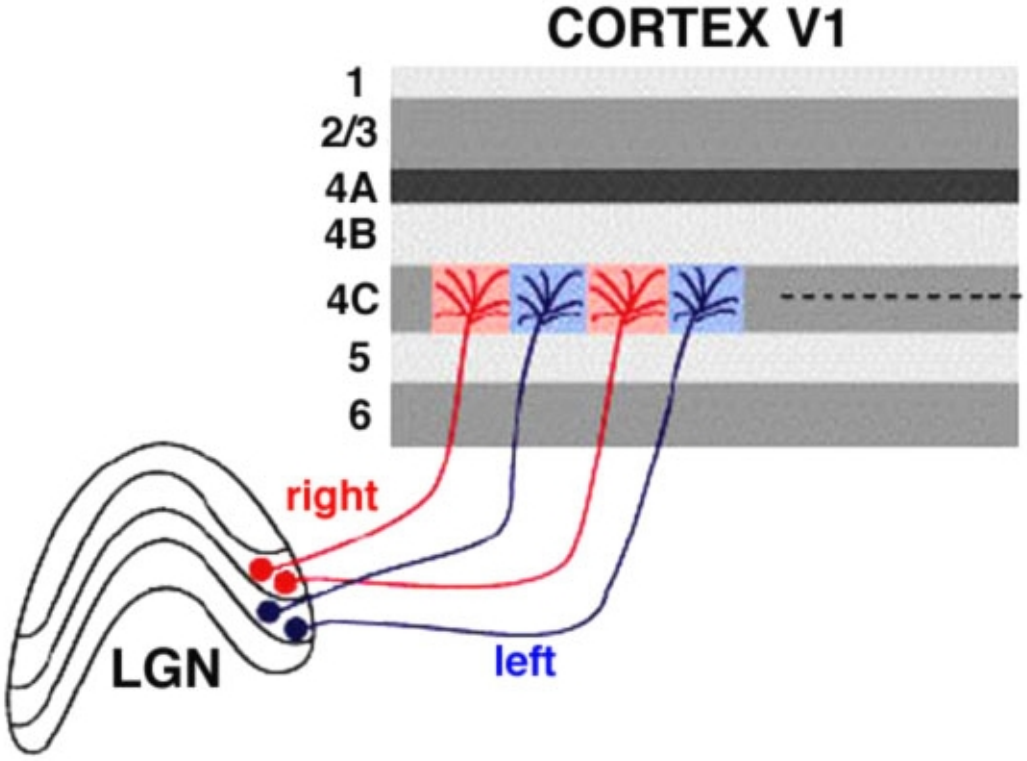

Figure 14. The signals from each eye are segregated into different ocular dominance columns within area V1, layer 4C.

Orientation and Direction Selectivity

V1 is the first site where strong orientation and direction selectivities are observed in the macaque monkey (16). Although the vast majority of V1 cells show some degree of orientation selectivity, only approximately 25-35% of V1 cells are strongly directionally selective (69, 70). The classic method for testing orientation and direction selectivity is to measure the spike rate of a single cell in response to drifting oriented luminance bars and/or drifting luminance spots (see Fig. 21).

The concept of an orientation column can be easily appreciated by examining Fig. 20 and Fig. 21. When an electrode is lowered into V1 at an angle relatively parallel to the cortical layers (Fig. 22), the orientation selectivities of the cells encountered vary systematically, where adjacent cellular regions share approximate orientation preferences.

Such recordings led Hubel and Wiesel to propose models of functional organization like the one shown in Fig. 23.

Recently, the orientation columns of V1 first described by Hubel and Wiesel have also been recast into more complex geometries, such as partial columns ("slabs") and pinwheels, as dictated by the increasing volumes of evidence (71).

Binocularity and Binocular Disparity

Hubel and Wiesel (15) first demonstrated the presence of cells in primate V1 that responded preferentially to visual stimulation in both eyes as opposed to one eye alone. They classified cells using a 7-point scale where:

- 1 – cells excited by the contralateral eye alone.
- 2 – cells with a strong bias for contralateral stimulation.

Figure 15. The ocular dominance columns in area V1 can be visualized by using markers. When the marker is injected into one eye, it is transported via the LGN nucleus to the cortex. The light bands in this tangential section show the places where the marker was located and thus reveal the ocular dominance columns. From Olavarria and Van Essen (94).

- 3 – cells with a weak bias for contralateral stimulation.
- 4 – cells that responded maximally to stimulation in both eyes.
- 5 – cells with a weak bias for ipsilateral stimulation.
- 6 – cells with a strong bias for ipsilateral stimulation.
- 7 – cells excited by the ipsilateral eye alone.

The proportion of monocular cells (points 1, 2, 6, and 7) *versus* binocular cells (points 3, 4, and 5) was found to vary with the layer in which cells were recorded. Cells in the retinogeniculato-recipient layers 4Cα and 4Cβ were found to be exclusively monocular. Anatomical studies have since shown that these cells receive monocular inputs from the LGNd that do not converge from the alternating layers (34, 39).

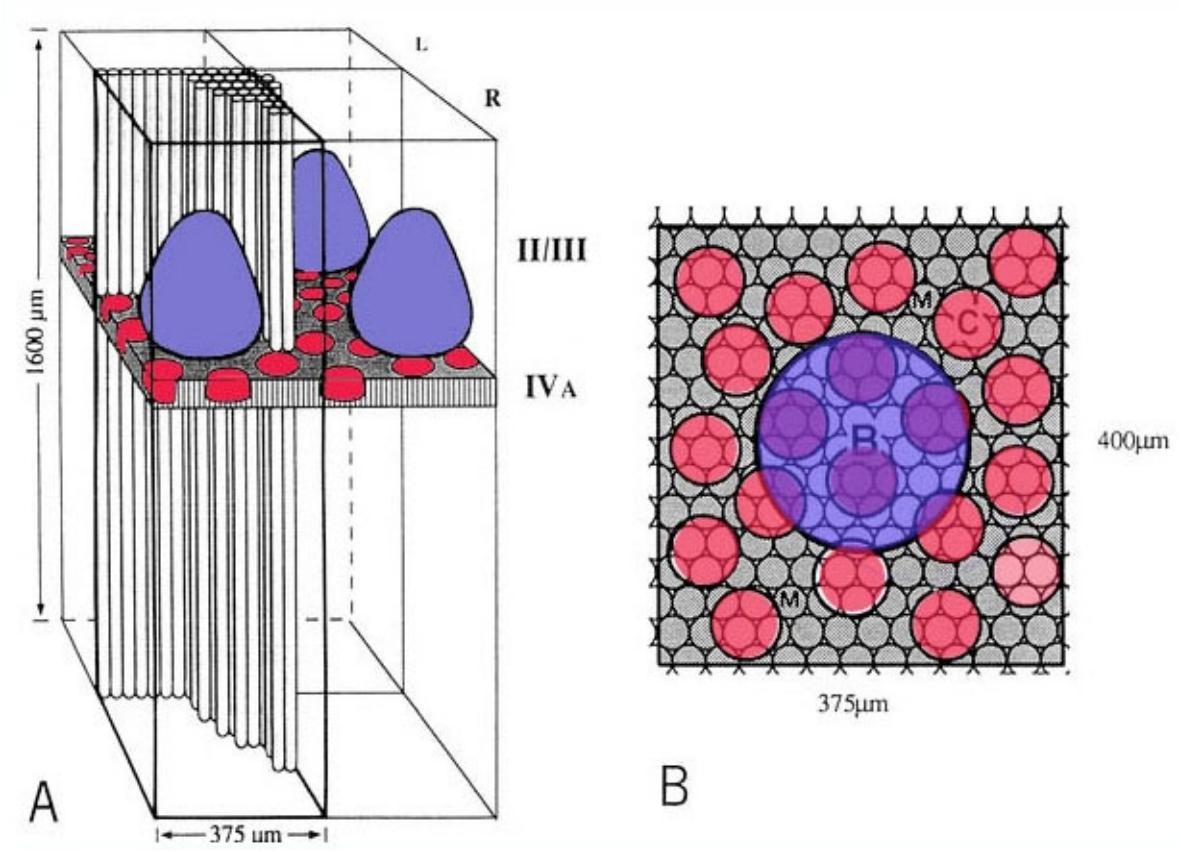

Figure 16. Diagrammatic representation of the relationships between CO "blobs", layer 4 cones, and pyramidal cell modules. A, three-dimensional representation. The "blobs" in layer 2/3I are aligned in single rows along the 400 µm-wide ocular dominance columns (R and L), and they have a center-to-center spacing of 375 µm. Each blob, which is the focus of a blob-centered module, lies above the cones of neurons in layer 4A, and throughout the entire cortex is a matrix of long, thin pyramidal cell modules. B, a diagram of the contents of a blob-centered module as though looking down from the pial surface. The blobs (B) are about 200 µm wide. An average of 20 layer 4A cones (C) would occupy such an area, which would also contain some 180 pyramidal cells modules (M). From Peters and Sethares (22).

What might be the usefulness of binocular cells? When an observer fixates on a visual object, the image of this object is positioned on corresponding regions of the two retinas. At the same time, however, objects in front of and behind the fixation point create images that lie on non-corresponding regions of the two retinas. The degree to which the images are non-corresponding (as measured by difference scores in retinal eccentricity for instance) is defined as binocular disparity. The ability to use binocular disparity to determine the distance of an object from oneself, and its relation to the fixation plane, is called stereopsis.

Hubel and Wiesel first described the presence of neurons in V1 that are sensitive to binocular disparity. That is, some neurons may show maximal firing rates when a stimulus has positive disparity and weak or even inhibited (below baseline) firing rates to 0 disparity stimuli (in the fixation plane) or negative disparity stimuli. These cells would be described as disparity sensitive and negative disparity tuned. If the tuning were reasonably sharp, the cell might be described as negative disparity selective, i.e., it responds soley, not simply preferentially, to negative disparity. We now know the percentage of disparity-sensitive cells and the proportion of positive, negative, and 0-disparity tuned cells. Clearly, there are no disparity tuned cells in layers 4Cα and 4Cβ because binocularity is a prerequisite for disparity sensitivity. As Livingstone (72) noted, it is safe to assume that negative and positive disparity selective cells are involved in stereopsis. Of the 0-disparity tuned cells, all may be involved in stereopsis or, alternatively, perhaps only those with very narrow tuning (i.e., selective ones) contribute to this perceptual ability (73). The work of DeAngelis, Newsome, and Cumming (74, 75) elegantly addresses this issue by

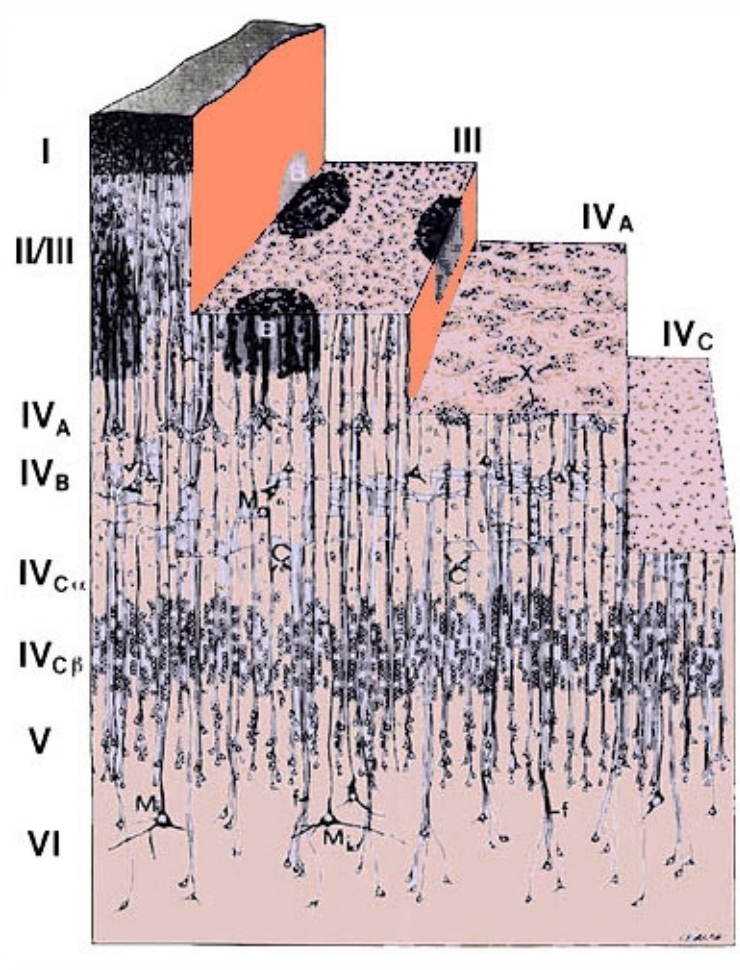

Figure 17. Schematic drawing of the visual cortex to show neurons, layers, columns, and CO blobs.

attempting to alter stereopsis in trained monkeys by microstimulating subregions of disparity-tuned cells in area MT.

Response Timing in the Visual Pathways

Another feature of visually evoked, single-cell response that is currently gaining attention is timing. The order in which visual areas become active and the range of activation times within any given area are important issues. As described above, a prevailing model of primate vision proposes hierarchical stages of visual areas based on anatomical connectivity (49, 50, 76-78). There is no doubt that a single stimulus initiates a characteristic flow of neuronal discharge from the retina to the LGNd to V1 in a hierarchical manner. Unfortunately, the complexity of corticocortical connections and functional differentiation in primate visual streams renders further predictions highly speculative (51).

We could hypothesize, for instance, that the heavily myelinated path from V1 to MT would lead to fast activation of this area. However, would all MT cells be activated in this manner, or would others wait for activation via the more indirect V1 to V2 to MT route? Many studies have reported response onset latencies from a single visual area. Using these data to construct a chart of activation times across the visual system, however, reveals a host of complications (79).

To begin with, the vast majority of studies that report latencies do so for only one or two visual areas. An activation analysis in 10 visual areas, therefore, might involve cross-comparisons between 5 and 10 separate

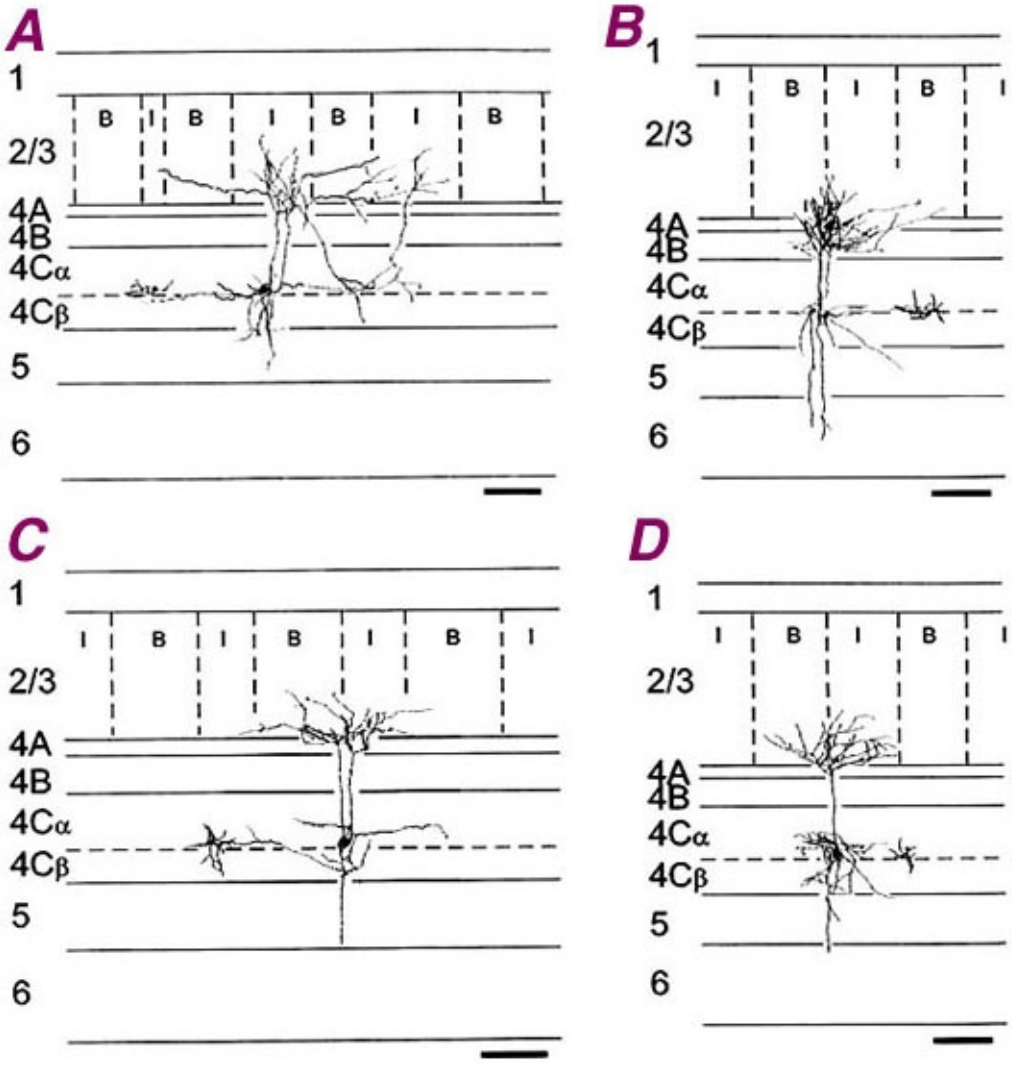

Figure 18. Reconstructions of neurobiotin-injected V1 4C cells that have dendrites confined to layer 4C and dense axonal terminations in interblobs (A, B) or dendrites extending into layer 4C and dense axonal terminations in both blobs and interblobs. From Yabuta and Callaway (37, 38).

studies. In one such comparison, we might conclude that, on average, V1 cells become active long before cells in the frontal eye field area (FEF) (80, 81). In another such comparison, we would be forced to conclude the opposite (82) (for a review, see Nowak and Bullier (79)).

The cause for this seeming discrepancy, and many others like it, is undoubtedly the use of different experimental and data analysis protocols. The visual stimuli used (flashing *versus* moving; spot, bar, grating, or otherwise; low *versus* high luminance or contrast, etc.), animal preparation used (anesthetized or not), and data analysis strategy taken for marking latencies (qualitative or quantitative, etc.) all vary across the existing reports.

Consequently, in a recent study, we sought to remove these confounds by obtaining onset latencies from many primate visual areas using the same experimental and analytical techniques (83). The results demonstrated that the two major functional streams in the primate visual system (the M/dorsal stream involved in motion perception and tracking and the P/ventral stream involved in object recognition and color coding) respond with very different time courses (Fig. 24).

In general, M-stream areas respond rapidly and concurrently, whereas their P-stream counterparts respond slowly and sequentially. Particularly relevant to this review, the LGNd M cells become active 15 to 20 msec faster

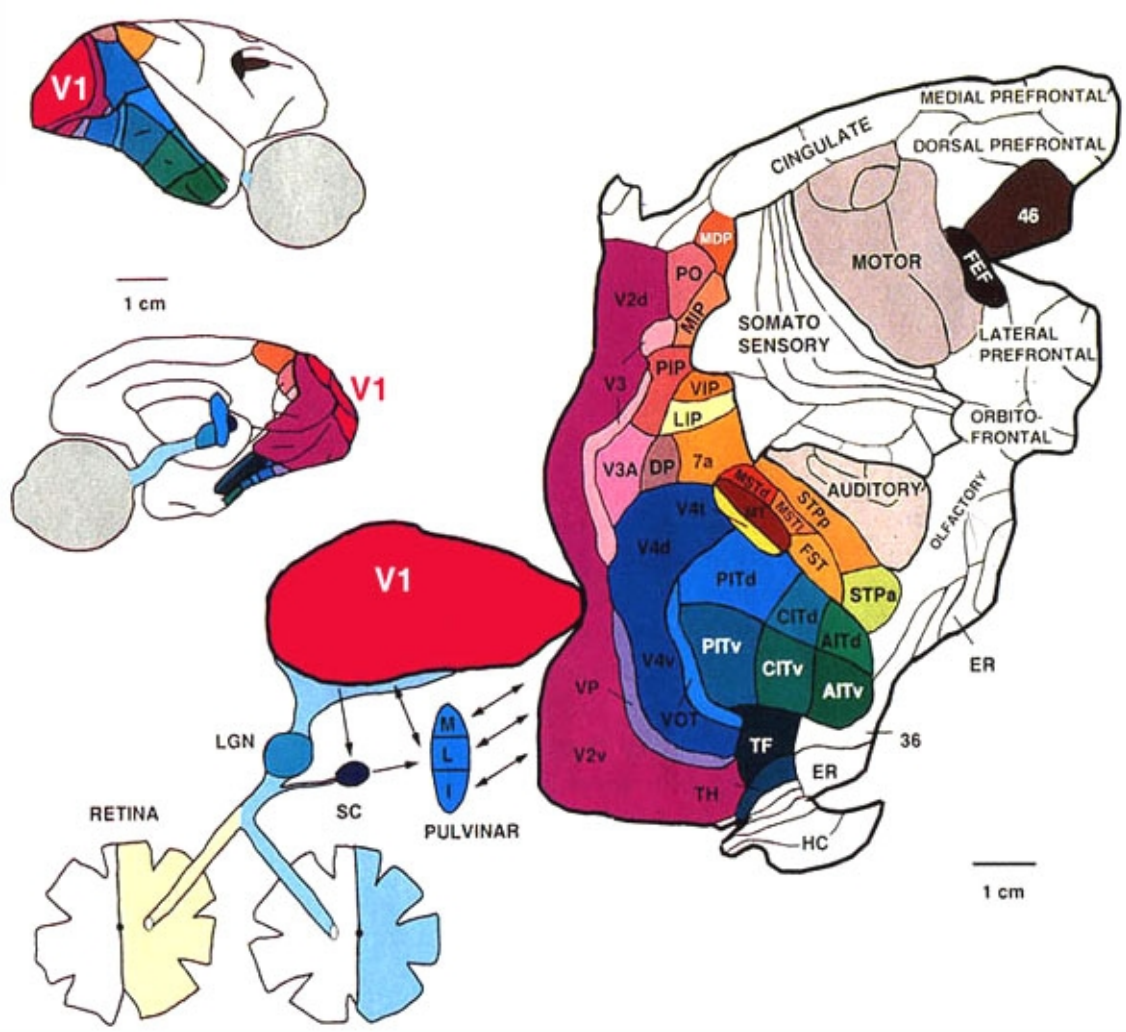

Figure 19. Much of V1 is located in the calcarine sulci, and its relationship to other brain areas is best shown by unfolding the brain and showing it flattened open. The visually responsive areas of the macaque monkey are shown in color. From Van Essen et al. (78).

than do their P-cell counterparts (83, 84), and this temporal separation is maintained in the geniculorecipient layers 4Cα and 4Cβ (80, 82, 83). Thus, a functional separation in response timing exists in the M and P pathways of the subcortex and V1 and appears to be conveyed to the dorsal and ventral streams of the extrastriate cortex.

Illusory Contour Perception

The modern view of visual perception is one of dynamic processes that go beyond the simple replication of visual information provided to the retina. For over 80 years, Gestalt psychologists have argued that the act of perception creates a Gestalt, a figure or form that is not a property of an object observed but represents the organization of sensations by the brain (85). This dynamism is thought to be crucial for the performance of simple, everyday visual tasks, such as the recognition of an object that is partially occluded. Thus, the study of how the brain is capable of filling in the missing pieces is an important topic; one that has most often been carried out through the use of "illusory contours".

Illusory contours (ICs) are defined by their subjective appearance in the absensce of any luminance differences in the image itself. A classic example of an IC is the illusory square, where four sectored discs oriented in an appropriate manner generate the percept of a square. In this instance, it is clear that no true luminance differences exist to form a complete square, and yet a square is perceived (Fig. 25).

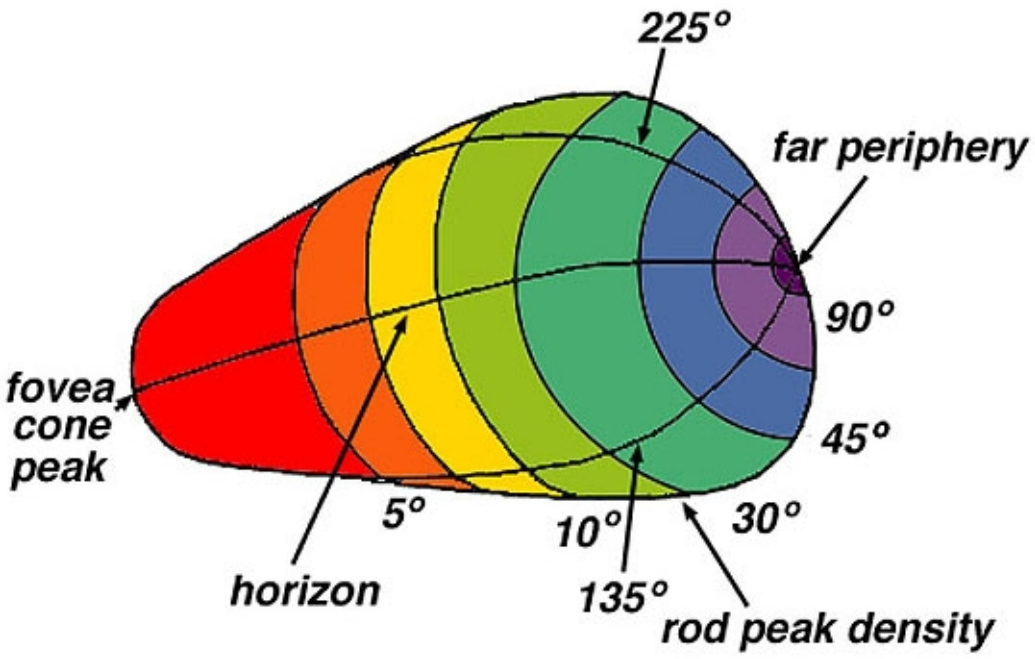

Figure 20. The unfolded striate cortex has a shape like a pear. It would be a quarter sphere if the visual fields were equally represented everywhere, but instead it is greatly distorted by the disproportionate representation of parts near the center of gaze (fovea), a feature termed "cortical magnification". In contrast, the far periphery is greatly underrepresented.

Behavioral tests indicate that cats and monkeys are capable of perceiving such contours (86-88). Recent physiological studies have examined whether single cells in striate and extrastriate cortex respond similarly to conventional luminance contours and those defined by illusions (89-92). In each of these studies, IC-responsive cells were reported. However, these studies provide conflicting evidence about the origin of IC responsivity, arguing for or against the presence of IC-responding cells in V1. The use of alternative ICs in the different studies confuses this issue further.

We sought to approach illusory contour perception from the broader issue of contour perception in general (93). The issue here is how the brain encodes a stimulus boundary (e.g., a square) when the visual cue that defines that boundary (e.g., color, luminance, texture, motion, illusion, etc.) is varied. As Gestalt psychologists would note, the stimulus is very different in each of these cases, but the fundamental percept, the square, remains the same. We asked two fundamental questions. First, are there V1 or V2 cells in cat and monkey capable of responding in a similar fashion to a boundary, regardless of the cue defining it? Alternatives to this include the origin of cue invariance at later stages of visual processing or the separate channeling of cue information via different subpopulations of cells, each responsible for one cue. Second, if such cells exist, are they equally prevalent in V1 and V2? Our results demonstrated that a subpopulation of cells in both regions can respond to a stimulus boundary, such as an oriented bar, in a cue-invariant manner, although this property was rare in V1 while prevalent in V2 (Fig. 26).

One conclusion from this work is that cells in the very first stage of cortical processing are already capable of responding to a single stimulus boundary in a complex manner that allows for object detection, even as the cues defining the object change or are partially occluded (93).

Understanding Vision: A Problem of Reverse Engineering

Our attempt to understand the visual pathways is very much like approaching a machine about which we know nothing but its basic functions. By way of analogy, we all know how to operate a car (more or less) and recognize

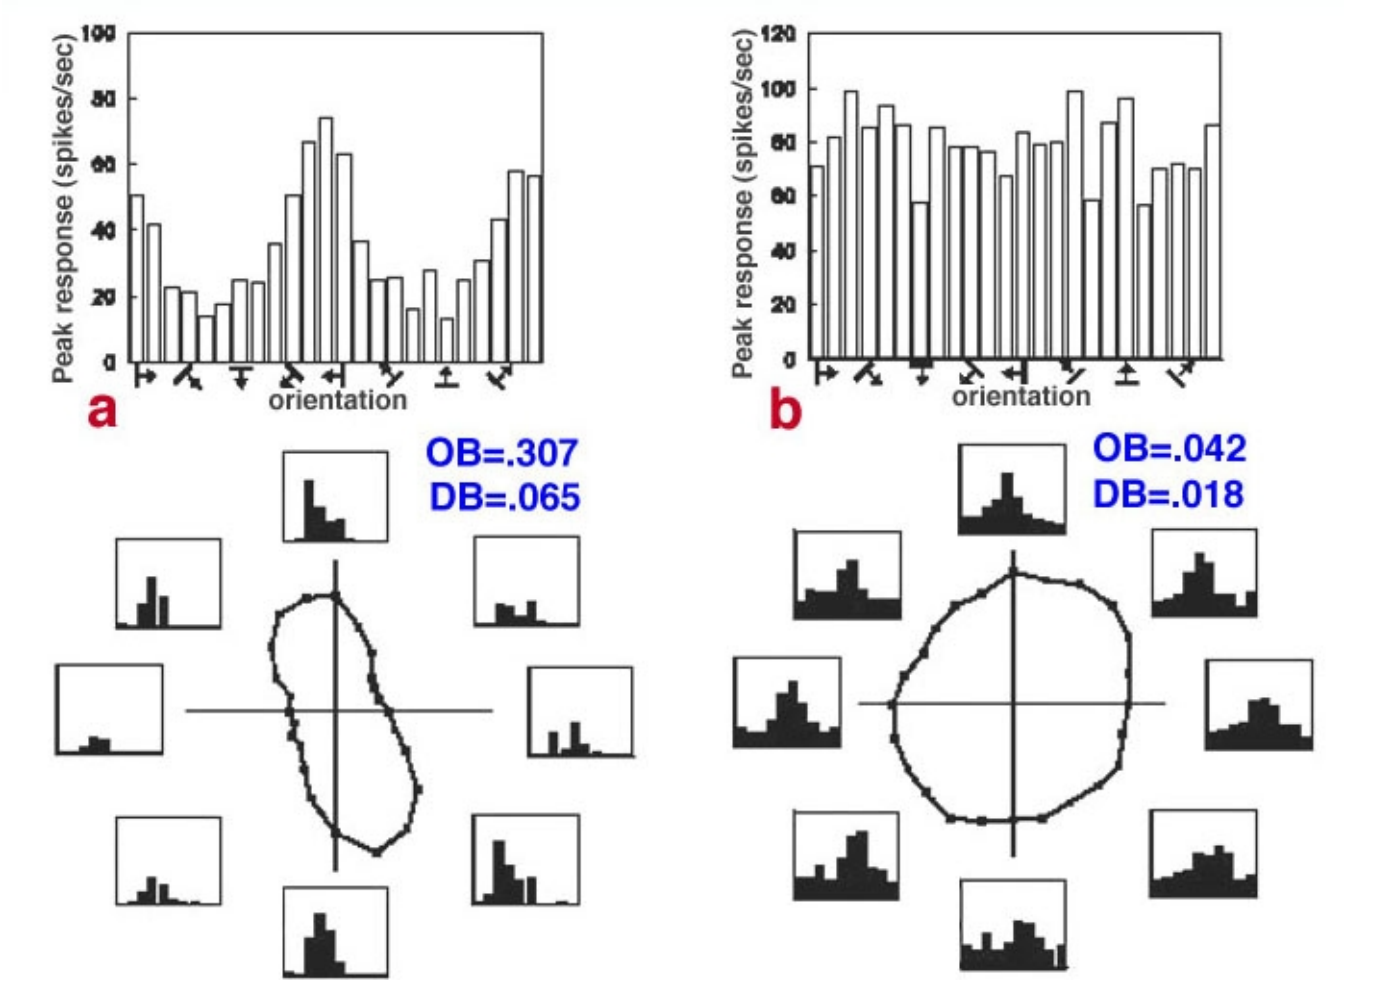

Figure 21. A tuning curve and corresponding polar plot obtained from two macaque V1 cells in response to drifting luminance bars of systematically varied orientation and direction. The responses of one orientation selective cell and one nonselective cell are provided for comparison. Histograms surrounding the polar plots demonstrate the cellular response as a function of time. Orientation bias (OB) and direction bias (DB) are measures of how selective a cell is, where >0.1 is significant and 0.3 is approximately an 8:1 maximum firing rate to minimum firing rate ratio. From Schmolesky et al. (95).

its basic function—to get us from one place to another. Now let us assume that we knew absolutely nothing but this and, for some reason, decided we should learn every detail of the car's inner workings. We might start by trying to figure out the parts of the car devoted to this central function and those that are not. We remove the bumper, horn, AC, and windshields and find that the car still runs splendidly. We remove small parts of the engine, piece by piece until the car no longer starts, analogous to the lesion studies in the brain. Slowly, we begin to understand what parts of the car (brain) are involved in locomotion (vision). In vision research, we are very much at this stage of the game, still wanting to know what each part actually does, when it does it, and how all the individual parts act in concert. It is the hope of many researchers, myself included, that a careful investigation into the structure and function of the visual pathways using chemical, electrophysiological, genetic, and behavioral approaches will culminate in a true understanding of how the brain provides us with this most crucial of sensory capabilities, vision (Fig. 27).

Under Construction

Additional sections dealing with RF properties are under construction: They include: 1) ON/OFF RF subunit composition; 2) transient *versus* sustained responsivity; 3) spatial and temporal frequency; 4) contrast sensitivity; and 5) color selectivity.

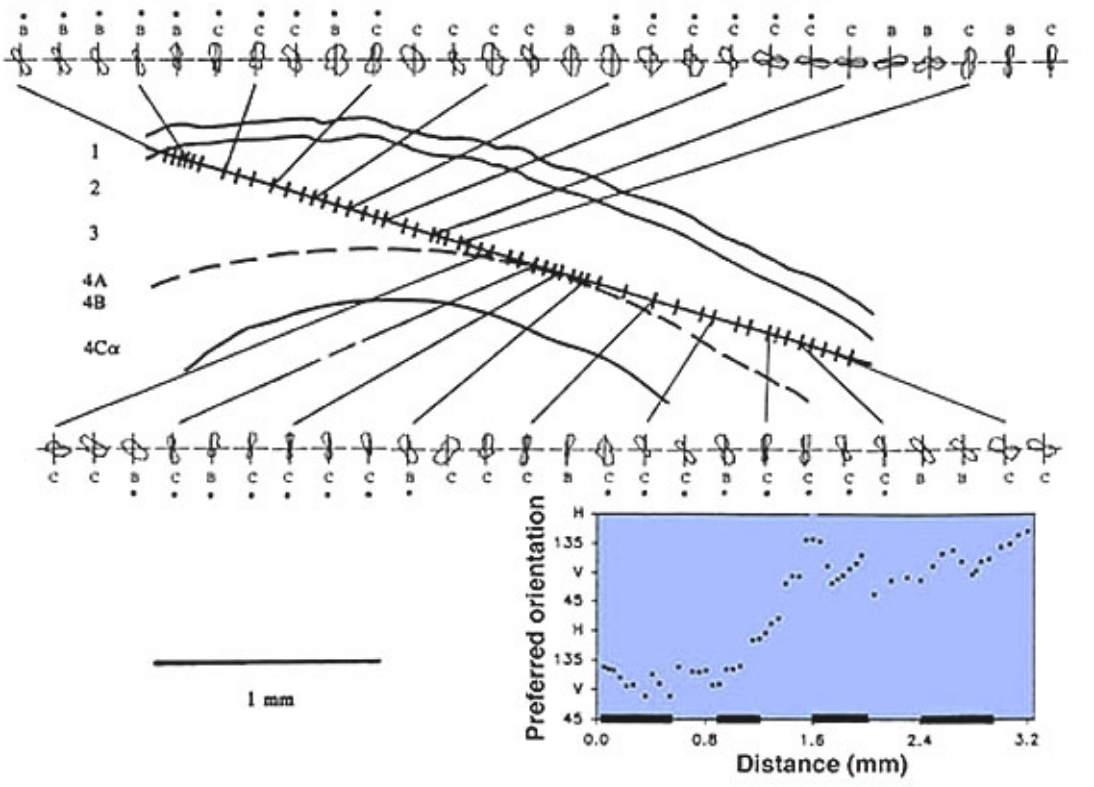

Figure 22. One extensive electrode penetration in macaque V1. The short, near-vertical lines represent recording sites, and polar plots for each site are indicated. This figure shows the preferred orientation of each cell in relation to the cortical layers, CO compartments (a filled circle indicates a blob; lack of this circle indicates an interblob), and color selectivity (C, color selective; B, broadband) in macaque V1. From Leventhal et al. (96).

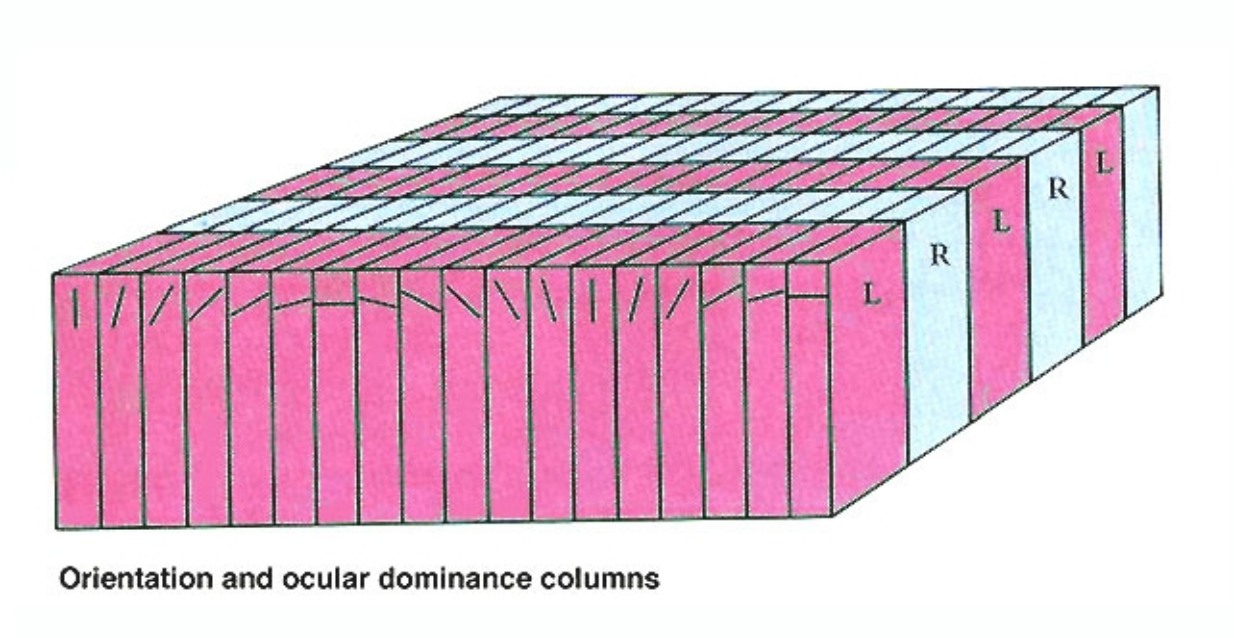

Figure 23. The ice-cube model of the cortex. It illustrates how the cortex is divided, and at the same time, into two kinds of slabs, one set of ocular dominance (left and right) and one set for orientation. The model should not be taken literally: Neither set is as regular as this, and the orientation slabs especially are far from parallel or straight.

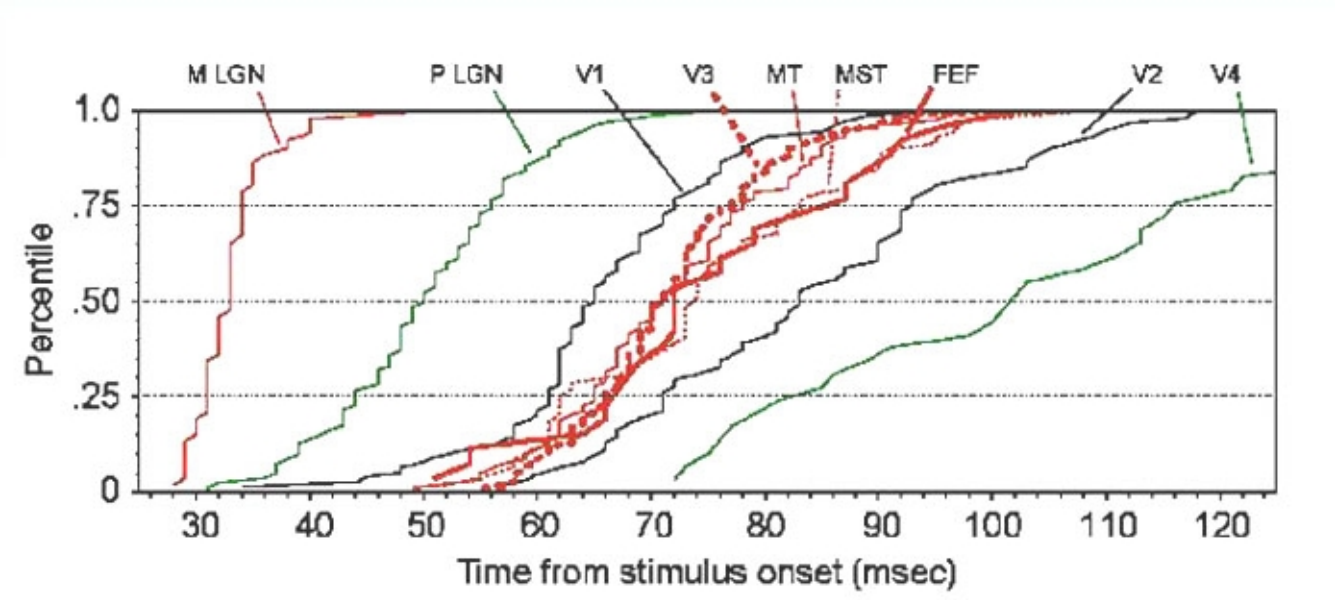

Figure 24. Onset latencies. Cumulative distributions of visually evoked onset response latencies in the LGNd, striate, and extrastriate areas as labeled. The percentiles of cells that have begun to respond are plotted as a function of time from stimulus presentation. The V4 curve is truncated to increase resolution of the other curves: the V4 range extends to 159 ms. From Schmolesky et al. (83).

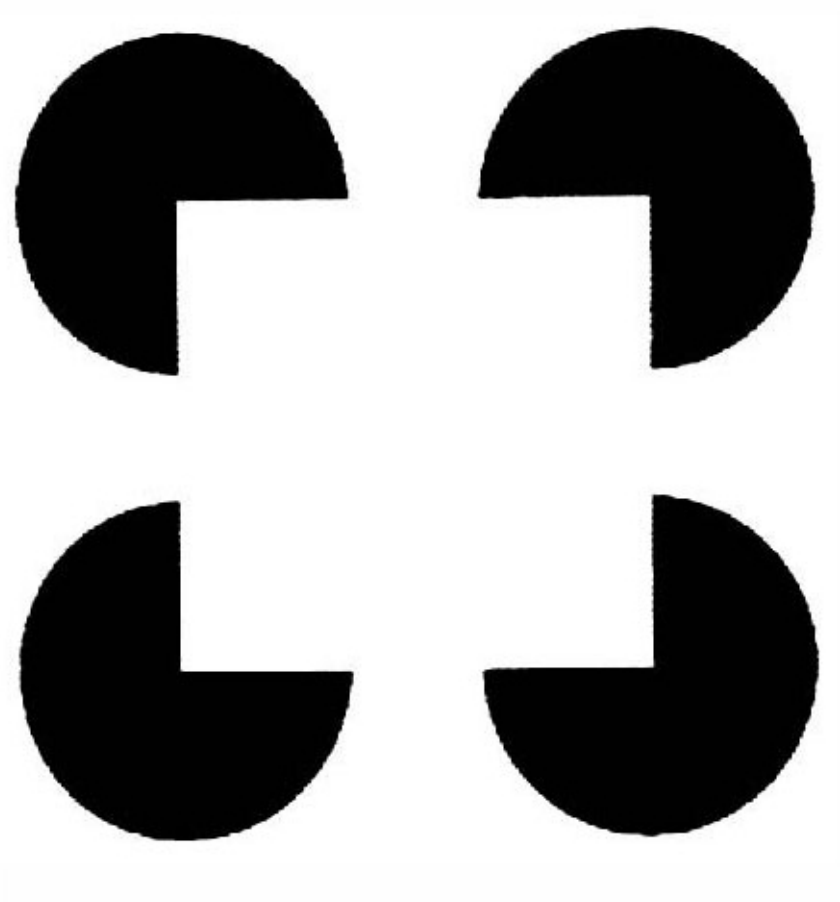

Figure 25. Illusory contours as seen in the illusory square.

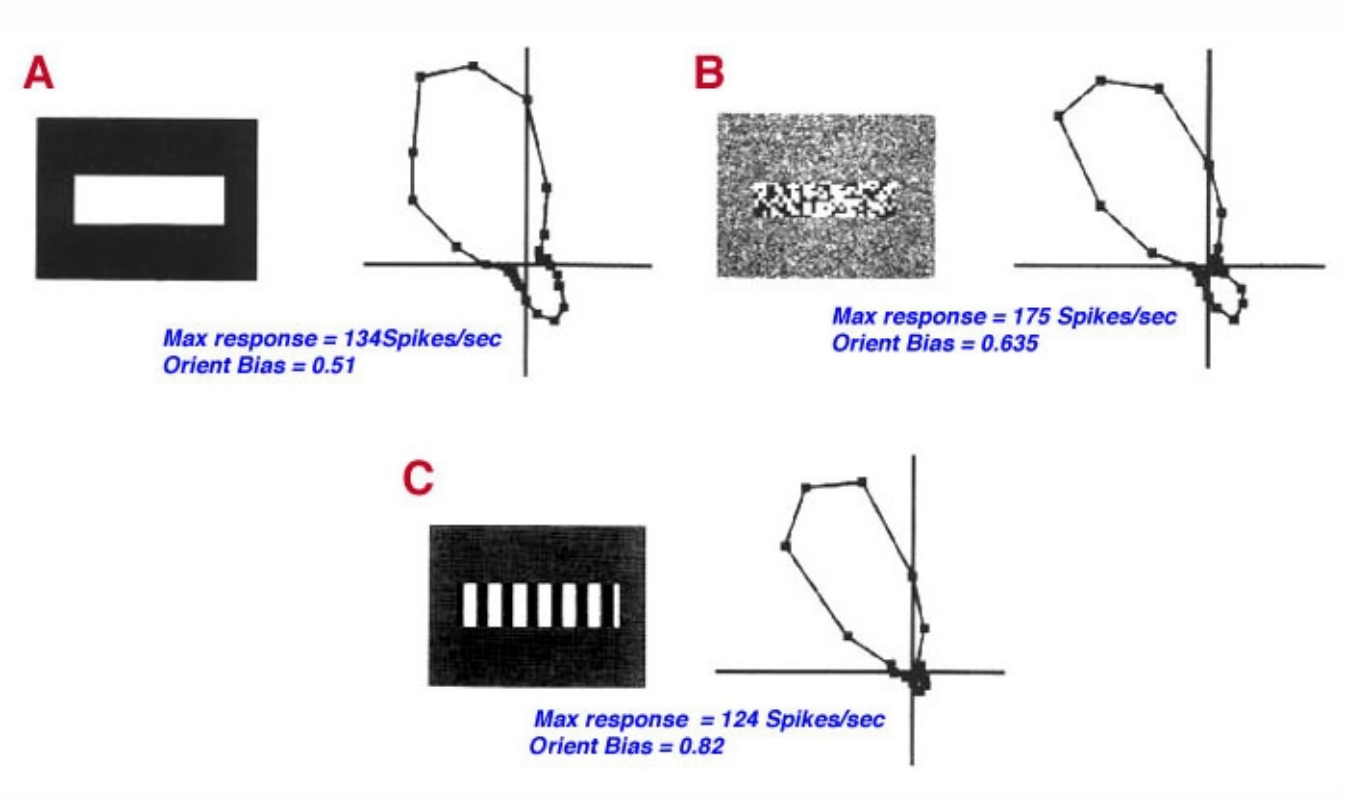

Figure 26. Example of a cue-invariant cell in cat area 18. This cell responds with the same degree of orientation bias and to the same preferred orientation, regardless of whether the bar is defined by simple luminance (top), texture (middle), or isoluminant gratings (bottom). From Leventhal et al. (93).

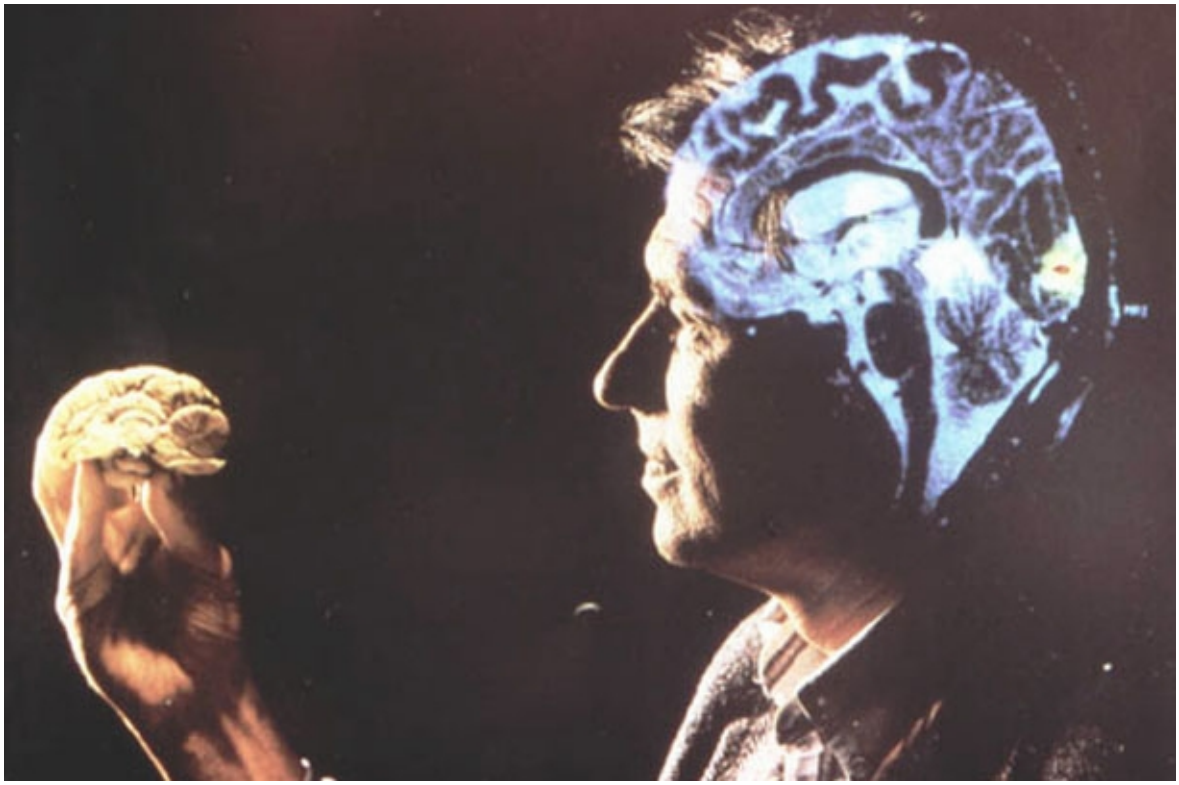

Figure 27. Reverse engineering: the brain studying the brain.

About the Author

Dr. Matthew Schmolesky was born in West Palm Beach, Florida. He received his B.A. in Psychology and Philosophy from Furman University, Greenville, South Carolina in 1993. He received his Masters in Experimental Psychology from Wake Forest University in 1995 and his Ph.D. in Neuroscience from the University of Utah in 2000, respectively. While studying at the University of Utah, he conducted research on the visual pathways in cat and monkey with Dr. Audie Leventhal, looking at aspects of color, orientation, and aging. He recently completed a Grass Fellowship at the Marine Biological Laboratory in Woods Hole, MA. Matt is currently a Research Fellow at Erasmus University Rotterdam in the Netherlands, where he is studying synaptic plasticity in the cerebellum at the cellular and behavioral levels.

Repair and Regeneration of Visual Neurons

Cellular Remodeling in Mammalian Retina Induced by Retinal Detachment

Steven K. Fisher, Geoffrey P. Lewis, Kenneth A. Linberg, Edward Barawid, and Mark R. Verardo

Created: May 1, 2005; Updated: July 3, 2007.

Introduction

What Is Retinal Detachment?

The retina is firmly attached to the apical surface of the retinal pigmented epithelium, or RPE (see earlier retinal anatomy sections). When the retina is separated from its normal position apposed to the RPE surface, it is said to be "detached." This detachment creates a pathological, fluid-filled space between the neural retina and the retinal pigmented epithelium. It also creates a greater distance between the photoreceptors and their sole blood supply, the choroidal circulation.

Clinical Retinal Detachments Occur as Different Types

There are three recognized types of retinal detachment in clinical practice:

1. Rhegmatogenous: the most common type. In this form, the retina experiences a physical tear through the retinal layers, and the torn retina peals away from the retinal pigmented epithelium by the movement of fluid into the space between the two.
2. Tractional: in which some force (usually contracting cells or vitreal "strands") acts on the surface of the retina to pull it away from the retinal pigmented epithelium.
3. Exudative: in which fluid accumulates between the neural retina and the retinal pigmented epithelium, pushing the two apart; the retinal tissue is not torn.

Retinal detachment can cause permanent visual loss or permanent reduction of visual function, especially if the macula is involved, in which case it is considered a medical emergency in the United States. For more information on the types and causes of retinal detachment, see the National Eye Institute's website.

Cellular Remodeling in the Retina

Many specific neural circuits have been identified in the retina (1-4), and only recently has evidence been found that these circuits change (remodel) in an adult mammal, usually in response to injury and disease. Before this, the retina was considered a "hard-wired" part of the central nervous system by most scientists. A change in circuitry may mean a change in vision, so understanding these changes and ways to prevent them or repair them is important.

Some Examples of Retinal Remodeling

The few earlier descriptions of cellular remodeling in vertebrate retina came from studies of fish retinas (5-7), where specific synaptic connections between photoreceptors and second-order neurons structurally changed with the daily lighting cycle. In 1984, Peichl and Bolz (8) described structural remodeling of retinal neurons in mammals in response to severe retinal degeneration induced by a neurotoxin, kainic acid. It was nearly a decade later that reports of cellular remodeling in mammalian retina in response to injury or disease began to appear with some regularity (9-12). Even total photoreceptor cell loss had not been regarded as causing significant changes to the inner retina until that time.

Photoreceptor Cell Death Differs Among Models

Many recent descriptions of structural remodeling in mammalian retina are from studies in humans or rodent species in which massive photoreceptor cell death is induced by light damage or genetic mutations (13). Retinal detachment provides information that complements those data because in most species there is not massive photoreceptor cell death after detachment. Another important distinction is that the earliest and most obvious damage induced by detachment, outer segment degeneration, is reversible by reattaching the retina. Retinal reattachment surgery probably induces its own remodeling of retinal circuits as recovery occurs, but this has been less explored at the present time.

Retinal Detachment and Reattachment as Experimental Systems

Fig. 1 illustrates cell types observed to remodel after detachment, these include: RPE, Muller cells, photoreceptors, rod bipolar cells, horizontal cells, ganglion cells, and astrocytes. It seems likely that remodeling will be identified in other cell types as well.

Outer segment degeneration, photoreceptor cell death, Muller cell hypertrophy, and changes in the RPE apical surface were all recognized as events induced by detachment in early studies (14-16). More recently, studies have demonstrated photoreceptor cell death occurs by apoptosis in both animals and humans. Currently, there is no method for replacing lost photoreceptors. Other events may be reversed by reattachment, often incompletely and usually slowly, over a time course that can vary from days to years.

Why Remodeling Is Difficult to Discover

The huge numbers of neurons and glial cells involved in the retina, the vast range of neuronal cell architectures, the small size of neuronal cell bodies relative to other cells, and the small size of the neuronal processes that intertwine to make up the plexiform layers of the retina make discovery of subtle changes in these cells difficult. Historically, it was the Golgi impregnation method that provided the breakthrough allowing for a detailed description of individual neurons and their morphologic diversity (17). A similar reliable method that would allow us to observe changes in the branching of individual neurons would be ideal for studying remodeling. Unfortunately, the Golgi method is unreliable and quixotic and, therefore, does not provide a method for the systematic study of events such a neuronal remodeling. What will undoubtedly emerge as technology evolves will be the invaluable tools for observing structural remodeling of retinal neurons in living tissue.

Making Use of New Technology to Describe Remodeling Events

Immunocytochemistry and other techniques that allow for the labeling of individual cells or populations of cells, coupled with advances in image technology such as laser scanning and confocal microscopy, have provided us with new and powerful tools for describing remodeling events in the retina in recent years.

Rod photoreceptor, rod bipolar, and horizontal cell remodeling (11) was the first to be studied in detail with this technology. In fact, results with antibody labeling confirmed speculation based on electron microscopy data published in 1983: "In addition to the effects of retinal detachment in the outer retina, we strongly suspect that the inner nuclear layer, IPL, ganglion cell layer and, perhaps, more central areas of the visual system may be affected as well" (15). Remodeling has now been firmly established in the inner retina and leads one to believe more strongly that central changes, for example ganglion cell axonal arborization and synaptic contacts, will be eventually identified as well. Technologies involving other forms of imaging, including the imaging of living cells in retinal wholemounts or tissue slices and techniques such as dye injection into single cells, will undoubtedly contribute greatly to this rapidly growing knowledge base.

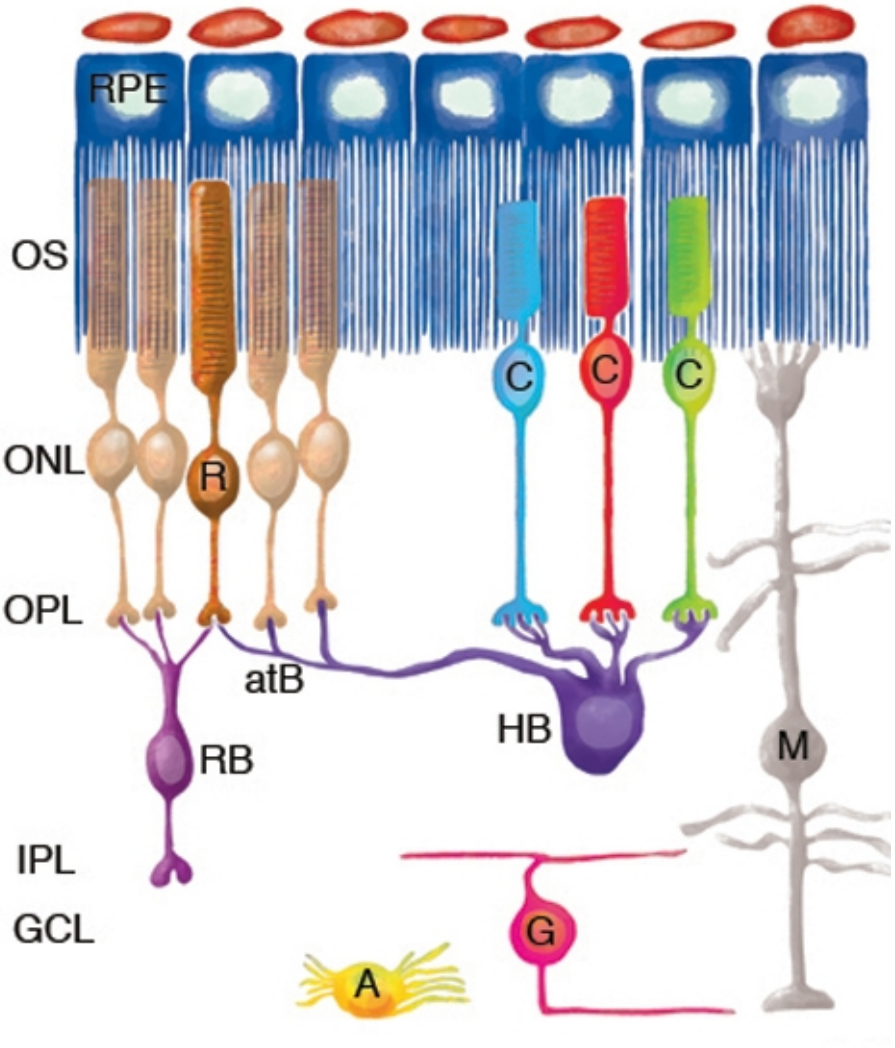

Figure 1. A drawing of the relevant retinal cell types discussed in this review. Blood vessels of the choriocapillaris lie adjacent to the retinal pigmented epithelium (RPE), opposite the retina. A, astrocytes; atB, axon terminal of B-type horizontal cell (HB); C, cone photoreceptors; GCL, ganglion cell layer; M, Muller cells; OS, photoreceptor outer segments; R, rod; RB, rod bipolar cells.

Levels of Remodeling

Remodeling can involve whole populations of cells; for instance, all RPE cells remodel their apical processes (Fig. 2, A-C, asterisk), and all photoreceptors undergo outer segment degeneration after detachment, or it can involve some subset of cells within a population. The apical surface of every RPE cell must remodel in response to both detachment and reattachment as the complex apical processes are transformed into microvilli after detachment and then regenerated after reattachment. Interestingly, the remodeling after reattachment does not appear to be consistent from cell to cell (Fig. 2, D and E). Thus, regeneration of the apical surface is not a perfect recapitulation of development. All Muller cells in the zone of detachment upregulate intermediate filament proteins, and all probably undergo some structural remodeling, but only some show extreme changes where they actually grow out of the retina, creeping into the subretinal space or onto the vitreal surface. Both of these conditions result in serious, sight-threatening, ophthalmic complications. Defining what stimulates this subpopulation to undergo such growth is medically important. Only a subpopulation of ganglion cells appears to

remodel in response to detachment (18), and identifying which types may lead to a better understanding of some of the visual disturbances that occur after successful reattachment surgery.

Retinal Deafferentation

Deafferentation in the central nervous system (CNS) refers to removing the sensory input from some motor pathway. Although there is no "motor" component to the retina's output to the brain, the massive loss of photoreceptors (usually approaching 100%) that occurs in some diseases such as retinitis pigmentosa (or in animal models of this disease) has been described as "deafferentation" (13). Remodeling in these systems and in such conditions as light damage in albino rats has been described as largely in response to this "deafferentation". The changes that we are focused on here are those that occur within hours or days of detachment, because it is these changes that may be successfully manipulated by therapeutic intervention and thus lead to better visual recovery. These are not responses to massive death of photoreceptors, although they may represent responses to the death of individual photoreceptors and therefore partial deafferentation of individual cells or neural circuits. Remodeling is also associated with the recovery phase after retinal reattachment, during a time when photoreceptor cell death does not occur.

Basic Information Relevant to Understanding the Responses to Retinal Detachment

Although the retina is a developmental outgrowth of the brain, it does have several features unique to its specialized functions. Photoreceptors have the highest metabolic rate of any cells in the body, and yet there are no blood vessels among them (their presence presumably would blur the visual image)—they are nourished almost solely by the capillaries of the choroid, which lie on the opposite side of the RPE (Fig. 1) (19). Traditional astrocytes are not scattered throughout the retina as they are in the brain and spinal cord but reside only among the ganglion cells and their axons. The retina has a large population of highly differentiated, polarized radial glia, or Muller cells, that may assume many of the functions of astrocytes in the brain and spinal cord but are, at the same time, distinct from them. Ganglion cell axons in most species are not myelinated until after they enter the optic nerve, and thus, the retina does not have a population of oligodendrocytes, the myelin-producing glial cells. The retina does have a resident population of microglial (scavenger) cells, but these appear to be restricted to the IPLs and outer plexiform layers (OPLs) in the healthy eye.

Animal Models of Detachment and Reattachment

The choice of which species to use has been driven by many issues including: 1) how closely the retina structurally resembles that of humans; 2) knowledge of retinal circuitry, physiology, or biochemistry in the species; 3) the reliability with which controlled detachments and reattachments can be created; and 4) the specific goals of the study.

Different Species React Differently: Finding the Best Model

Different species do react differently to detachment, and not all of these accurately reflect what little we know about the reaction of the human retina. The rabbit retina (with about the same rod/cone ratio as the feline retina) exhibits very rapid and complete degeneration of much of the neural retina (20, 21); thus, it is not a good model for longer-term events. The ground squirrel has a retina dominated by cones (22, 23) and thus is a potential model for the reactivity of the human macula (except that ground squirrel cones do not structurally resemble macular cones). The ground squirrel retina, however, shows a rapid and eventually complete degeneration of the photoreceptor layer but almost no RPE or glial reactivity or neuronal remodeling (24, 25). Unlike the rabbit, it does not show inner retinal degeneration. We have used all of these in various studies, but the species that seems to most closely model what is known about events in human detachments is the common

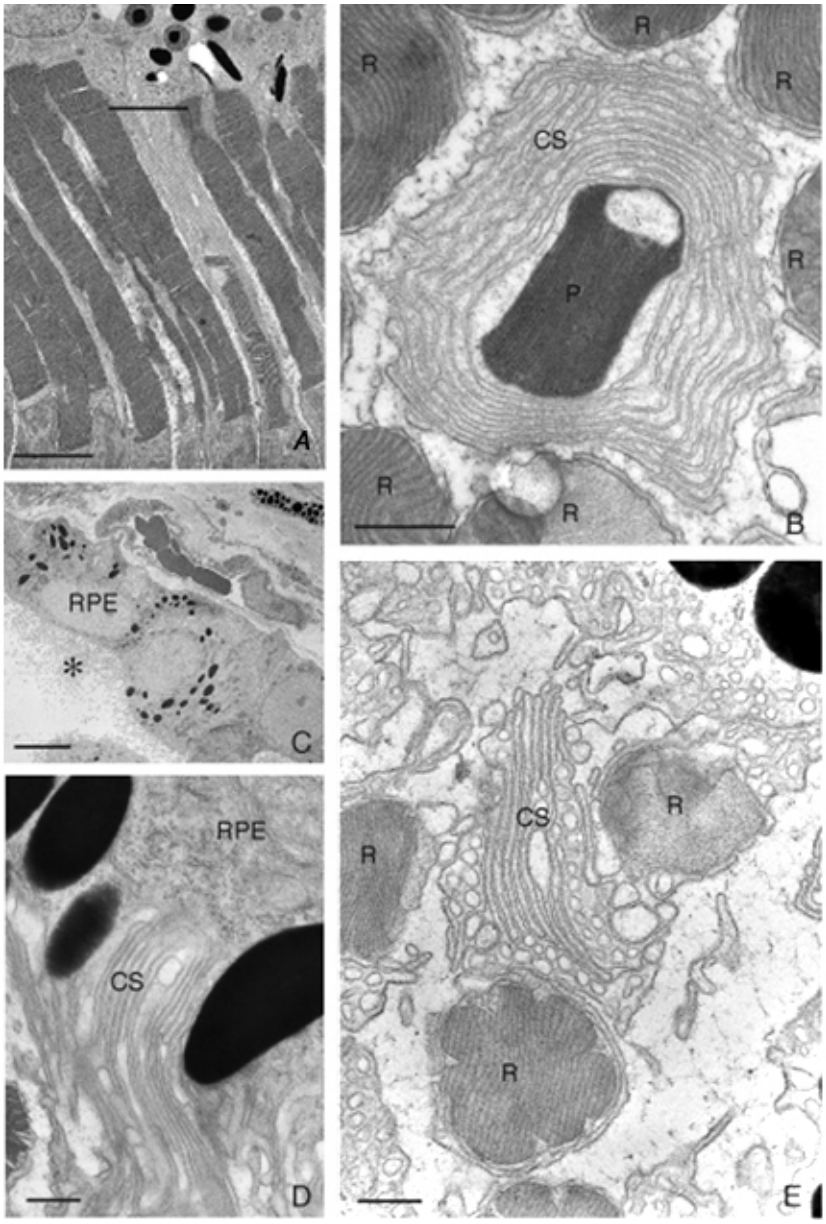

Figure 2. Electron microscopy. A, normal feline retina. Rod outer segments (ROS, R) terminate close to the retinal pigmented epithelium (RPE). Cone outer segments (COS) are shorter and surrounded by an elaborate cone sheath arising from specialized apical processes. From Fisher and Anderson (123). B, a cone sheath (CS) in cross-section (at the location of the line in part A). P, a phagosome shed from the cone. C, the apical surface of the RPE after detachment consists of a fringe of microvilli (*). D and E, the retina detached for 3 days and reattached for 28 days. CS are always structurally different from those in normal retina. (compare to parts A and B). Scale bars: A and C, 2 μm; B, D, and E, 0.5 μm.

domestic cat. The retina of many primate species are foveated, but their use is often prohibitive for a variety of ethical and financial reasons.

Developing New Model Systems

Because of the availability of genetic information and the ability to readily do genetic manipulations, developing a reliable method for producing large, controlled detachments in the mouse eye has become a high priority in recent years (e.g., Nour et al. (26) and Yang et al. (27)). Current data from that model show many of the same reactions found in the feline model, although there may be less Muller cell reactivity. The height of a detachment, that is, the distance separating the detached neural retina from the RPE, is probably an important parameter in

human detachments, and high detachments are harder to produce in mice because of the small size of the eye and the fact that the lens fills much of the vitreous cavity. Reattachments using the same procedures as in humans can be done in larger species; whether they will be possible in a mouse eye remains to be seen. Simply allowing the retina to settle instead of actively reattaching it provides one method, but with less precise control over the time of reattachment. Another promising area is the use of cold-blooded animals (e.g., frogs, fish, and salamanders) in similar experiments because their retinas are relatively easy to maintain in culture, and because many of them have very large photoreceptor cells that are amenable for high-resolution imaging and other types of single-cell analyses. Currently, most work is, however, being done with mammalian species.

The Feline Model

The feline retina, similar to the peripheral human retina, is rod dominated. It is a species with a robust intraretinal circulation (as in all species, it is excluded from the photoreceptors). The cat retina has also been the subject of decades worth of anatomical and physiological studies. The feline eye is large, allowing for easy surgical access, and for the production of defined detachments and simple reattachments using the same procedures as in human patients.

Detachments are created by slowly infusing fluid into the interface between the RPE and neural retina through a tapered glass pipette with a tip diameter of about 100 µm (28). It has been argued (29) that this does not model a rhegmatogenous detachment because there is no large tear (referred to as a "retinal break") through the retinal tissue. However, our observations of tissue from human rhegmatogenous detachments and reattachments tend to validate the feline model as producing the same cellular responses (30).

The Details of Cellular Remodeling after Detachment and Reattachment

Fig. 1 shows the cell types that have been identified to date as undergoing remodeling after detachment and reattachment. We have only preliminary evidence for the structural remodeling of amacrine cells, although this has been described in late-stage human retinitis pigmentosa (10). Little is known about changes in retinal astrocytes except that they proliferate after detachment. Retinal microglia respond robustly to detachment by assuming macrophage-like characteristics (31, 32). They will not be discussed here, although they undoubtedly play an important role in the overall "injury response" of the retinal tissue.

Retinal Pigmented Epithelium

The morphology of the RPE changes stereotypically after detachment in all species studied. In species such as cat, dog, rabbit, and human, there are vast differences between the apical processes that interact with rods and cones (33-36), with the "cone sheath" forming a unique structure consisting of a highly complex, multi-layered array of sheets of apical processes (Fig. 2, A, and B). Regardless of their structure in the normal eye, these apical processes all disappear after detachment and are replaced very quickly, probably within hours, by a fringe of simple microvillus-like processes (37) (Fig. 2, C, asterisk). The RPE has the remarkable ability to re-form these elaborate apical processes after reattachment. In the case of the feline retina, this also means regenerating the highly complex cone sheaths. However, a month after reattachment, these cone sheaths still do not appear "normal". The presence of slightly truncated, often thickened or misaligned, cone sheaths is almost always a clear indicator that the retina was detached at some earlier time (compare the structures labeled "CS" in Fig. 2, A, B, D, and E). The fact that the cone sheaths re-differentiate only in association with cone outer segments indicates some form of signaling mechanism retained in the adult retina that allows for the RPE to know when its apical surface is opposite a cone.

The RPE proliferates in response to detachment, and this can result in a complete remodeling of the geometry of this layer. Newly proliferated RPE cells can migrate into the subretinal space, where they assume complex

geometric arrangements: single cells, long strands, or multiple layers with reversed apical-basal polarity (38). If the basal surface faces the neural retina, photoreceptor outer segment regeneration does not occur after reattachment (39). It is not known if photoreceptor function is compromised when outer segments regenerate in the presence of multiple layers of RPE.

Photoreceptor Deconstruction, Outer Segment Degeneration, and Cell Death

In the feline model, and probably in the human retina, detachment sends all of the photoreceptors, both rods and cones, within the zone of detachment, along a pathway of structural changes that we have termed "deconstruction" (40). The outer and inner segment response appears to be the same in rods and cones, but the synaptic terminal responses differ. In both feline and human retinas, it is clear that many cells survive detachment for very long periods of time. Deconstructive changes may occur as a mechanism to assure the cells' survival under adverse environmental conditions, i.e., a means of saving metabolic energy. It is not clear why in some species (ground squirrel, rabbit) detachment leads to deconstruction and cell death of virtually all photoreceptors, whereas in other species, the majority survive for long periods of time.

After detachment, outer segment material is lost until only a few disks remain, along with the connecting cilium (14). The complex mechanism of disc morphogenesis is not lost in these cells (41) because once reattached, they retain their ability to reconstruct an outer segment even though that reconstruction may not be perfect. Remaining rod photoreceptor outer segments, even if composed of only a few discs (Fig. 3, A-C) are still positive for their respective opsins (Fig. 3 and Fig. 4) (42, 43) as well as other proteins.

Death by Apoptosis

Most photoreceptor cell death after detachment is by apoptosis (programmed cell death). On the basis of our results in the feline retina, there is an early period, around the first 3 days after detachment, when about 20% of the photoreceptors die by apoptosis (44, 45), but retinas detached for 450 days can retain at least 50% of their photoreceptors (15). Observations of human detachments also show that apoptosis is a part of their response to detachment, but as in the feline model, large portions of the photoreceptor population also survive (46). There is no information about the survivability of foveal photoreceptors after detachment. Cell death in the inner retina in response to detachment is very rarely observed in the feline model; although sporadic cell death may be important, it is also difficult to document.

Internal Reorganization of Photoreceptor Inner Segments

After detachment, electron microscopy as well as immunocytochemical labeling for mitochondrial components shows a decrease in the number of mitochondria in the inner segments as well as a much less distinctive compartmentalization of all organelles (14, 15, 40). Maintaining the highly compartmentalized and polarized structure of a photoreceptor must be metabolically costly. Having the cells assume a much simpler organization may assure their survival under environmentally challenging conditions. In the case of detachment, that challenge would include hypoxia and probably hypoglycemia that is created by physically moving the retina away from its choroidal blood supply (19, 28, 40). This hypothesis is supported by studies in which providing increased environmental oxygen lessens photoreceptor deconstruction and cell death after detachment (25, 28, 47).

A Comparison of Rod and Cone Responses

The outer and inner segment of rods and cones undergo similar structural changes, but a prominent response of rods is the withdrawal of their axons (Fig. 5, A and B) and a reconfiguration of the single synaptic invagination with its 3-5 postsynaptic processes (48, 49). This response is not observed in cones.

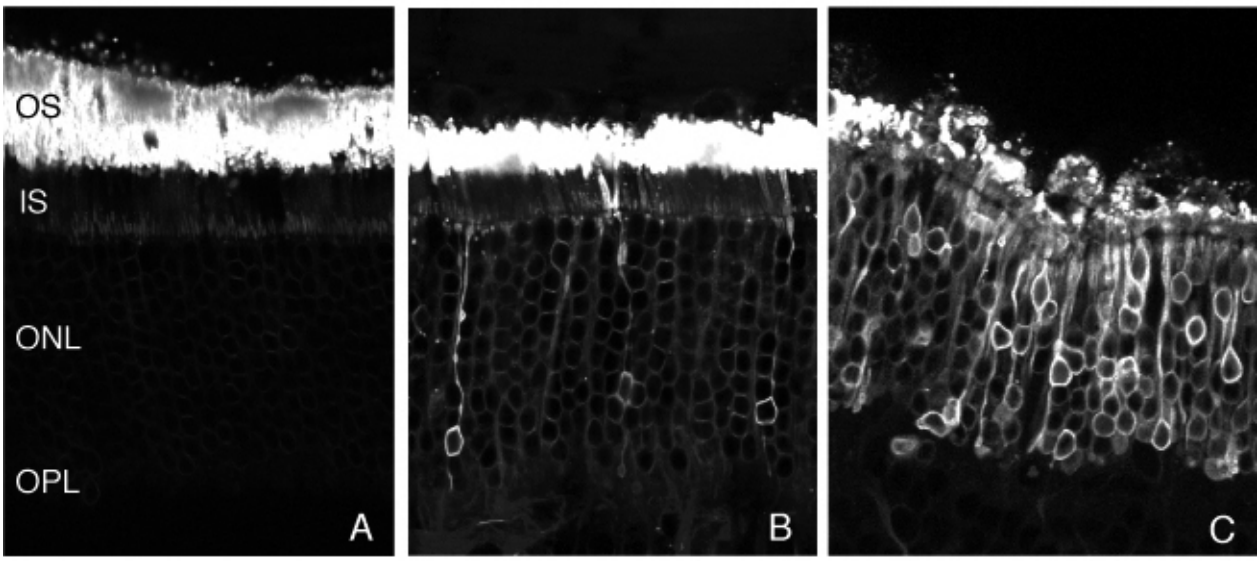

Figure 3. Normal and detached retina labeled with an antibody to rod opsin. A, normal retina. Rod outer segments (OS) are labeled. B, retina detached for 3 days. The OS layer narrows as rod OS degenerate, and the antibody now labels the plasma membrane of rod cells in the ONL. C, retina detached for 28 days. Remaining fragments of rod OS contain rhodopsin.

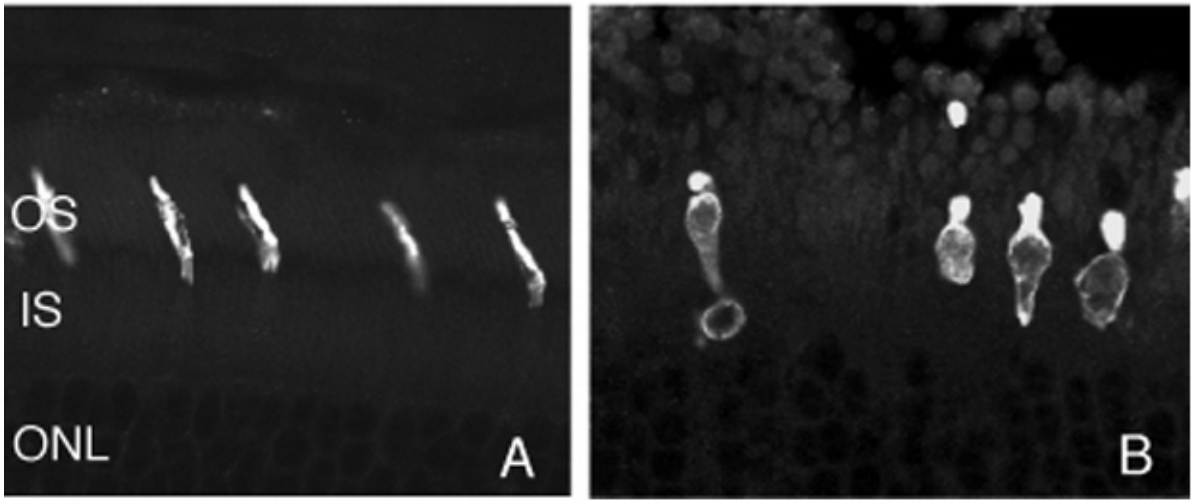

Figure 4. Normal and detached retina labeled with an antibody to medium (M)- and long (L)-wavelength-sensitive cone opsins. A, in normal retina all M-COS are labeled. B, retina detached for 3 days. The M-COS are degenerating, and the antibody labels the plasma membrane of cones in the ONL. After 3-7 days of detachment, there is down-regulation of protein synthesis by these cells and no labeling.

This disruption can be appreciated by immunocytochemical labeling with antibodies to presynaptic vesicle proteins, such as synaptophysin (Fig. 5) or VAMP (synaptobrevin). After detachment, labeled terminals appear near the rod nuclei scattered throughout the outer nuclear layer (ONL) (Fig. 5B). Terminal withdrawal and reorganization begins within a day. The electron micrograph in Fig. 6 shows the highly compact organization of the rod terminals in the OPL in a normal feline retina. After detachment, the deep synaptic invagination in each becomes more shallow (Fig. 7, A and B, arrows) and is eventually lost altogether (Fig. 7, C and D). There are still membrane specializations associated with the "postsynaptic" processes adjacent to the base of the retracted terminals (Fig. 7, B-D). Those terminals that do not retract may also change with a "looser" organization of postsynaptic processes (Fig. 7B).

Withdrawn rod terminals show a sparse population of synaptic vesicles and synaptic ribbons that vary more in size, configuration, and location than expected. Although there are one or two long, arc-shaped synaptic ribbons in normal feline rod spherules (48, 50), the presence of 1-3 shortened ribbons is common in the retracted terminals (Fig. 7, A, C, and D, arrowheads).

Cone pedicles do not withdraw from the OPL. However, the pedicle itself undergoes unpredictable changes in shape. The axons of some become tortuous instead of streaming straight across the ONL from their cell body (Fig. 8, A-C). In all cases, however, these terminals appear to lose the 9-14 synaptic invaginations (48) (Fig. 9, A and B), giving their base a flattened appearance (Fig. 8C) (also see Erickson et al. (15)).

Presynaptic Ribbons Change in Both Rods and Cones

Presynaptic ribbons appear to grow shorter, and some may disappear (Fig. 9, A and B). This ribbon response is dramatic when observed by immunocytochemical labeling using antibodies specific to them (51). Ribbons in rod terminals appear as "clumps" (compare the red synaptic ribbons in Fig. 10, B and C, to those in Fig. 10, D). Within the cone pedicles, the characteristic array of ribbons (Fig. 10, C, arrowheads) is no longer detected in the OPL (Fig. 10D). By electron microscopy, very short ribbons remain within the affected cone terminals, and some post-synaptic processes are still recognizable (Fig. 9).

Following the remodeling of rod terminals has been made relatively simple because of their outlining by displaced rhodopsin. Documenting longer-term changes in cone synapses is complicated by the fact that the expression of proteins in the cones rapidly decreases to levels that are below detection (52, 53), making them difficult to visualize by immunocytochemistry. (Fig. 8, A-D). In Fig. 11, there are long expanses of the retina in which only the rod outer segments (green) are labeled by the anti-PDEg, and there are no labeled cones.

The Population of Cones Is Heterogeneous

The lectin, peanut agglutinin (PNA), labels the extracellular matrix domain (matrix sheath) around cone photoreceptors (54) and can be used to define the total population of cone cells. Fig. 12A is a density map of PNA-labeled cone sheaths in the superior temporal quadrant of a control (normal) feline retina (also see Steinberg et al. (55)).

There are specific antibodies that recognize the different spectral classes of cone photoreceptors (56-58). The feline retina contains mid-wavelength-sensitive (M) and short-wavelength-sensitive (S) cones, and the latter are not distributed evenly over the retinal topography (Fig. 3A). Whereas the total number of cones peaks in the area centralis, the density of S-cones is highest in the inferior retina, but even there, they compose only about 20% of the cone population (52).

The expression of opsin genes reliably defines distinct subpopulations of photoreceptors. The expression of other proteins by these cells is less consistent. An antibody to the calcium binding protein calbindin D labels entire cone cells in many species, including humans and felines. The density of calbindin D-positive cells matches very closely the density of PNA-labeled cone matrix sheathes in the peripheral retina, but there is significant disparity in the area centralis, where the antibody fails to label a majority of cones (Fig. 14A). This phenomenon also occurs in monkey and human retinas, where foveal cones do not label with anti-calbindin D (59-61).

Protein Expression in Cone Photoreceptors after Detachment: Analyzing the Surviving Cone Photoreceptor Array

What follows is a fairly detailed description of changes in the cone population after detachment and reattachment as summarized in Fig. 12 and Fig. 13. For those who want to skip the details: cones appear to be lost from the retina after detachment because they: 1) lose their outer segments; and 2) lose the expression of specific proteins. Using the return of cone proteins as an indicator of cone recovery after reattachment shows

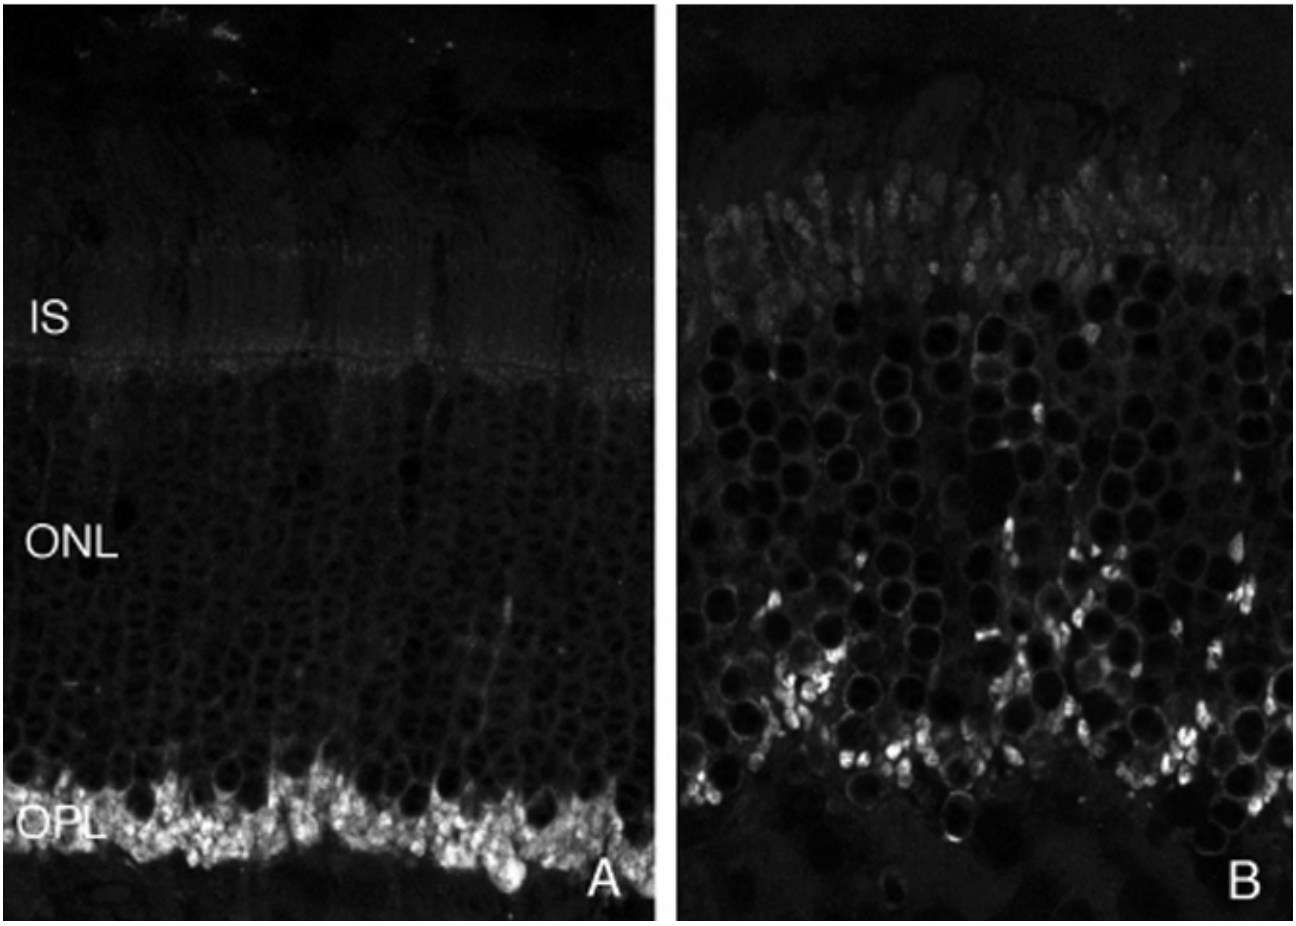

Figure 5. A, normal retina labeled with an antibody to the presynaptic protein, synaptophysin. Labeling is specific to the layer of photoreceptor synaptic terminals in the OPL. B, retina detached for 3 days. The compact OPL is disrupted, and RS retract into the ONL.

that at 28 days after reattachment, the cone mosaic is not the same as in normal retinas. Both types of cones recover, although the recovery of the S-cones may not be as complete as that of the M-cones. The retinal cone mosaic is disturbed by detachment, and inconsistencies in its recovery may account for visual defects after reattachment, especially if the fovea is involved. There is nothing known about the recovery of the cone mosaics within the fovea.

As rod outer segments degenerate, rod opsin labeling begins to increase in the plasma membrane of the cells until the whole cell is outlined (see Fig. 3) (24, 42, 43, 53). Thus, antibodies to rod opsin can be used as markers for the presence of rod cells (and the redistribution of labeling is also a remarkable indicator of stress or injury to them). Although antibodies to the cone opsins begin to show a similar redistribution (Fig. 4) after only 24 h of detachment, many cones fail to label with these antibodies (53). A similar phenomenon occurs in retinas of humans with late-stage genetic degeneration (62).

Thus, markers for cones in the normal retina are not reliable for estimating the cone population that survive detachment (52). Indeed, if the lack of labeled cones after detachment was an accurate reflection of cone survival, then the effects of detachment on the cone population would be devastating (52). Further confounding the use of markers for cones is the fact that the response is not consistent from marker to marker, nor even from one retinal region to another.

In the central region of a control retina, anti-calbindin D labels about 19,700 photoreceptors/mm^2, and the antibody to S-cone opsin about 1,100/mm^2. After 24 h of detachment, these numbers drop to 9,000/mm^2 (46%

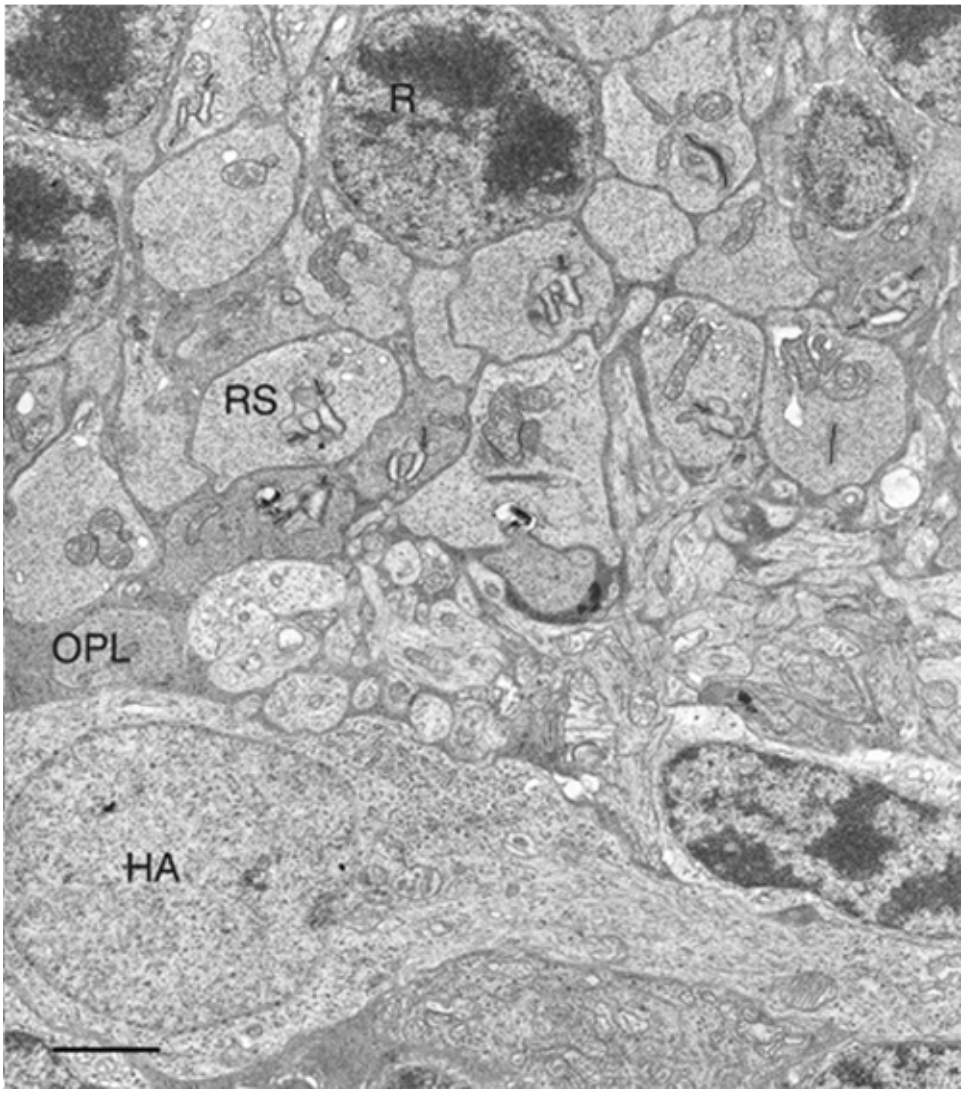

Figure 6. The OPL of normal feline retina. RS lie just distal to the OPL. R, rod nuclei in the ONL. Scale bar, 2 μm.

of control values) and 700/mm^2 (63% of control values), respectively. By 28 days of detachment, there were no cells labeled with the anti-calbindin D, but 200/mm^2 (18% of control values) labeled with the anti-S-opsin (52) (Fig. 13, B, and Fig. 14, B-D). In detached retinas, there are large areas in which no labeling appears at all with the cone markers (see the example for PDEg in Fig. 10 and Fig. 11), as if all of the cones in the region were gone. These dramatic changes are reflected in the density maps for both S-opsin and anti-calbindin D labeling (Fig. 13 and Fig. 14). In the latter, the central area is nearly unrecognizable by 1 day of detachment and completely undefined after 3 days. Similarly, the number of S-cones drops from between 700 and1,100/mm^2 in the control retina to less than 300 in a 3-day detachment. Because of the relatively large bins used to create these maps, they do not show the substantial islands in which there were no labeled cones. The wide variations in numbers of labeled cones gives the retinal wholemounts a "patchiness" that is not observed in control retinas, where the transitions in cone density are smoothly graded.

We approached the question of cone survival in another way: by examining the recovery of cone markers after reattachment (63). We chose 3 days of detachment because there is already a significant drop in the cone population labeled with peanut agglutinin (PNA), anti-cone-opsin, or anti-calbindin D at that time. The superior retina in the right eye of three animals was detached for 3 days and then reattached for 28. The retinas were harvested and labeled with PNA (Fig. 12, PNA = all cones, only the superior temporal quadrant is illustrated)

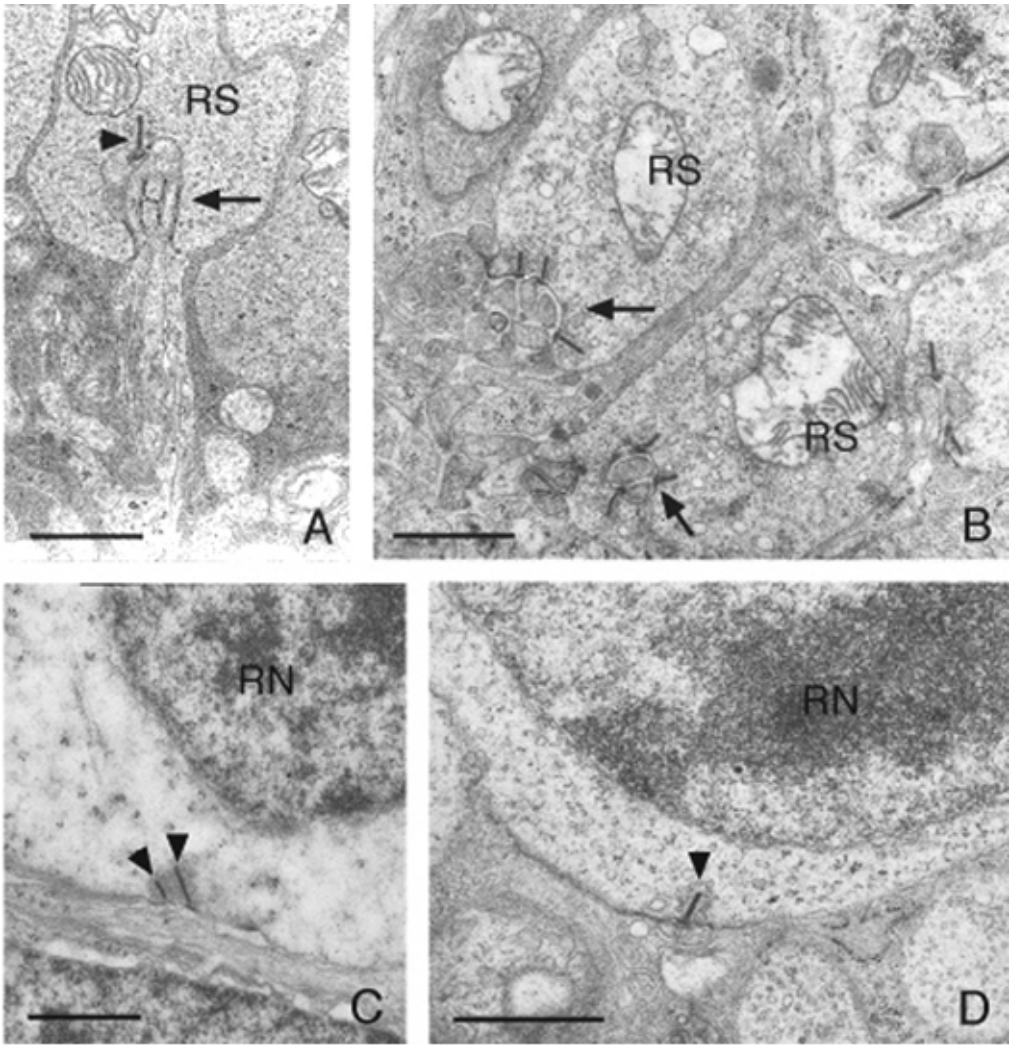

Figure 7. A, normal retina. Organized postsynaptic processes enter the synaptic invagination (arrow) of the RS. Arrowhead, presynaptic ribbon in a RS. B, in a detached retina, the synaptic invaginations (arrows) are flatter, and post-synaptic processes are less organized. Note the three synaptic ribbons at each invagination. C and D, two examples of retracted RS lying in the mid ONL. Short synaptic ribbons (arrowheads) are adjacent to sites without deep synaptic invaginations. RN, rod nucleus. Scale bar, 1 μm.

and the antibody to S-opsin (Fig. 13). Comparisons can be made to the maps for total cones (calbindin D labeling, control and 3 days, Fig. 14, A and C; PNA labeling, control retina, Fig. 12, A) and S-cones (S-cone opsin labeling, control and 3 days, Fig. 13, A and B). There is a recovery of both the PNA and S-cone population after reattachment; indeed, a central-to-peripheral gradient is apparent in the PNA labeling pattern, although the density remains depressed. None of the animals recovered densities greater than 17,000-20,000 cones/mm^2 (Fig. 12, B-D). Similarly, the S-cone population recovers, but recovery is not complete (Fig. 13, C-E). The high density area of S-cones in the far periphery of the superior-temporal quadrant is not recovered at 28 days of reattachment, and in all three animals, recovery in the central retina was in the range of 300-700 cells/mm^2, compared with the 700-1,100 cells/mm^2 observed in the control retina (the detachment did not extend into the yellow/red colored area in the central area of Fig. 13, E).

Because these numbers are generated as counts from small sampling areas and the contour lines on the maps drawn by eye, it is difficult to choose an average value for cone density within the reattached retina, but using estimates of cone density sampled over a fairly broad region, results from two animals with reattachments show a recovery of 40-60% of PNA labeling in the area centralis and approaching 100% recovery in the periphery.

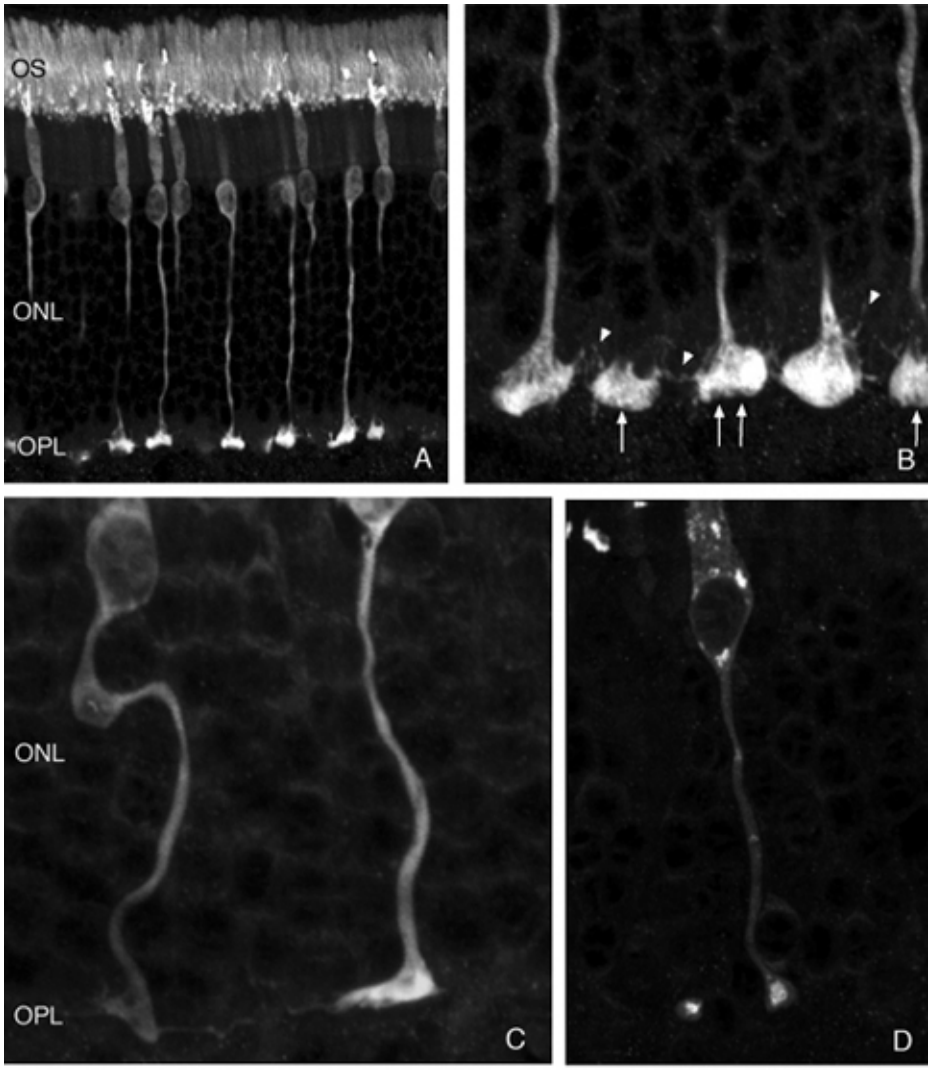

Figure 8. Expression of the g subunit of the photoreceptor-specific phosphodiesterase (PDAg). A, normal retina. The antibody labels both rod and cone outer segments (OS), and cones in their entirety. B, CP labeling in normal retina. Arrowheads, fine telodendria. Multiple synaptic invaginations in single CP are indicated by the arrows. C and D, retina detached for 7 days. Labeled cones are difficult to find and often assume tortuous paths across the ONL.

S-cone recovery seems more variable, ranging between 0 and 40% with no pattern readily discernable across the retina. Whereas PNA-labeled cone matrix sheaths were remarkably evenly distributed across the retina and showed a central to peripheral decline, S-opsin labeling showed large swatches within the reattached retinal map with no visible labeling. These data demonstrate quantitatively that the absence of marker molecules in the detached retinas does not indicate the absence of cone photoreceptors, because cells recovered across the entire retina, in some cases to numbers comparable with those in the control eyes. It is unknown, of course, if there would be more recovery of these proteins over a longer reattachment time.

Structurally, the S-cone outer segments in the 28-day reattached retina are not equivalent to those in the normal eye. They are often only punctate "dots," a fraction of their normal size. The S-cone population has been reported to be more sensitive to damage in human retinas with detachments (64) with all S-cones either lost or showing signs of "irreversible damage" within a few days of detachment. Our data from feline retinas may support the concept that S-cones are more fragile, more susceptible to cell death, and slower to recover than the M-cones; however, it does not support the conclusion that all of the S-cones are irreversibly damaged.

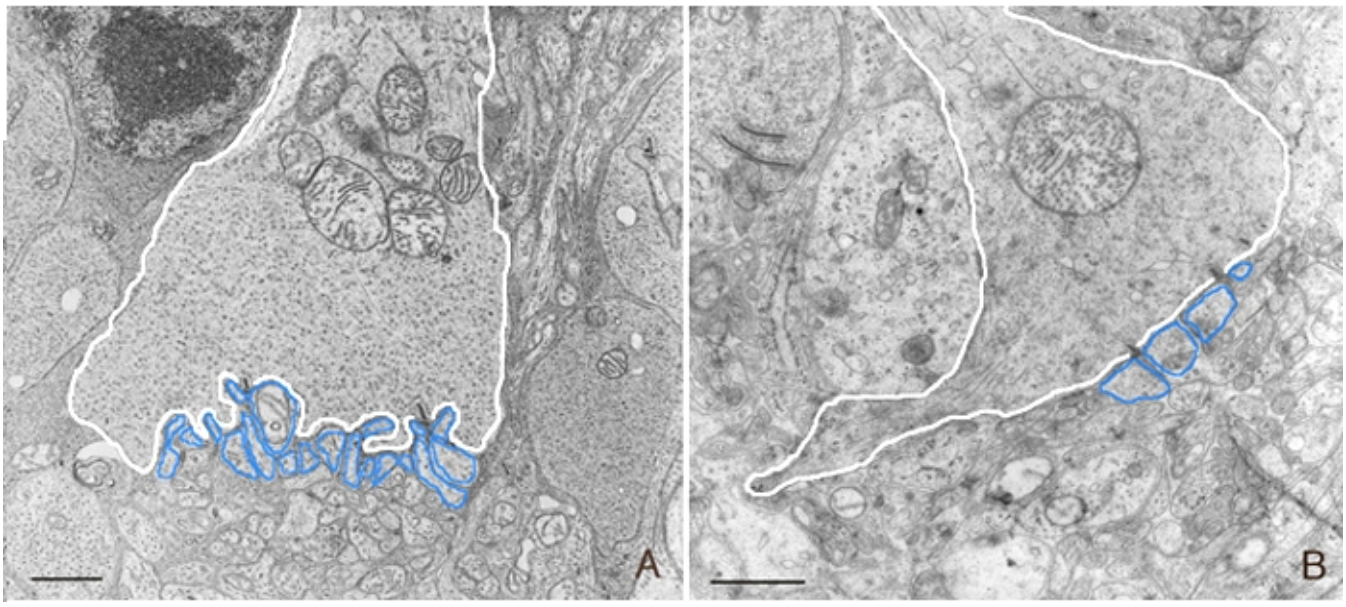

Figure 9. Cone synapses. Electron micrographs of CP (outlined white) in normal (A) and detached (B) retina. Post-synaptic processes outlined with blue. Notice lack of deep invaginations and reduced number of post-synaptic processes after detachment. The population of synaptic vesicles and ribbons appears reduced in CP of the detached retina. Also see Fig. 10. Scale bar, 1 μm.

Combined electrophysiological (ERG) and immunocytochemical studies in the cone-dominant ground squirrel retina did not show any particular difference in recovery of signals from S- and M/L-cones in that species (65).

What may be the most remarkable conclusion from this and other studies is that cones appear to stop expressing specific proteins when the cells are under some type of physiological stress, and then, at least in the case of reattachment, to begin re-expressing these proteins as part of a recovery process. In their studies of human retinal tissue, Nork et al. (64) reported that carbonic anhydrase reactivity became an unreliable marker for M-cones after detachment, indicating that it may join the list of severely down-regulated proteins, and its loss may not be an indicator of irreversible damage.

Whether foveal cones show similar responses is an unanswered question. Peripheral cones are structurally different from foveal cones in the primate retina (33, 66), so their reaction to injury and their capacity for recovery may differ as well.

A differential loss of M/L- and S-cones, or a differential recovery of these cells in humans, may explain some of the color vision deficiencies reported in reattachment patients and could underlie losses in visual acuity when the fovea is involved.

Remodeling of Photoreceptors after Reattachment

The fact that photoreceptor outer segments regrow after reattachment has been recognized since 1968 (67-69). This remarkable ability is mechanistically explained by the fact that photoreceptors constantly add new outer segment material as part of the outer segment renewal process (70). Thus, they are poised to rebuild their outer segment as soon as favorable conditions allow.

Studies of detached retina in fact show that radiolabeled proteins continue to be transported into the truncated outer segments of rods that degenerate after detachment (43), although studies of rod-opsin, peripherin/rds (42) and ROM-1 (G.P. Lewis and S.K. Fisher, unpublished observations) distribution suggest that protein targeting and trafficking is altered when the outer segment degenerates in the rod cells.

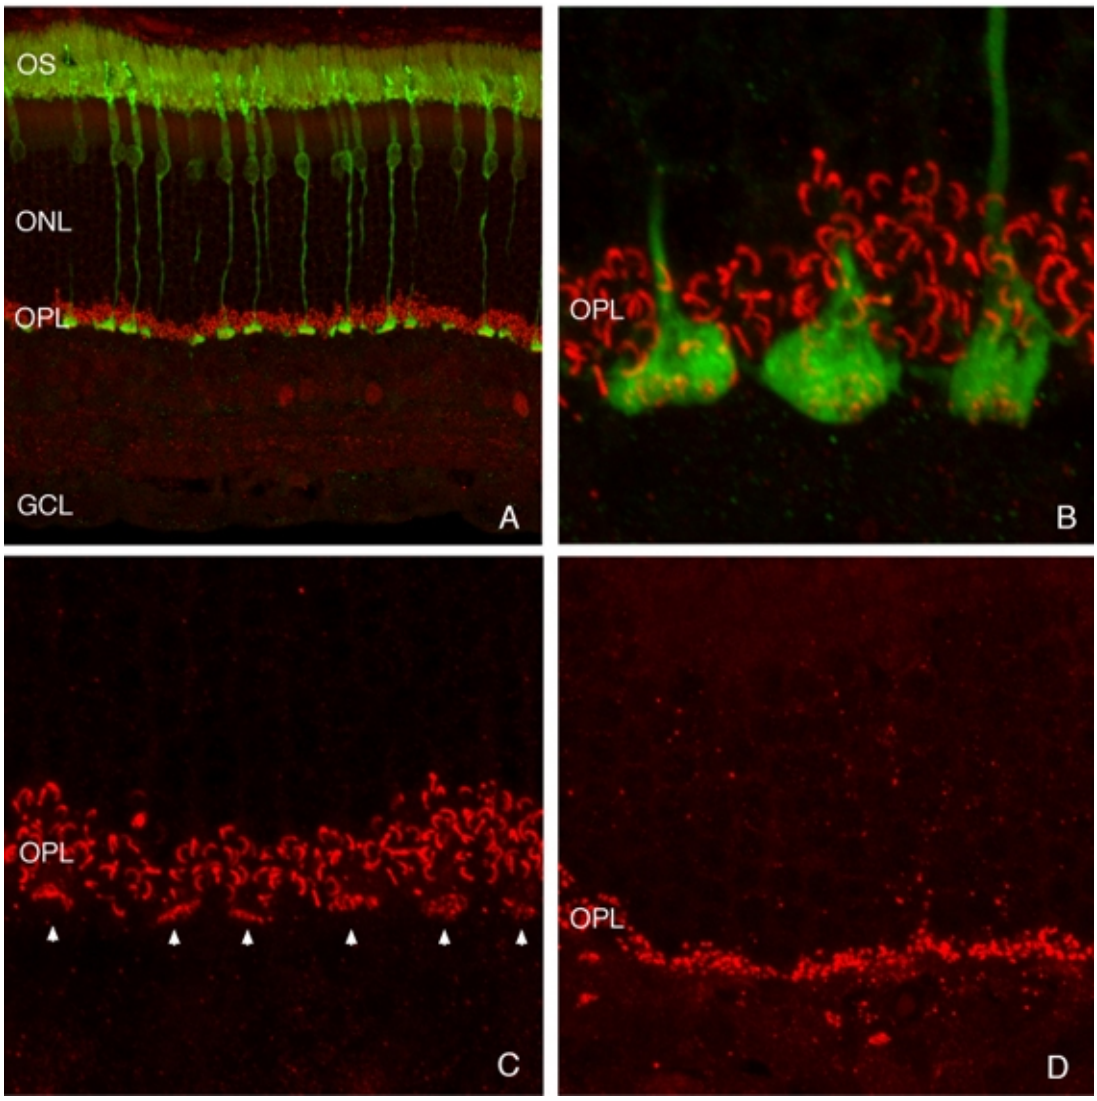

Figure 10. Labeling with anti-PDEg (green; see Fig. 8) and with anti-CtBP2 (red), which labels synaptic ribbons. A, normal retina. The antibody to CtBP2 labels synaptic ribbons in rod and cone synaptic endings (green). B, normal retina. CP contain many ribbons (their yellow color coming from the superposition of the green and red labeling). Note the arcuate shape of the individual rod ribbons. C, normal retina. Organized arrays of ribbons in individual CP (arrowheads). D, retina detached for 3 days, CtBP2 labeling. Note lack of organized arrays of cone ribbons and the smaller "clumped" appearance of ribbons in RS. Labeling in the ONL represents ribbons within retracted RS.

There is some evidence from experimental data that the presence of opsin in the plasma membrane may make photoreceptors more vulnerable to apoptotic cell death (71).

The recovering rods appear structurally more like those in a normal retina than do cones, which are often distorted in shape. Recovering primate cones also show altered outer segment structure when observed by electron microscopy (72). It is now recognized that vision may continue to recover over years in reattachment patients (73, 74), and this may reflect a slow recovery of cone outer segments in the fovea. The recovery of cone vision may be further complicated by the complex optical nature of cones and their alignment with respect to the pupil (see the discussion in Rodieck (75) and also the Stiles-Crawford effect (76)) (reviewed by Enoch (77) and Rodieck (75)), and their structurally specialized interface with the apical RPE.

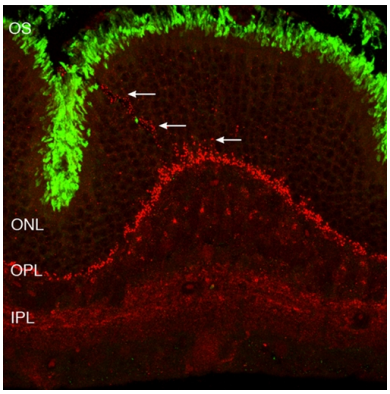

Figure 11. A 7-day detached retina. Demonstrates the prominent reduction in labeling with cone-specific antibodies after detachment. Labeled with the anti-PDEg (green) and CtBP2 (red). Rod outer segments (OS) still label with the antibody to PDEg, but there is a complete lack of cone labeling proximal to the outer segment layer (compare to Fig. 10A). Also notice the large amount of CtBP2 labeling found in the ONL arising from ribbons in retracted RS (arrows).

The Recovery of Photoreceptor Synaptic Terminals

The opposite pole of rod cells must also recover. Some recovery of the withdrawn rod terminals occurs because after 1 month of reattachment, the outer border of the OPL is again composed of a relatively compact layer of rod synaptic terminals. This is in contrast to the highly disrupted layer occurring in the detached retina (Fig. 5, compare B to A). There have been no detailed structural, molecular, or physiological analyses of these regenerated synapses.

Some Rod Axons Overgrow

Because some rods continue to express opsin in their plasma membrane after reattachment, we were able to identify rod axons that extend well beyond the OPL and into the inner retina, terminating at different levels in the INL and IPL (Fig. 15, B-D, arrowheads). The endings of these "overgrown" axons also label with antibodies to the proteins associated generally with synaptic vesicles, synaptophysin and VAMP (not shown), but they do not express the ribbon-specific protein, ribeye.

A population of rods also "overshoot" their synaptic target layer during early retinal development, providing much the same picture as we observed in the reattached retina (78), in human retinas with advanced inherited retinal degeneration (10), and in those with a history of complex detachments and reattachments (30). It is curious that they do not seem to occur in the detached feline retinas, only appearing after reattachment. The ectopic terminals have fine filopodia-like extensions (Fig. 15, C and D, arrowheads). Whether the overgrown axons remain in place or are eventually retracted, or even if the cells bearing them eventually die, is unknown for both development and reattachment.

Remodeling of Cone Terminals after Reattachment

To date, there is little data on the "redifferentiation" or remodeling of the extraordinarily complex synapses of the cone terminals after reattachment. Cone pedicles with synaptic invaginations do reappear in retinas detached for 3 days and reattached for 28. In general, the redifferentiation of photoreceptor synapses, along with profiles for the expression of specific pre- and postsynaptic molecules after reattachment, is unexplored territory, but one that seems critical to fully understanding the events related to visual recovery.

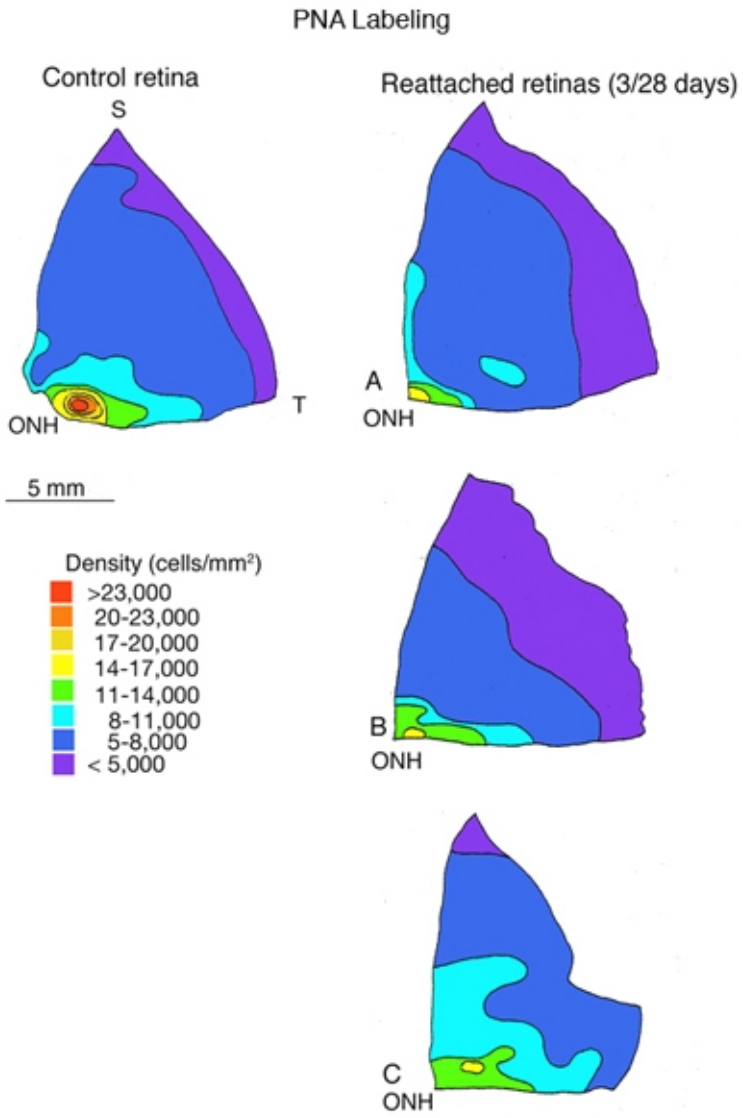

Figure 12. The lectin peanut agglutinin (PNA) binds to extracellular matrix around the cone outer segments (COS; cone matrix sheath) as seen in wholemount retinas. The wholemounts were photographed, and the number of labeled cone sheaths were counted and expressed as isodensity contours. A retinal detachment was created that covered most of the superior (S)-temporal (T) quadrant, and the retina was reattached 3 days later. Reattached tissue was harvested 28 days later. In general, the central to peripheral gradient of cone density is restored in the reattached retina; however, the area of highest cone density, or area centralis, (the red/orange area in the control retina) has not recovered at 28 days and in the 3 experimental eyes (A, B, and C). The density of cone sheaths in the central retina was only about 50% of that in normal retina. ONH, optic nerve head.

Remodeling of Second- and Third-Order Neurons

Rod Bipolar Cells

Rod bipolar cells innervate the rod spherules. Each rod spherule is usually presynaptic to two different rod bipolar cells, and each rod bipolar cell contacts between 16 and 20 rod spherules (79). The rod bipolar dendrites penetrate deeply into the invagination of the rod spherule to terminate opposite one of the two (on average) synaptic ribbons (Fig. 6 and Fig. 7A) (48).

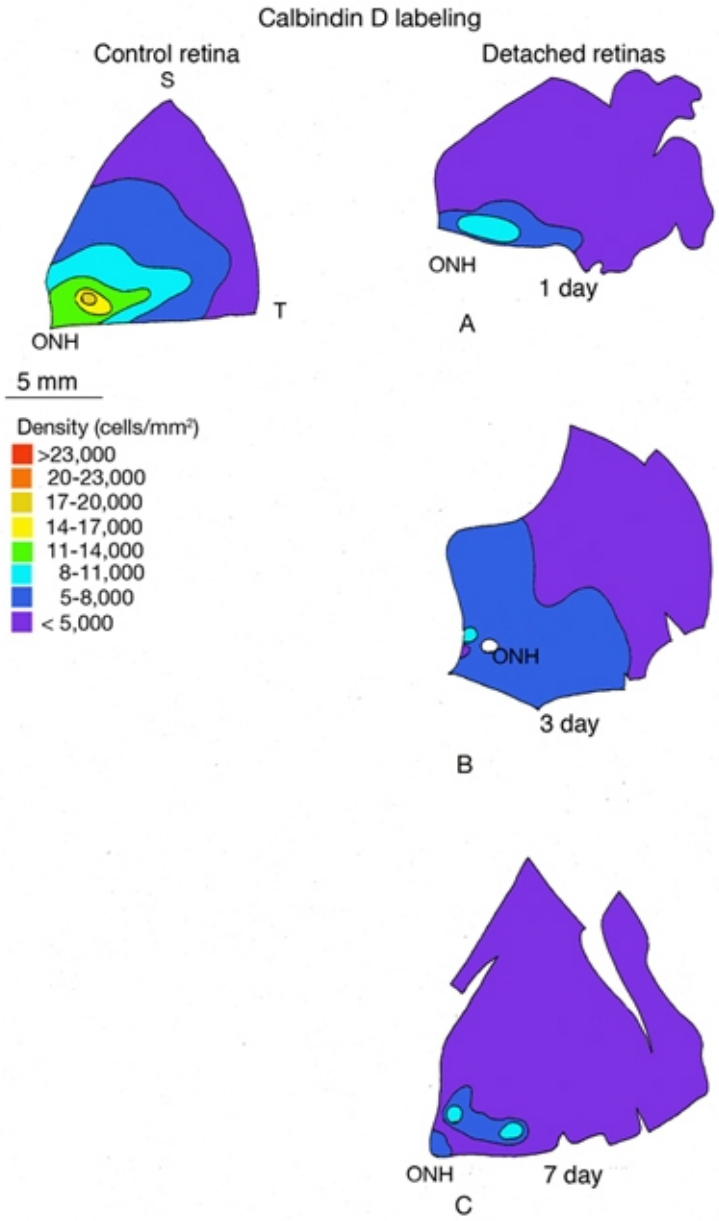

Figure 14. Isodensity contours for cones labeled with an antibody to the calcium binding protein calbindin D in normal (left) and detached (right) feline retinas. In the periphery, this antibody binds to all cone outer segments except in the area centralis, where cones fail to label (see difference between the density of cones in central retina here and in Fig. 12). After detachment (A, B, and C), there is a rapid drop in the number of labeled cones, and there is no central to peripheral gradient.

The general relationship between rod bipolar cells and rod spherules can be observed by confocal imaging using antibodies (80, 81) to label each cell type (Fig. 16A). In the normal feline retina, the compact layer of rod spherules stands out (Fig. 5A and Fig. 16A, green). Rod bipolar dendrites do not extend beyond them into the ONL.

Rod Bipolar Dendrites Remodel as Rod Terminals Withdraw

As the layer of rod terminals becomes disrupted after detachment, there is an emergence of fine, tapered dendritic processes that reach from the rod bipolar cells into the ONL, usually ending adjacent to withdrawn rod synaptic terminals (Fig. 16B, arrowheads). Such remodeled dendritic branches are readily apparent within 3 days of a detachment, and their number increases with detachment time.

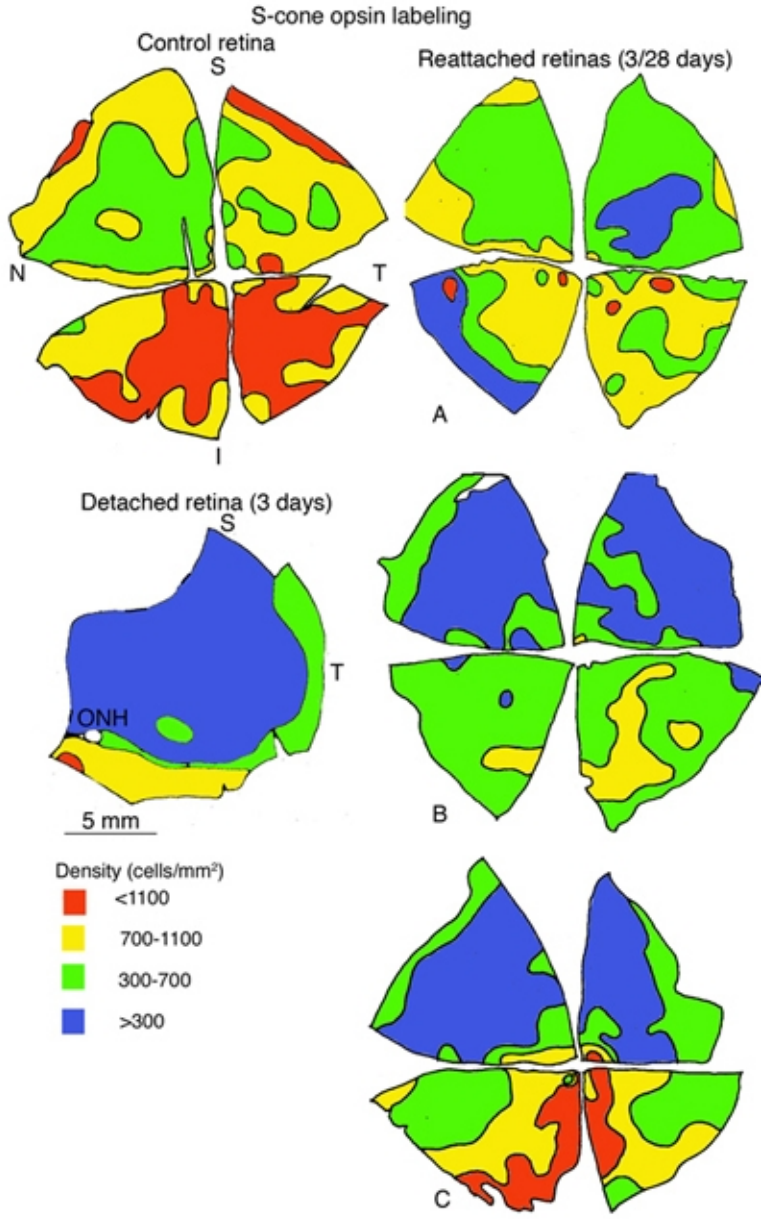

Figure 13. Isodensity contours for short-wavelength sensitive (S)-cones labeled with an antibody to S-cone opsin in normal, detached, and reattached feline retinas. The greatest density of S-cones occurs in the inferior retina in control retina. When the retina is detached for 3 days, S-cones drop dramatically (the yellow and orange areas inferior to the optic nerve head (ONH) were not detached). In the three reattached retinas (A, B, and C), most of the superior retina was detached for 3 days and then reattached for 28. S-cone labeling in the reattached retinas was patchy and of low density by comparison with the normal retina. Many areas showed no S-cone labeling at all.

There probably is also "pruning" of dendritic branches on these cells. In control retinas, the dendrites appear as fine, "wispy" outgrowths extending from the cell body into the OPL (Fig. 16D). In detached retinas, these are not nearly as prominent, leading to the impression that some dendrites have withdrawn while others have grown in length (Fig. 16E). Pruning of dendrites appears to be the major response of bipolar cells in other forms of retinal degeneration (13), but in those cases the response appears late in the diseases.

Horizontal Cells

The feline retina has two morphologically distinct horizontal cells (Fig. 17): one with stout tapering dendrites and no axon (A-type), and the other with somewhat finer, highly branched dendrites and a long thin axon that

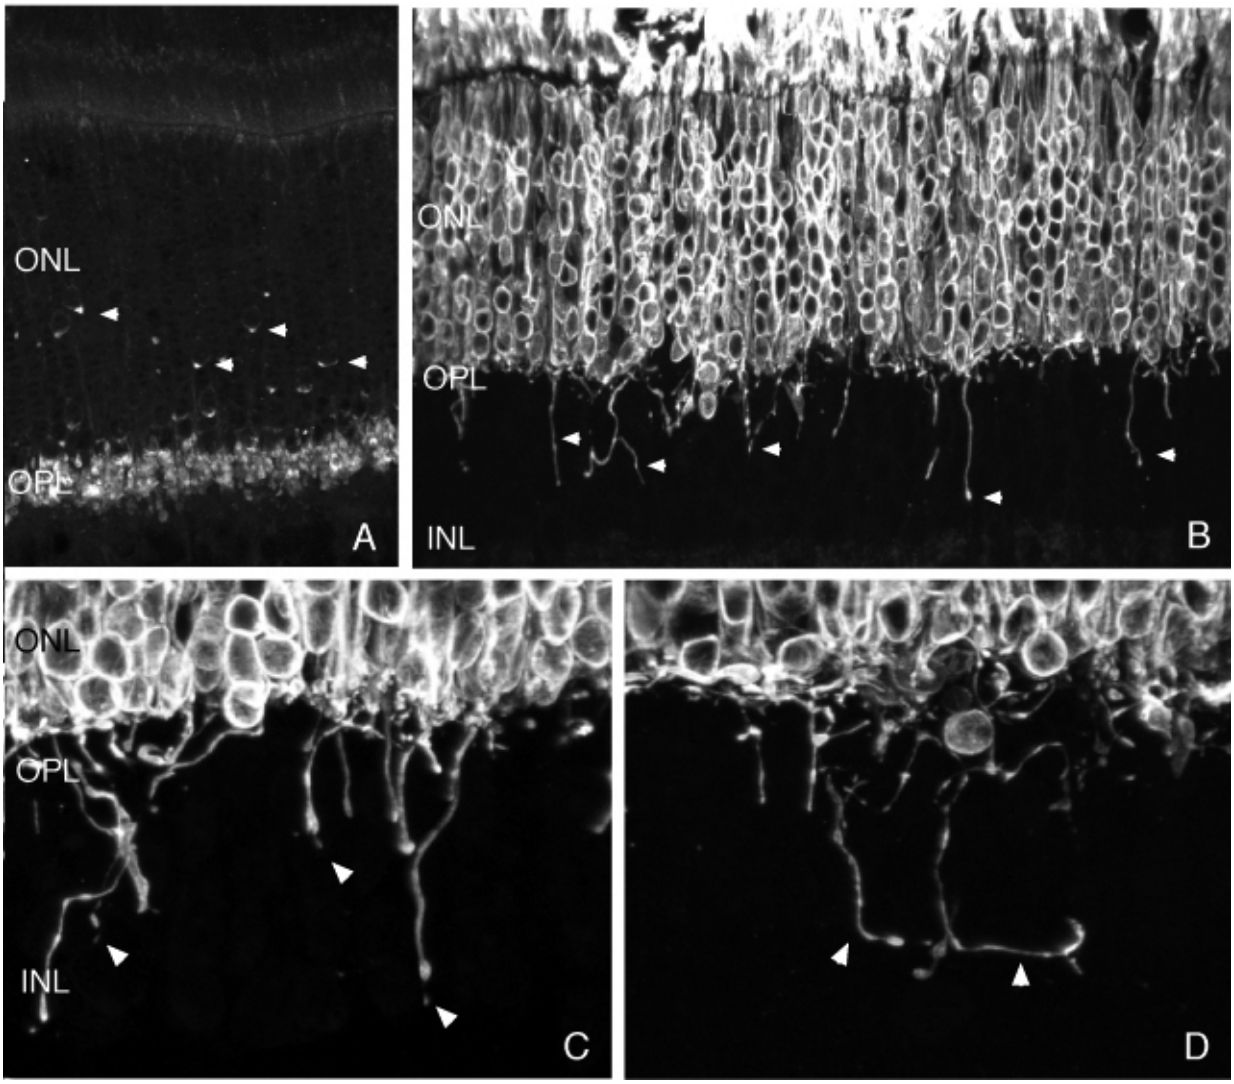

Figure 15. Labeling of RS and rod outer segments (ROS) in retinas detached for 3 days and reattached for 28. A, anti-synaptophysin labeling shows a relative return of organization to the layer of synaptic terminals in the OPL. The number of labeled terminals (arrowheads) in the ONL is dramatically reduced. B-D, anti-rod opsin labeling shows that there is growth of rod axons (arrowheads) into the inner retina after reattachment. Most terminate in a rounded terminal with fine projections. More recent (unpublished) data indicate that these overgrown terminals do not contain synaptic ribbons.

forms an elaborate axon terminal (B-type) (82, 83). Electron microscopy demonstrated that the dendrites of both the A- and B-type cells innervate the cone terminals, whereas only the branches of the axon terminal innervate rod spherules (49). The thin B-cell axon does not communicate electrically with the cell body (84).

Antibody Labeling Signatures Define Horizontal Cell Subtypes

Neurofilaments are plentiful in the A-type cell, and although not completely absent, they are sparse in the B-type cell. This is reflected in the heavy labeling of the A-type cell by antibodies to the 70- and 200-Kd subunits of the neurofilament protein complex. Antibodies to the calcium binding proteins calbindin D and calretinin also label horizontal cells. The use of these three antibodies allowed us to differentiate the two subtypes in feline retina.

We initially observed fairly thick, beaded calbindin D-positive processes in the ONL after detachment (red process, left of Fig. 18A; green processes, Fig. 18C). These outgrowths label with the antibody to neurofilament protein. Indeed, there is a large increase in the intensity of horizontal cell labeling with this antibody after

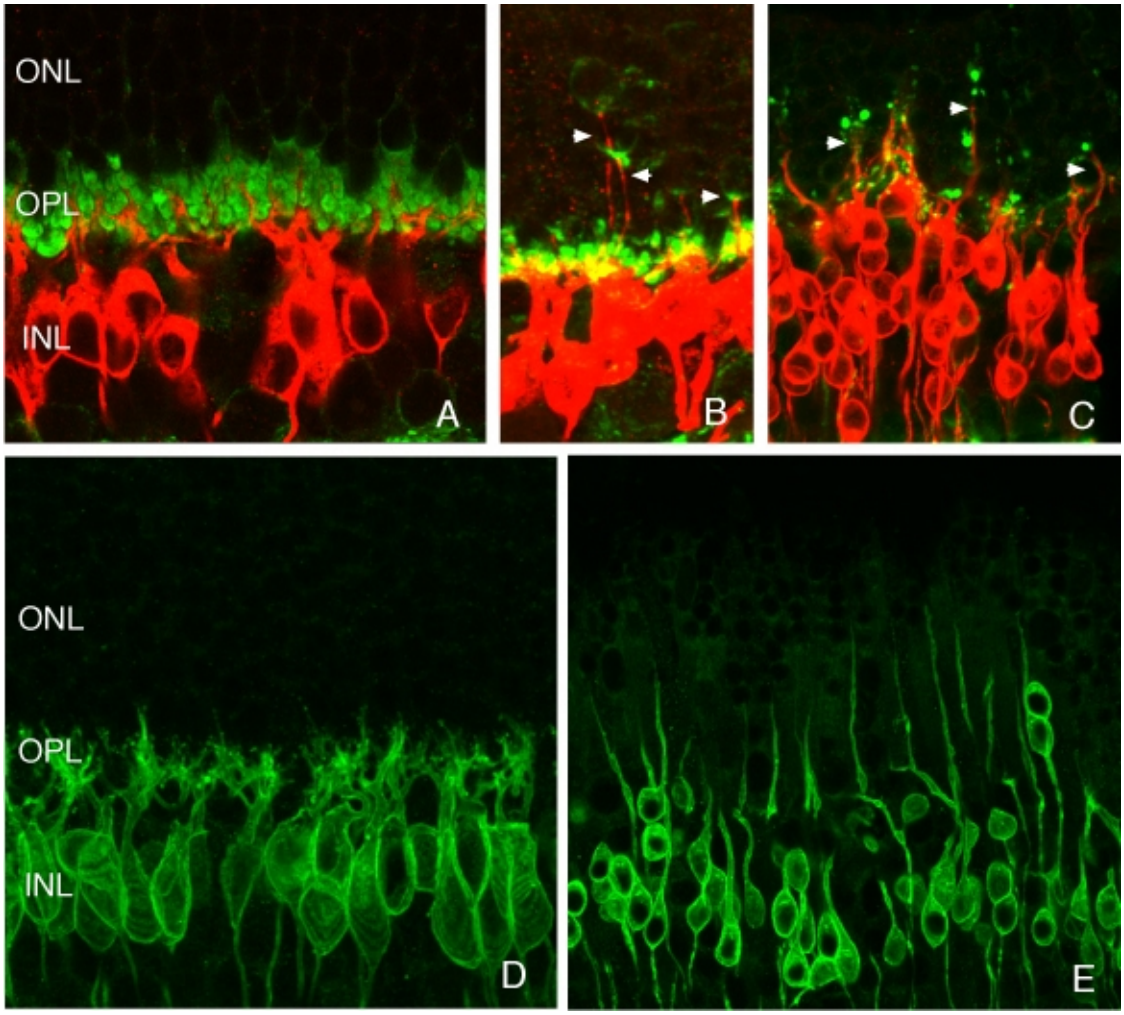

Figure 16. Remodeling of RB cells after detachment. In parts A-C, RB cells are labeled with anti-protein kinase C (PKC, red) and photoreceptor synaptic terminals with anti-synaptophysin (green). In parts D and E, only anti-PKC labeling (green) is shown. A, dendrites of RB cells specifically enter the synaptic invaginations of the rod spherules. B and C, 3 days detached. Many fine RB cell neurites (arrowheads) extend into the ONL, where they terminate adjacent to retracted RS. D, normal retina. RB cell dendrites have a "thin and wispy" appearance. E, 28 days of detachment. The RB dendrites have a thicker appearance as they grow into the ONL. Many of the short, "wispy" processes appear to be missing, perhaps indicative of pruning as well as outgrowth.

detachment (Fig. 19, A and B, red, OPL), most likely indicating an upregulation of protein expression in the remodeled cells (85).

Using any of these three antibodies, we can actually detect two types of horizontal cell outgrowths: those that terminate adjacent to retracted rod spherules (Fig. 18, A and B, arrowheads), i.e., "directed" and those that do not, i.e., "undirected" (examples in Fig. 18A, Fig. 19B, and Fig. 20, D and E). Whether the strikingly dramatic "undirected" outgrowths serve some functional or survival role for the horizontal cells or are merely vestiges of an injury response is unknown. Amazingly, in detachments of 3 days or longer, these outgrowths often extend beyond the outer limiting membrane and into the subretinal space. This always occurs in conjunction with Muller cell processes (Fig. 19, B and C, green). Once in the subretinal space, the horizontal cell outgrowths (Fig. 19D, red) were never observed growing on the exposed photoreceptor cells themselves but always embedded within a meshwork of Muller cell processes (Fig. 19D, green), where they could run for long distances.

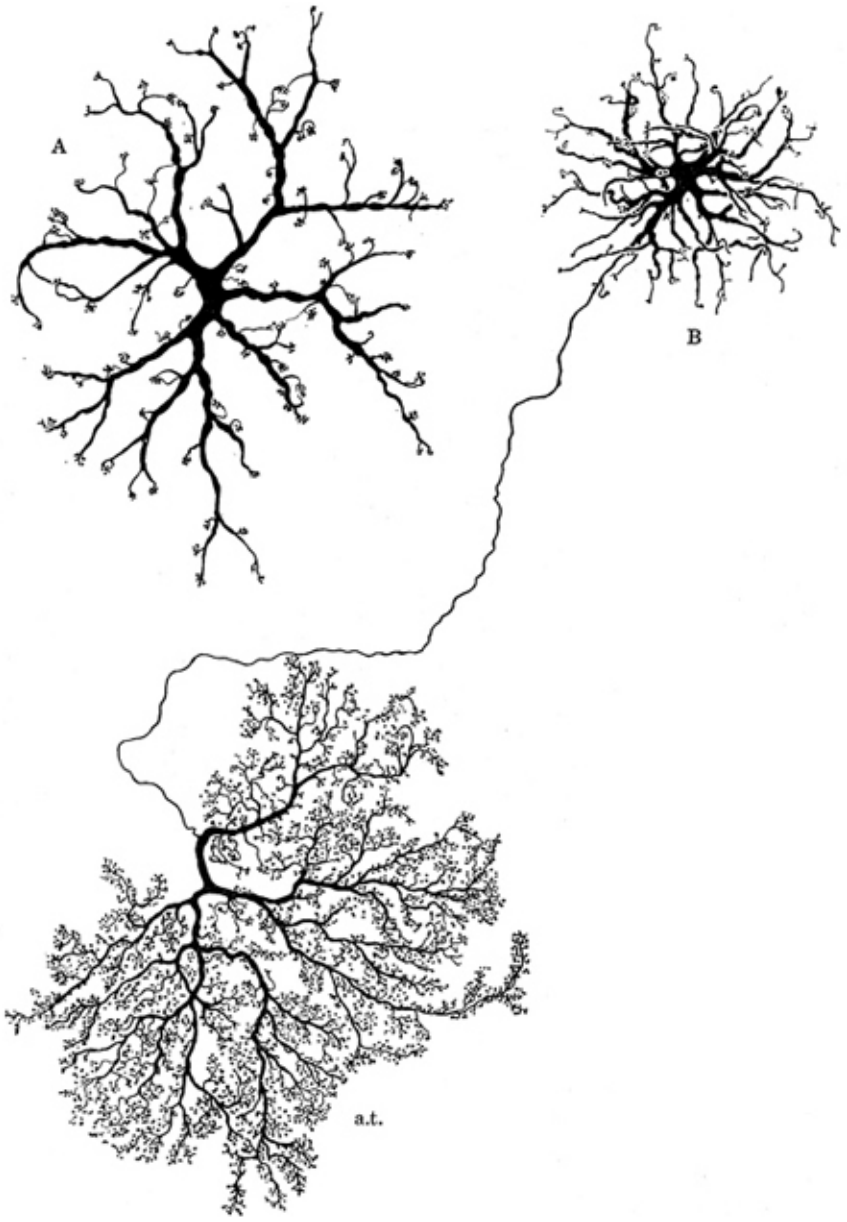

Figure 17. Two types of horizontal cells in the feline retina. A, HA with a dendritic spread of about 250 μm × 250 μm has no axon, and its dendrites contact only cone photoreceptors. B, HB has a smaller dendritic field than HA (about 150 μm × 150 μm) but an elaborately branched axon terminal system (a.t.). The dendrites of HB contacts only cones, whereas the axon terminal contacts only rods. From Fisher and Boycott (83).

Horizontal Cells Extend Both Ascending and Descending Neuritis

Some horizontal cell outgrowths are fairly thick processes descending from the horizontal cells into the inner retina, although these were observed with much less regularity than those ascending into the ONL. The descending processes were also observed by Marc et al. (13, 86) in the detached feline retina and in other forms of retinal degeneration. Indeed, they seem to be the most commonly encountered form of horizontal cell remodeling in cases of extreme photoreceptor loss (13). The "undirected" ascending processes in both sectioned material and wholemounts appear in two structural types: one composed of thin, often beaded cylindrical processes, and the other as flattened, ribbon-like processes. These can both occur singly and in clusters (Fig. 18C). Within the subretinal space, the long extended processes all appear thin, cylindrical, and often beaded (Fig. 19D). But, when thicker, fleshier processes occur there, they usually branch profusely, giving rise to

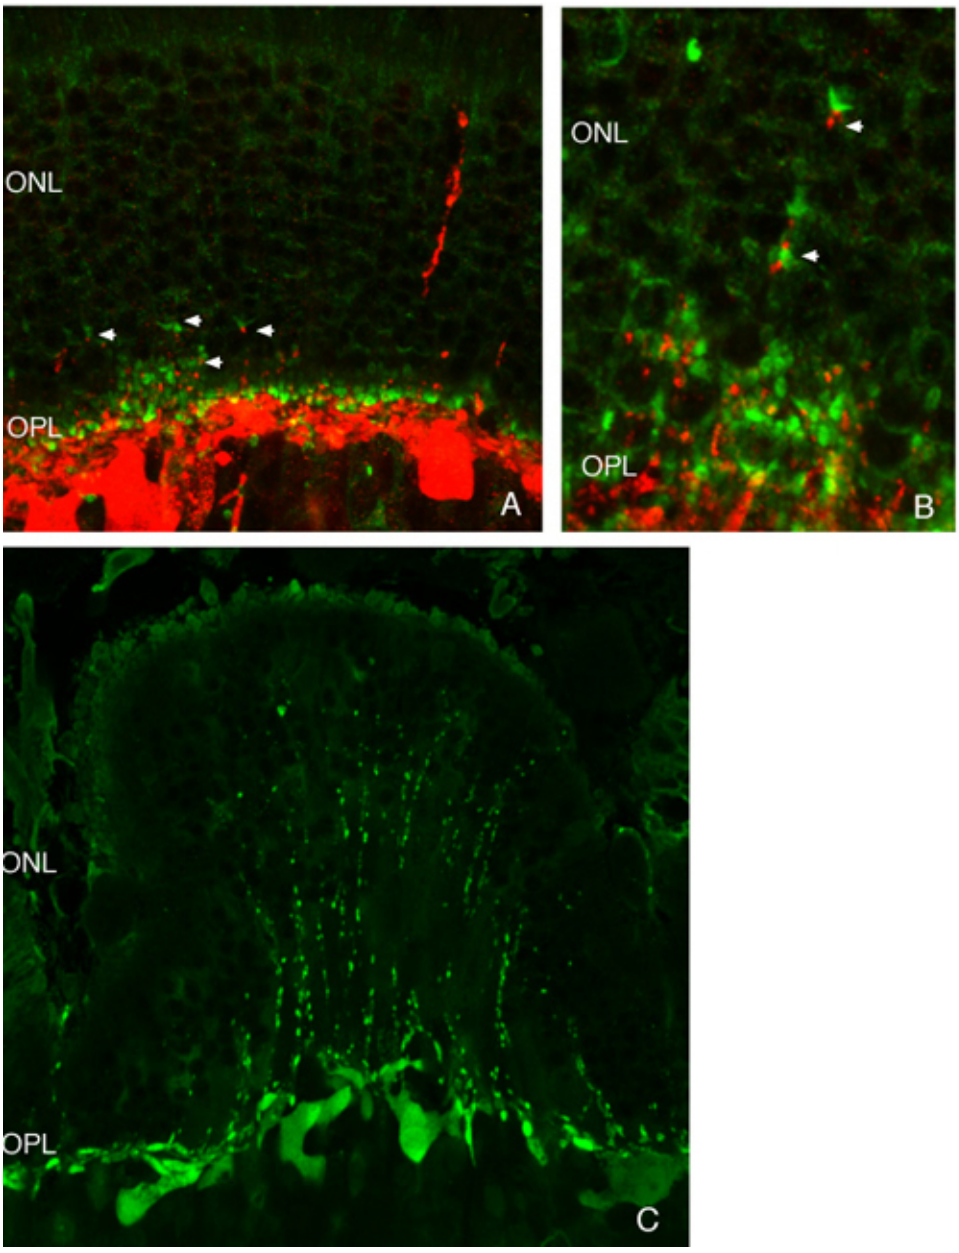

Figure 18. Horizontal cell remodeling after detachment. A and B, horizontal cells (red) are labeled with anti-calbindin D and the synaptic terminals of photoreceptors with anti-synaptophysin (green). Many fine red processes from the horizontal cells extend into the ONL (arrowheads). Many terminate adjacent to withdrawn RS, but some do not, such as the thick process in part A. C, anti-calbindin D labeling. A cluster of fine, beaded horizontal cell outgrowths extending into the ONL after 7 days of detachment.

complex assemblies reminiscent of sparse versions of axon terminals of the B-type cell within the OPL (Fig. 20F).

The Origin of the Horizontal Cell Outgrowths

By labeling with a combination of antibodies to neurofilament protein, calbindin D, and calretinin and assigning the output colors as green, blue, and red, respectively, we determined that the characteristically shaped A-type cells are blue/white in color (i.e., heavily labeled with all three antibodies; HA in Fig. 20, A-C), whereas cells with the appropriate shape and location to be the B-type are red or near-red in color (because of the near lack of labeling with the anti-neurofilament antibody; HB in Fig. 20, B and C). The outgrowths into the ONL, including the long processes that reach the subretinal space, all bear an immunochemical labeling "signature" of the B-type

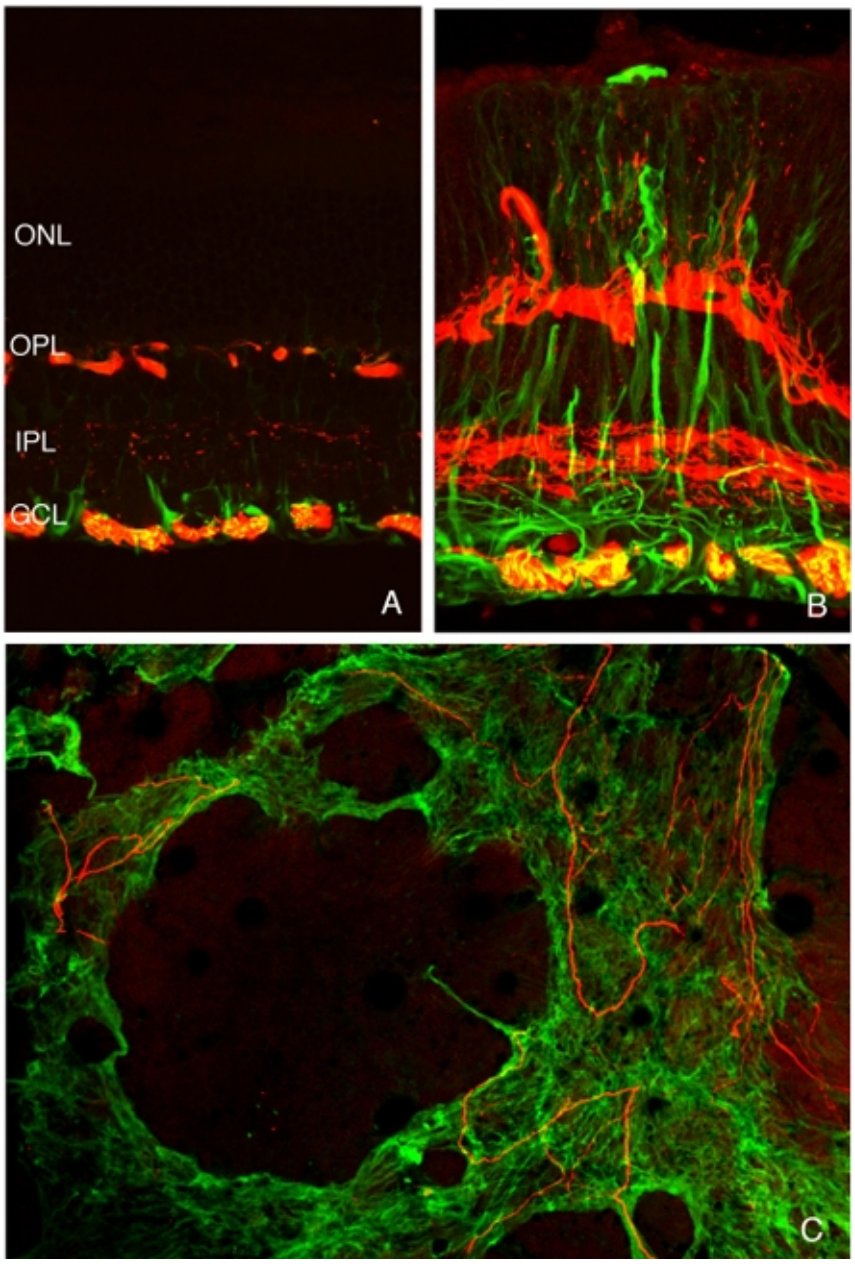

Figure 19. Horizontal cell remodeling after detachment seen by anti-neurofilament protein labeling (red). Anti-GFAP (green) is used to label Muller cells. A, normal retina. Prominent labeling with anti-neurofilament of thick horizontal cell processes in the OPL, probably those of the A-type horizontal cell, of ganglion cell axons in the GCL, and some labeling of fine ganglion cell dendrites in the IPL. B, 7 days of detachment. There is an increase in labeling of the horizontal cells (and ganglion cells), and many horizontal cell neurites extend into the ONL. Strong responsiveness by horizontal cells is accompanied by a high degree of anti-GFAP labeling in Muller cells. C, the subretinal space in a retinal wholemount of detached retina. Long, fine anti-neurofilament labeled outgrowths of horizontal cells (red) occur in the subretinal space, where they are always associated with Muller cell processes (green). (See movie.).

cell (Fig. 20, D-F, arrows). When an outgrowth that gives rise to a branched process in the subretinal space was traced back through the ONL, it was found to arise from a complex plexus with an organization characteristic of the axon terminal and with the B-type cell immunochemical signature (Fig. 20, D and E, arrows). Thus, the evidence points to these processes as arising from the axon terminal of the B-type horizontal cell (see the movie of horizontal cell neurites growing out of a surrounding mass of Muller cells).

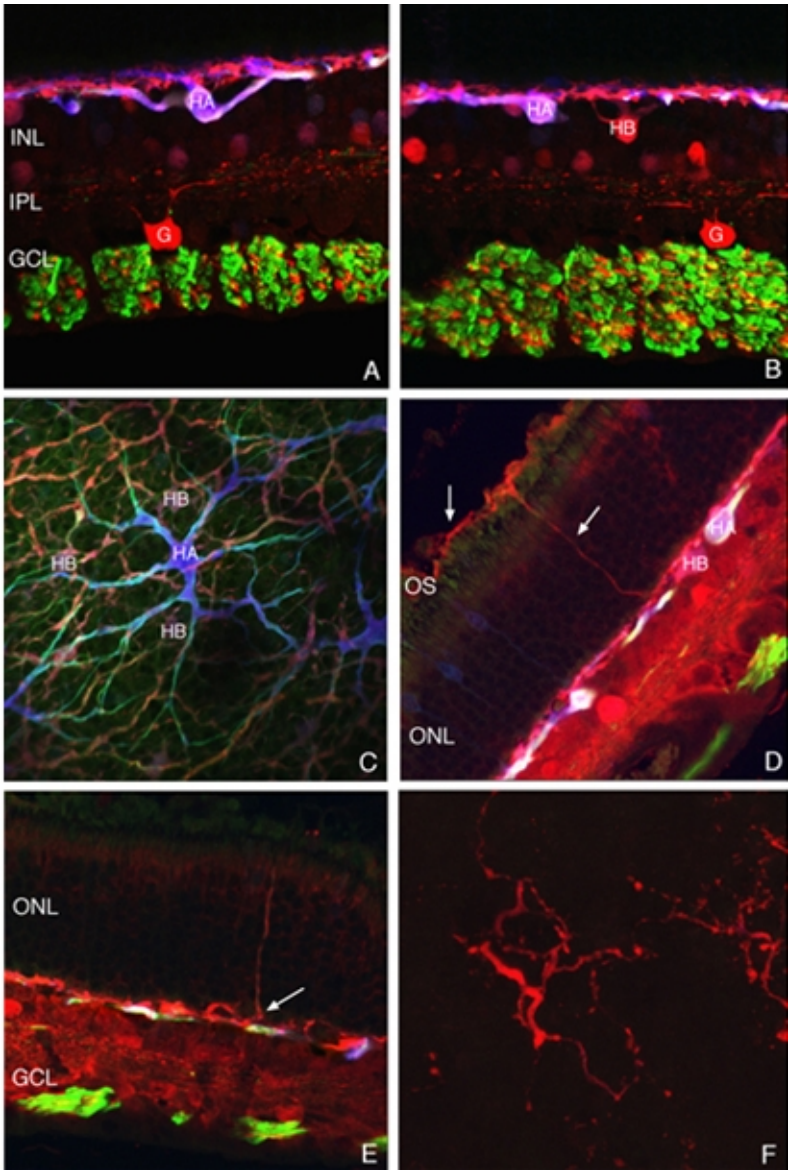

Figure 20. Remodeled horizontal cell processes probably arise from the axon terminal system of HB cells. Labeling is with: anti-calretinin (red), anti-calbindin D (blue), and anti-neurofilament (green). A and B, radial sections, normal retina. HA have a "blue/white" color, stout processes, and a cell body that lies on the outer border of the INL. HB are red, have finer processes emerging from the cell body, and lie lower in the INL. G, calretinin-positive ganglion cells with their cell bodies in the GCL and dendrites extending into the IPL. C, flat-mounted retina. The plane of focus is at the level of the A-type cell bodies (HA) with the smaller, finer B-type cell bodies (HB) lying slightly deeper in the tissue. D, a radial section of retina detached for 28 days. One of the fine horizontal cell outgrowths (red, arrows) extends through the ONL into the subretinal space, where it branches extensively (OS). E, a radial section after 28 days of detachment. A fine HB cell outgrowth (arrow) runs through the ONL. This process arises from a dense plexus on the border of the OPL characteristic of the axon terminal system of these cells. F, an optical section through the subretinal space in a flat-mounted retina detached for 28 days. The three sets of red branching processes in this figure were traced back through the ONL to the OPL to HB axon terminals.

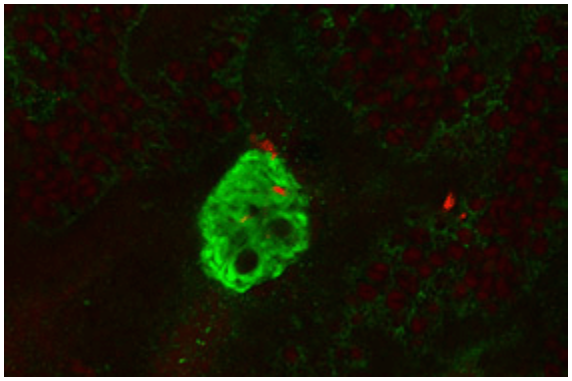
What Drives the Outgrowth of Rod Bipolar and Horizontal Cell Neurites?

Although growth in response to the release (or lack) of some factor from the rods is one possibility, another mechanism is suggested from studies of cultured neurons in which mechanical tension can elicit neurite outgrowth (87). If the rod bipolar cell dendrites and the horizontal cell axon terminal endings remain mechanically connected to retracting rod spherules, tension generated by the retracting rod spherules may



Movie 1. A movie of horizontal cell neurites (red) growing out of a surrounding mass of Muller cell processes (green) in a detached retina.

Download video

initiate a growth response from the post-synaptic neurons. Whether the same mechanism accounts for the generation of directed and undirected outgrowths is unanswered.

Remodeling of Ganglion Cells

A subset of ganglion cell remodels vigorously in response to detachment. Ganglion cells are the retinal neurons farthest removed from the site of the detachment. It is important, however, to remember that ganglion cells are surrounded by Muller cell processes, and the apical end of the Muller cells are in direct physical contact with the actual site of the injury (the subretinal space). Muller cells also react to detachment very quickly (88) and, thus, could easily drive ganglion cell reactivity. Additionally, ganglion cell responsiveness could be dependent on the trans-neuronal changes originating with changes at the rod and cone synapses.

GAP 43 Expression, Neurofilament Protein Expression, and Ganglion Cell Remodeling

Growth associated protein (GAP 43) expression is generally associated with axonal growth cones and synaptogenesis (89-92), and it is generally down-regulated significantly after the developmental period associated with synaptogenesis (89-91, 93-97). Mice in which GAP 43 has been genetically removed show a tangling of axons in the optic nerve (98), whereas mice overexpressing GAP 43 show an enhanced sprouting of axon terminals in both central and peripheral neurons (99).

GAP 43 expression in the retina appears as the ganglion cells migrate into their specific layer and begin the process of axon outgrowth. It remains in adults only as stratified labeling in the IPL (90, 95, 100-102). This is the pattern observed in the adult feline retina (18). Immunoblot analysis also reveals that there is some GAP 43 protein expressed in normal adult feline retina (18).

Immunoblot, immunocytochemical, and real-time PCR data all show a rise in GAP 43 expression beginning 1 day after a retinal detachment and continuing to increase at the last experimental timepoint at 28 days. Immunohistochemistry data reveal a population of ganglion cell bodies that are heavily labeled in the 7-day postdetachment animals (Fig. 21A, red processes) (18). The GAP 43-positive ganglion cells also show a major increase in labeling with the anti-neurofilament protein antibody. In the normal retina, this antibody labels only a few processes in the IPL and ganglion cell axons (Fig. 19A, red, IPL and GCL labeling) (18). After detachment, it heavily labels processes in the IPL and cell bodies in the ganglion cell layer (Fig. 19B and Fig. 21, B and C: red, IPL, GCL labeling). This labeling colocalizes with the increased anti-neurofilament labeling.

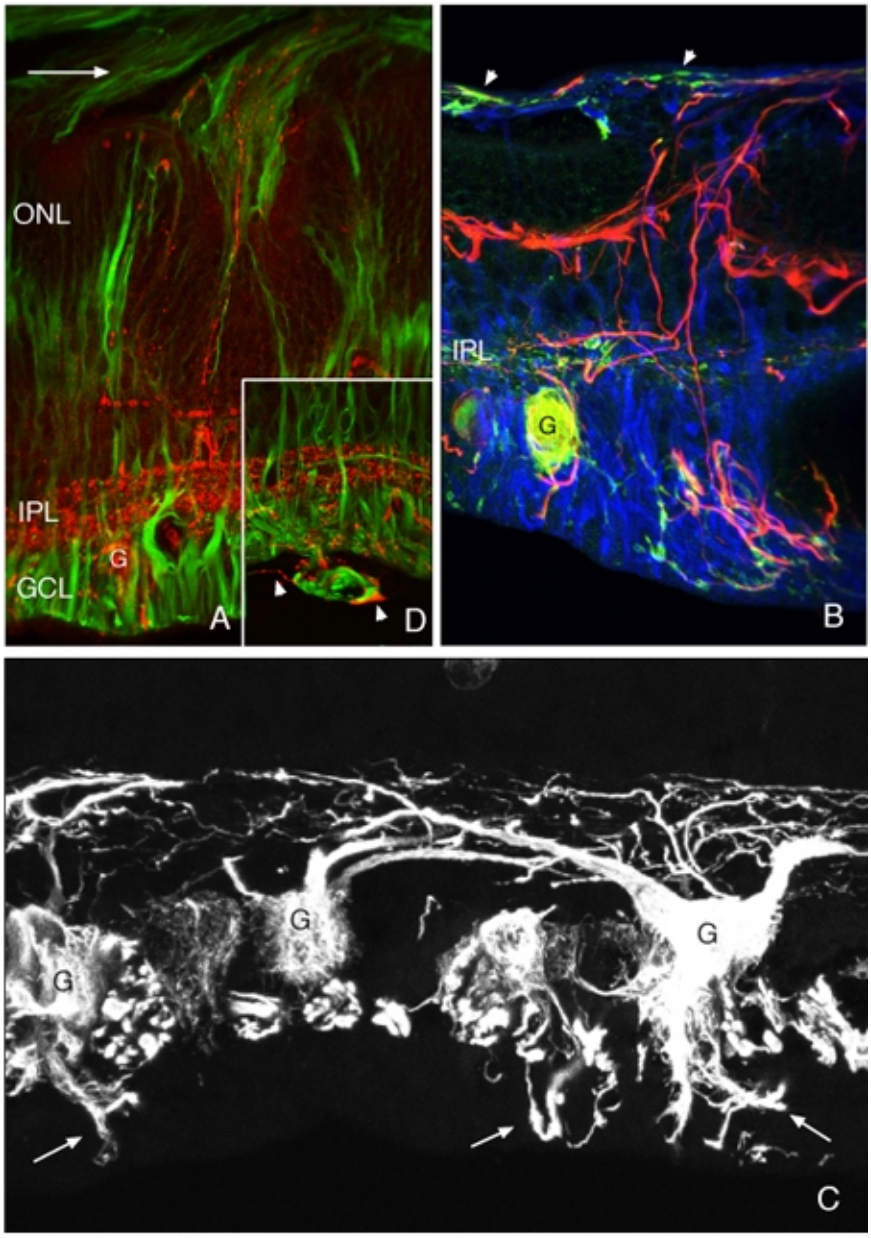


Figure 21. Reactivity of ganglion cells to retinal detachment. A, anti-growth associated protein 43 (GAP 43, red) labels only fine processes in the IPL of normal adult retina. In retina detached for 28 days, anti-GAP 43 labels a subpopulation of cell bodies in the GCL, many processes in the IPL, and some that grow beyond the IPL into the ONL and often into the subretinal space (arrow). GAP 43-positive processes in the outer retina are always closely associated with reactive Muller cell processes (anti-GFAP, green). B, detached (28 days) retina triple-labeled with antibodies to neurofilament protein (red), GAP 43 (green), and GFAP (blue). In detached retina, a subpopulation of ganglion cell bodies label heavily with both the neurofilament and GAP 43 antibodies, giving the yellow color to the cell labeled "G." Red processes represent remodeled process from the horizontal cells. The fine yellow/green processes in the subretinal space (arrowheads) represent outgrowths from remodeled ganglion cells. C, the inner retina after detachment. Anti-neurofilament labeling. Labeling in the normal retina is limited to fine processes in the IPL (Fig. 15A). In the detached retina, large ganglion cells label, along with their processes in the IPL. The labeled ganglion cells have many branched, "spikey" processes growing from their basal surface toward the vitreous (arrows). D, after retinal reattachment, neurites from ganglion cells (arrowheads) can grow into the vitreous in association with Muller cell endfeet (green) and form epiretinal membranes.

Ganglion Cell Morphology after Detachment

After detachment, the GAP 43/neurofilament-positive ganglion cells exhibit an unusual morphology, unlike any reported in the literature for feline (or other mammalian retinas) ganglion cells, with numerous small, spikey processes extending from their cell body toward the nerve fiber layer (Fig. 21C) (18). As detachment duration increases, there is an astonishing increase in GAP 43/neurofilament-positive neurites that extend from the labeled ganglion cells and course completely across the neural retina and into the subretinal space (Fig. 21, B and C, arrows). These processes are generally of a uniform caliber without obvious branching.

Remodeling of Ganglion Cells Is "Extreme"

Thus, the picture that emerges for remodeled ganglion cells is very much like that of the remodeled horizontal cell axon terminals, inasmuch as both produce a large number of "undirected" processes that can grow for long distances through the retina and into the subretinal space. The neurites from ganglion cells also tend to appear adjacent to the processes of reactive Muller cells, either within the retina or in the subretinal space. Interestingly, neuronal processes have been identified in subretinal membranes removed surgically from human eyes (G.P. Lewis and S.K. Fisher, unpublished observations).

Which Ganglion Cell Type(s) Remodels?

Size measurements from retinal wholemounts were used to produce a frequency distribution for the somal area of the GAP 43-labeled ganglion cells. The data show a large peak at 600 μm^2 but also a small population of cells clustering around 3,000 μm^2 (18), suggesting that it is the alpha ganglion cell types (103, 104) that remodel.

Ganglion Cell Remodeling after Reattachment

Retinal reattachment appears to elicit the extensive growth of ganglion cell neurites into the vitreous, where they associate with epiretinal membranes produced by Muller cells (Fig. 21C, arrows; Fig. 21D, arrowheads). Thus, the response in the vitreous is similar to the response in the subretinal space; neurite outgrowths associate with reactive Muller cell processes, but the vitreal growth is initiated only after reattachment, probably because reattachment also initiates the growth of Muller cells into the vitreous cavity (105). Data from pathology specimens of human vitreal membranes also show the presence of anti-neurofilament labeled processes (30).

Glial Cell Remodeling

Muller Cells

Muller cells undergo extensive hypertrophy after detachment. They also show nuclear migration, cell division, and growth into the subretinal space. All of these are obvious by simple histological observation (14, 15, 39, 69).

The Intermediate Filament Cytoskeleton and Remodeling

The structural hypertrophy of these cells correlates with increased expression of intermediate filament proteins, glial fibrillary acidic protein (GFAP), and vimentin (106, 107). Electron microscopy also shows a large increase in the number of intermediate filaments in the cytoplasm of these reactive cells (Fig. 22) (108).

Astrocytes in the brain and spinal cord react similarly, especially with respect to an upregulation of GFAP (14, 109).

The Muller Cell Response Is Distinct and Dramatic

What makes the Muller cell GFAP response so dramatic is the fact that these filamentous proteins are almost exclusively localized to the endfoot region in a normal retina (Fig. 23A, red/yellow labeling) and, in some species

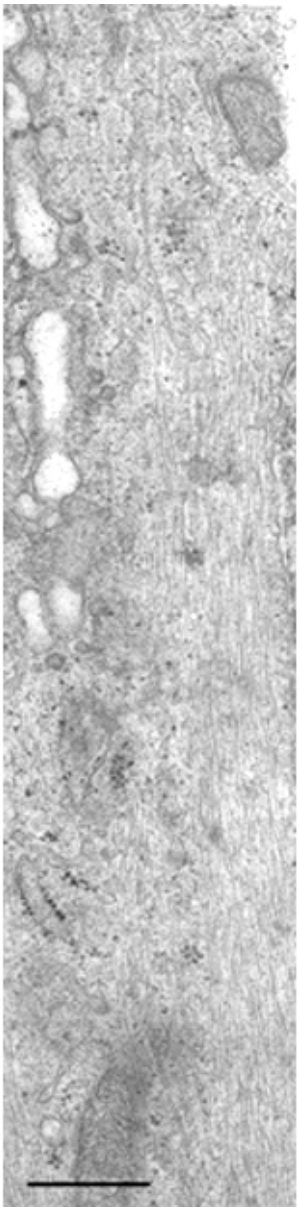

Figure 22. 10-nm-diameter filaments in the cytoplasm of a Muller cell in the outer retina after retinal detachment. These intermediate filaments label with antibodies to both GFAP and vimentin. In the normal retina, they are mainly limited to the endfoot region of these cells. Scale bar, 0.5 μm.

such as rats and mice, barely detectable by current immunocytochemical technology (Fig. 23C) (110-112). On injury, the cytoskeletal remodeling in these cells correlates closely with changes in morphology. Indeed, the correlation is so close that they are generally assumed to be functionally linked events. In support of this argument is the fact that in the ground squirrel retina, Muller cells do not hypertrophy in response to detachment, and their intermediate filament cytoskeleton remains unchanged (24). Following brain injury, astrocytic scar formation is impaired in $vim^{-/-}/GFAP^{-/-}$ mice but not in mice lacking only one of the two intermediate filament genes (113). Whether a similar principle applies to Muller cells remains to be determined.

The Muller Cell Endfoot as the Origin of the Intermediate Filament Response

Within a day of a detachment, intermediate filament proteins within the endfoot become more dense in number, often forming whorl-like or wavy bundles (Fig. 23B, red/yellow labeling) (108). They appear to grow from this

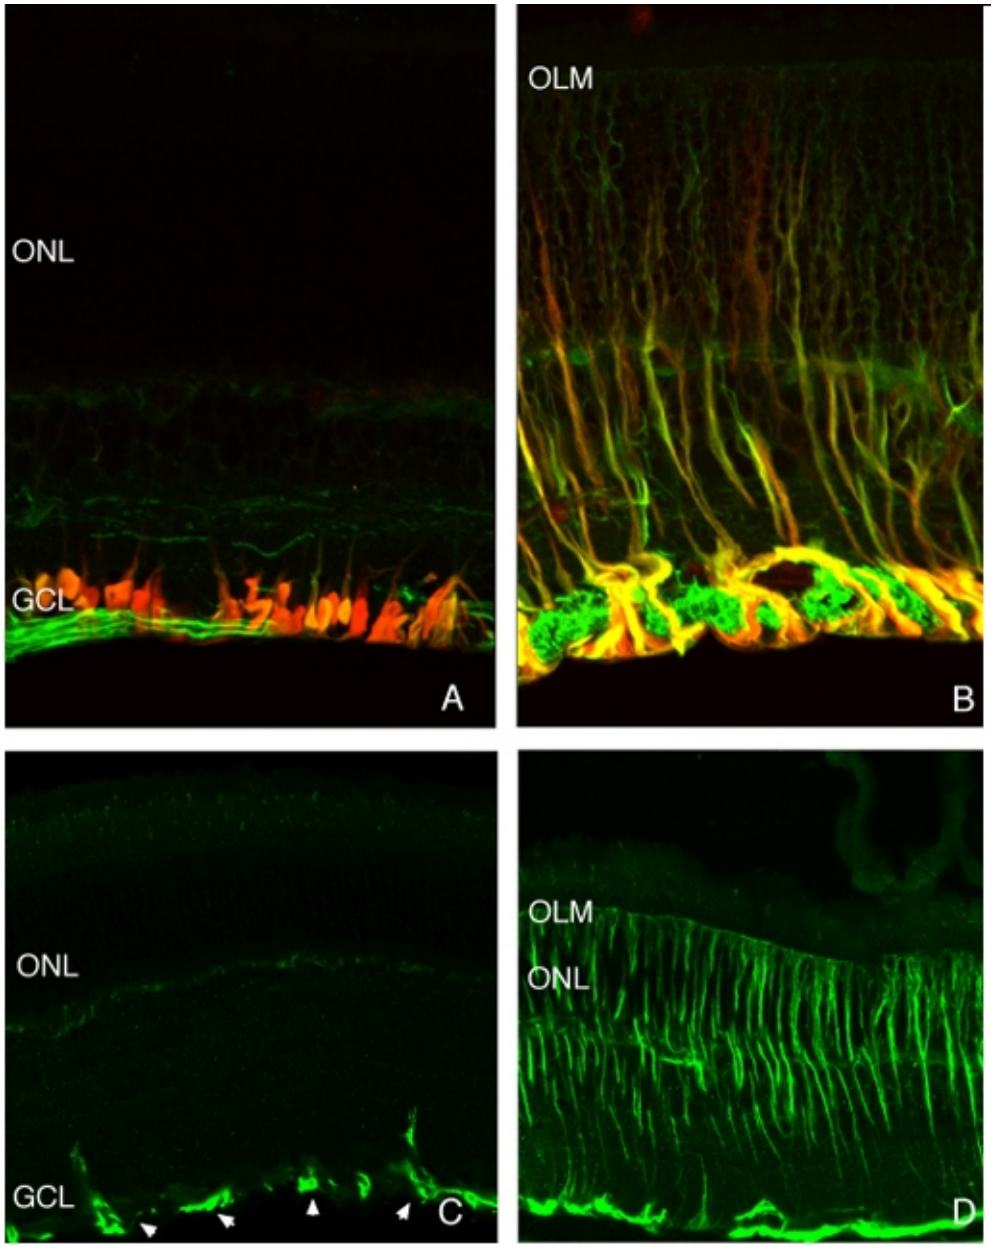

Figure 23. Labeling with antibodies to the intermediate filament proteins GFAP (green) and vimentin (red). A, in the normal retina, they are concentrated in the endfoot region of the Muller cells. Vimentin predominates over GFAP (astrocytes, however, show a preponderance of GFAP). B, after 3 days of detachment, the intermediate filaments expand from the endfoot into the outer retina. There is also a shift toward the yellow and green colors, indicating a greater increase in GFAP than vimentin. C, mouse retina labeled with the antibody to GFAP. In some species such as the mouse, there is no detectable GFAP in Muller cell endfeet, the only labeling occurring in astrocytes (arrowheads). D, when the mouse retina is detached for 7 days, the GFAP reactivity of Muller cells is striking, with labeling extending across the entire neural retina to the outer limiting membrane (OLM).

distal mass, extending both into branches of the endfoot, which increase in size and in number with detachment time, and apically towards the cell body and then into the outer retina (Fig. 23 and Fig. 24) (107, 114).

Subretinal Growth of Muller Cells after Detachment

As intermediate filaments expand into the apical cytoplasm of the activated Muller cells, some of them begin to grow, expanding into the subretinal space where they can elaborate into multilayered clinical "membranes" (Fig. 25, A and B).

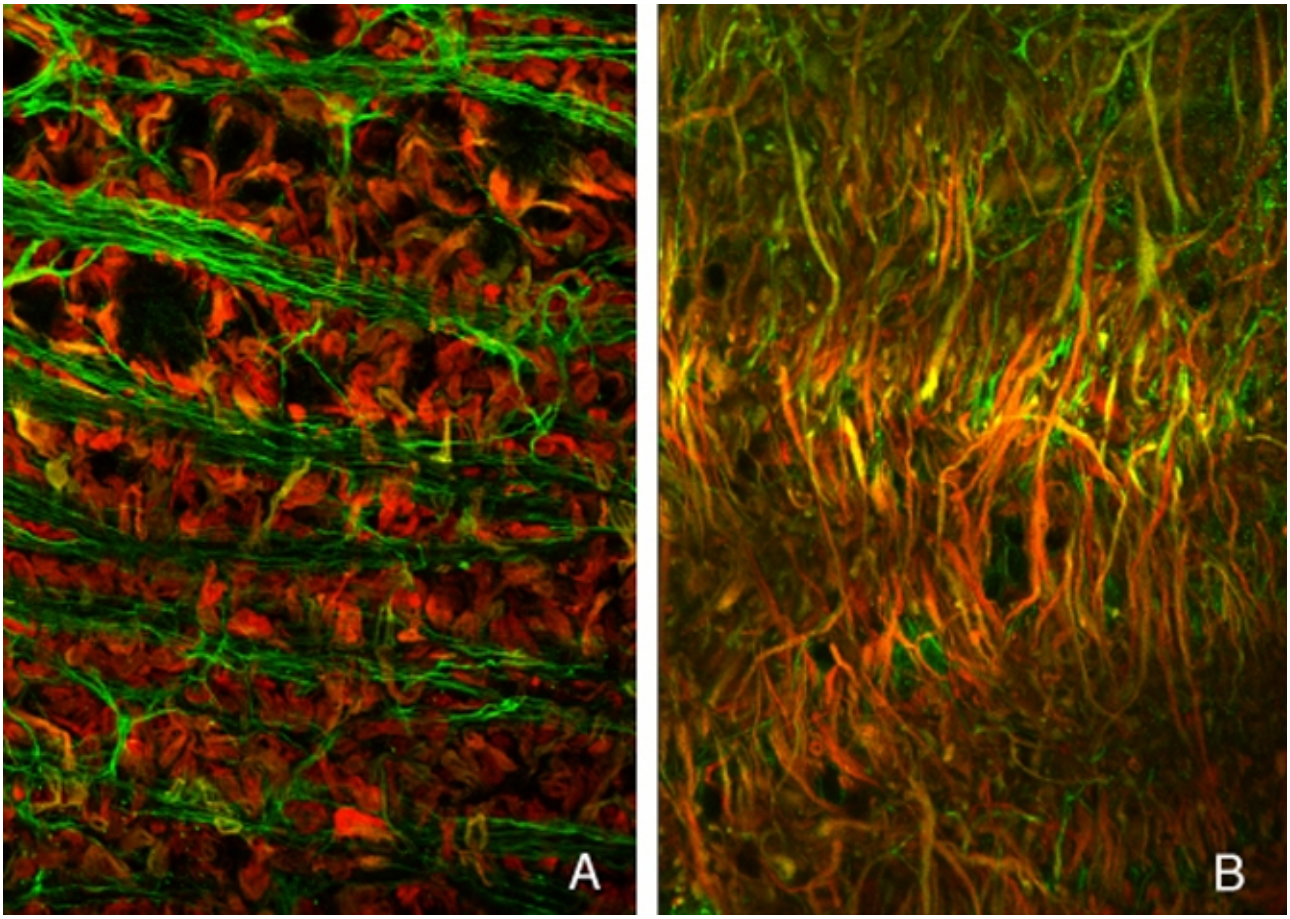

Figure 24. Retinal flat-mounts labeled with antibodies to GFAP (green) and vimentin (red) viewed from the ganglion cell surface to show changes in the Muller cell endfeet after detachment. A, normal retina. The endfeet are "hoof-shaped", and their labeling is dominated by vimentin. The long, thin green processes are from astrocytes. The "holes" represent ganglion cell bodies that are negative for both proteins. B, retina detached for 7 days. The endfeet processes have grown on the retinal surface. Astrocyte processes appear disorganized. Axon bundles are no longer prominent, probably because they are overlaid by the thicker endfeet processes.

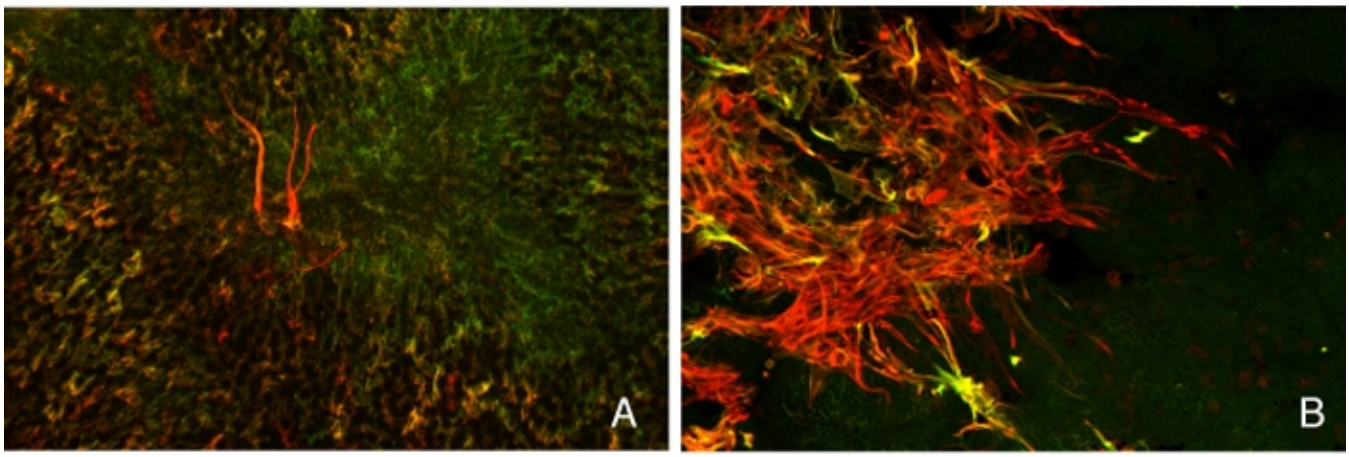

Figure 25. The subretinal space in retinal flat-mounts prepared after detachment and labeled with antibodies to vimentin (red) and GFAP (green). A, retina detached for 3 days. Initial outgrowth of a Muller cell process (red) from the neural retina into the subretinal space. The greenish background represents labeling with anti-GFAP within the neural retina. The processes that grow into the subretinal space show a predominance of vimentin. B, 28 days of detachment. At this time, there is a large "membrane" growing in the subretinal space composed of overlapping Muller cell processes. Vimentin continues to predominate over GFAP.

GFAP and Vimentin: Details of Their Responses in the Muller Cells Subretinal Space

GFAP and vimentin can copolymerize to form intermediate filaments, but we have observed in double-labeling studies that there is a differential expression of the two in feline Muller cells. In the normal retina, vimentin predominates. The endfeet label most heavily with this antibody, and labeling extends farther into the neural retina than it does for GFAP. In the main trunk of the reactive cells, GFAP seems to predominate. As the apical microvilli begin to grow into the subretinal space, vimentin labeling predominates (Fig. 25A, red tapering forked processes). This imbalance in expression continues as the processes expand into the subretinal space (Fig. 25B) (114). The "leading edge" of the growing processes always shows a predominance of anti-vimentin labeling, with GFAP expression becoming increasingly intense at the point of exit from the neural retina. These processes or "membranes" essentially form glial scars in the subretinal space. Their presence does not appear to prevent physical reattachment of the retina, but it does inhibit the regeneration of outer segments (39) (see the movie of Muller cell processes growing out into subretinal space).

Reattachment Stimulates Growth of Muller Cells

Vitreous Space

A novel endfoot response occurs in the feline retina in response to reattachment. In this case, the branched endfoot processes that remained closely adherent to the vitreal surface of the retina begin growing into the vitreous chamber. It is these "branchlets" of the endfoot that expand into the vitreous to form epiretinal membranes. The initial outgrowths appear as fine, flat "ribbons" of cytoplasm extending away from the neural retina into the vitreous cavity (Fig. 26, A and B) (see the movie of Muller cell endfeet growing out into the vitreous).

These delicate, flattened processes have a very different morphology from the fine, tapered, and branched processes that expand into the subretinal space. In these endfoot outgrowths, GFAP expression dominates over that of vimentin (Fig. 26, A and B). Although vimentin expression "leads the way" in the expanding Muller cell processes within the subretinal space, it is GFAP that holds this position in the endfoot processes that grow into the vitreous (Fig. 26, C and D). The growth of these cellular processes into the vitreous can have significant consequences on vision because they can become contractile (115) and cause wrinkling and eventual re-detachment of the neural retina—a serious sight-threatening event if the fovea is involved.

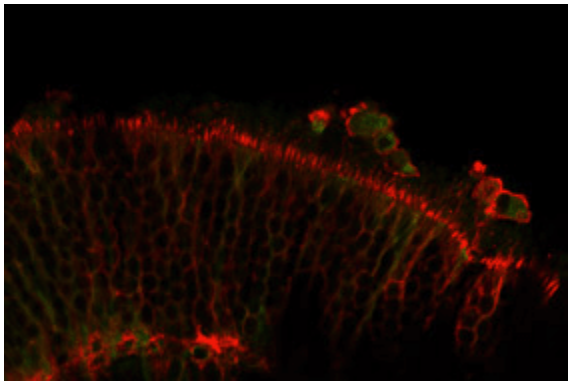
Astrocytes

There is little known about the reactive capacity of these cells in the retina. They proliferate in response to detachment (116, 117), and observations of optic nerve fiber layer in retinal wholemounts show that their regular array and stellate shape are lost as the endfeet of the Muller cells expand on the retinal surface (114).

Retinal Remodeling after Detachment and Reattachment: An Overview

Studies of detached (and reattached) retina have shown us that the mammalian retina has remarkable remodeling capabilities. Fig. 27 shows, in summary form, the remodeling of the neural retina described here.

Rod outer segments and cone outer segments are greatly shortened and separated from the apical surface of the pigmented epithelium. Many RS are withdrawn from the OPL. After reattachment, some rod axons grow into the inner retina (the cell on the left). CP remain in place, although they undergo significant structural remodeling. The dendrites of RB cells grow into the ONL, where they terminate adjacent to withdrawn RS. The axon terminals of HB remodel extensively, with some processes terminating next to withdrawn RS, whereas



Movie 2. A movie of Muller cell processes (green) growing out into subretinal space in a detached retina.

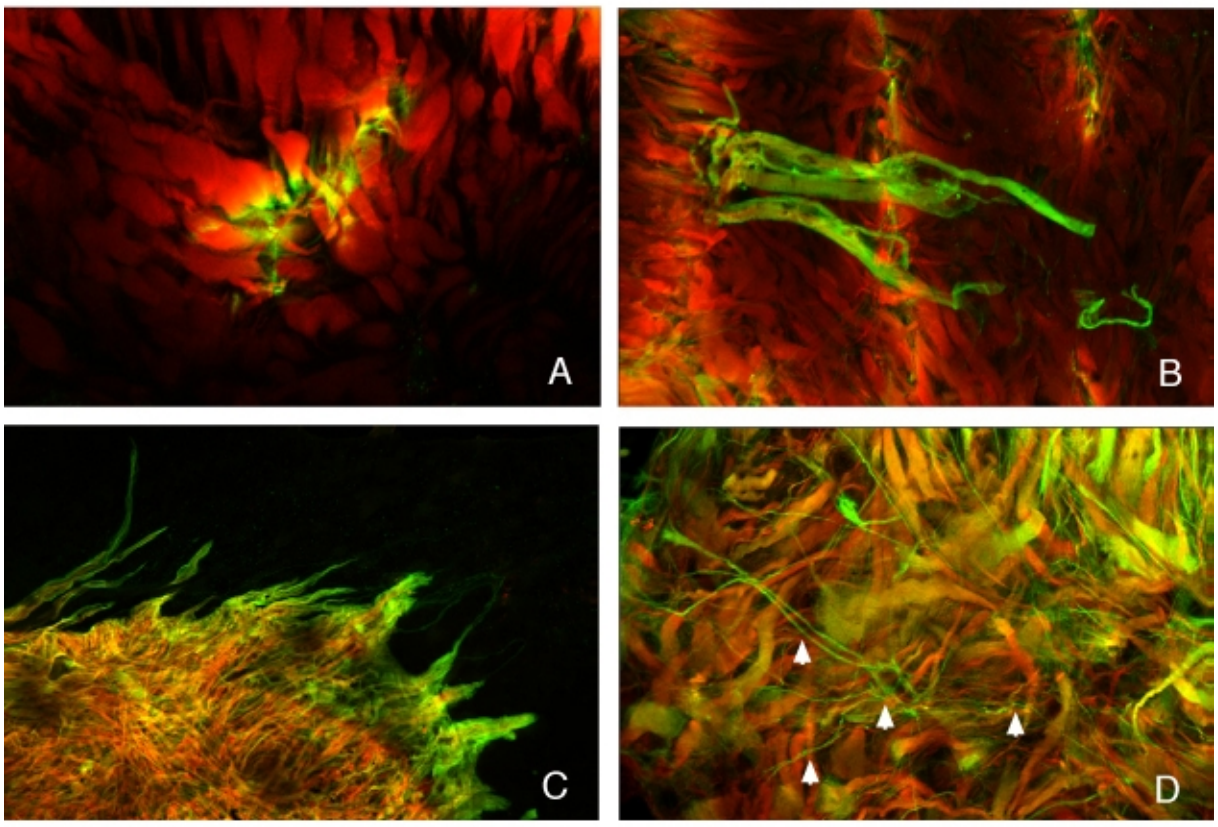

Figure 26. The vitreal surface of retinal flat-mounts prepared after the retinas were detached for 3 days and reattached for 28 days and labeled with antibodies to vimentin (red) and GFAP (green). A, high magnification image of the retinal surface. The Muller cell endfeet are largely club shaped, and the red color indicates a predominance of vimentin. The vitreal edge of some of these endfeet show predominant GFAP (yellow/green color). B, an image showing the outgrowth of ribbon-like extensions of Muller cells' cytoplasm into the vitreous. Within the retina the endfeet are red, indicating a predominance of vimentin, whereas the endfeet outgrowths into the vitreous are green, indicating a shift to GFAP. C, a complex epiretinal "membrane" growing on the vitreal surface. These membranes consist mainly of Muller cell processes in which the "leading" edge of the membrane shows a predominance of GFAP (green). D, a higher magnification image showing the complex structure of the epiretinal membranes with their mixture of Muller cell endfeet and branched cells, presumed to be astrocytes based on their structure and labeling with the antibody to GFAP (arrowheads).

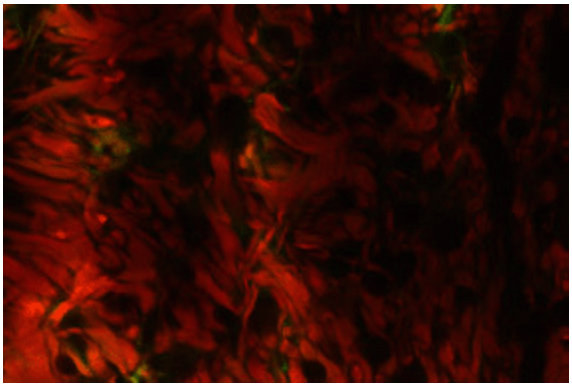
others grow wildly into the outer retina and into the subretinal space adjacent to reactive Muller cells. HB axon terminals can also grow into the inner retina, although this reaction appears less frequently. A subpopulation of



Movie 3. A movie of Muller cell endfeet (green) growing out into the vitreous in a detached retina.
Download video

ganglion cells extend short, spikey neurites from their base after and can also grow processes into the outer retina, where they behave much like the neurites of horizontal cells. In the reattached retinas, ganglion cell processes can also grow into epiretinal membranes formed by Muller cell growth into the vitreous. Muller cells are highly reactive to detachment and grow in the subretinal space to form membranes or glial scars on the exposed photoreceptor OS. After detachment, their endfeet expand but remain within the ILM. After reattachment, their specialized endfeet can grow into the vitreous to form epiretinal membranes as part of the disease, proliferative vitreoretinopathy. Astrocytes proliferate and often appear in epiretinal membranes, but their responses to detachment have not been characterized in detail.

Muller cell changes may occur in response to photoreceptor cell deconstruction and/or cell death or they may arise independently. Although it would seem logical that the remodeling changes in second-order neurons would be signaled from photoreceptor changes and remodeling of third-order neurons signaled by changes in bipolar cells, this has not been proven experimentally.

Future Challenges

Data from the detachment model, as well as from a variety of other studies, now suggests that retinal neurons remain capable of significant structural remodeling in adult mammals. This in turn may provide increased optimism for a variety of therapies for blinding diseases in which photoreceptor degeneration is the primary cause of visual loss. Although preventing photoreceptor cell death is the optimum therapy in these diseases, alternatives to this daunting challenge include technology for replacing photoreceptors, whether it is by way of cellular transplantation (118) or the use of progenitor cells (119-121). This success, however, would be hollow if the second-order neurons did not retain sufficient plasticity to form functional connections with the new photoreceptors. It may seem far-fetched at the present that such connections would form circuitry for functional vision. However, the degree of remodeling we have observed may be an indicator that the inner retina has more of a capacity for remodeling itself than previously imagined. Studies of patients with foveal reattachments—indicating that visual recovery may occur over years, not weeks—could conceivably represent the re-formation of appropriately functional retinal circuits, or even a remodeling of the RPE/photoreceptor interface to properly align the foveal cones. In the case of detachment, preventing both photoreceptor and Muller cell reactivity may also be key to treating the injury and preventing threats to sight through diseases such as subretinal fibrosis and proliferative vitreoretinopathy. Adjuncts to therapy do not seem so distant in these cases, because treatment with something as simple as elevated oxygen concentration appears to help attain these goals in animal models (25, 40, 47, 122).

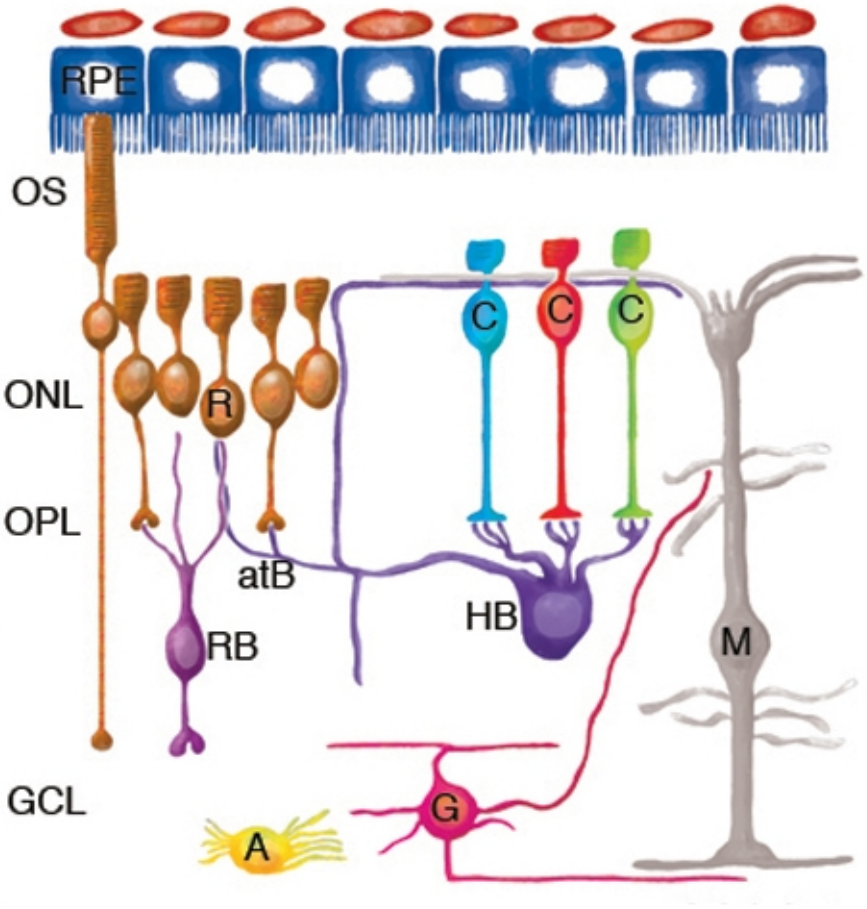


Figure 27. A drawing summarizing the remodeling events in the feline retina as a result of detachment. A, astrocytes; atB, axon terminal of B-type horizontal cell; C, cone; COS, cone outer segments; G, ganglion cells; HB, B-type horizontal cells; M, Muller cells; OPL, outer plexiform layer; ONL, outer nuclear layer; R, rod; ROS, rod outer segments; RB, rob bipolar cells; RPE, retinal pigmented epithelium.

About the Author

Dr. Steven Fisher was born in a small farm village in northern Indiana. He received his B.S. (Experimental Psychology, 1964), M.S. (Physiology, 1966), and Ph.D. (Neurobiology, 1969) degrees from Purdue University. His

mentor for the Ph.D. was (the late) Professor Marcus Jacobson. Steve then did an NIH Postdoctoral Fellowship in 1969 in the laboratory of Dr. John Dowling at the Wilmer Institute. His first academic appointment was in 1971 as an Assistant Professor of Biology at the University of California, Santa Barbara. He remains at UCSB as Professor of Molecular Cellular and Developmental Biology and a member of the Neuroscience Research Institute. He was the founding Director of that Institute. His research interests include the organization of the vertebrate retina, the cell biology of retinal injury regeneration within the retina. Recently, he has moved into the world of bio-image informatics, and he is now part of the Center for BioImage Informatics at UCSB (http://www.bioimage.ucsb.edu/). The NSF-supported Center has as its mission the building of large, distributed, searchable databases of biological tissue and the building of special tools for the analysis of biological images. He has been honored with a Research Career Development Award and a M.E.R.I.T. Award from the National Eye Institute, and in 2002 with the Ludwig Von Sallmann Prize for Vision Research.

Regeneration in the Goldfish Visual System

Sam Nona

Created: May 1, 2005; Updated: June 20, 2007.

Overview

The visual system of the goldfish has been the subject of intensive studies for over a quarter of a century. It differs from the visual system of most other vertebrates, including mammals, in that it continues to grow by the addition of new neurons throughout much of the animal's life. This unusual characteristic has presented neuroscientists with an opportunity to examine how the existing visual pathway accommodates the new growth, for example as the axons of the newly born retinal ganglion cells exit the eye to join the older axons in the optic nerve tract—a conduit that carries visual impulses from the retina to the brain. Furthermore, for largely unknown reasons, the visual system of the goldfish is endowed with the capacity for repair if injured, culminating in the recovery of vision. Much research has been undertaken to identify the cellular and molecular components that support this phenomenon, not least because the knowledge gained may be helpful in the quest to understand why a similar injury in mammals—including humans—invariably leads to an irreversible loss of function.

The following commentary is a pictorial journey through the visual system of the common strain of the goldfish, *Carassius auratus*. It highlights, by the use of species-specific immunocytochemical markers and electron microscopy (EM), the system's many unique structural features, which are quite unlike those in other vertebrates, and are thus of interest because of the likelihood that they reflect a patterning better suited for the restoration of its cytoarchitecture after injury.

In this commentary, I first describe the organization of the normal goldfish visual system and point to those features that distinguishe it from the visual system of other vertebrates. This will be the foundation for the main theme of the commentary, in which I describe some of the cellular events that accompany the process of repair in the injured optic nerve of the goldfish.

General Features of the Goldfish Visual System

Like the brain and the spinal cord, the visual system of the vertebrates is a component of the central nervous system (CNS). In the goldfish, the visual system is made up of three distinct compartments (Fig. 1):

- the retina
- the optic nerve
- the tectal target in the brain

The **retina** lines the posterior of the eye. Axons of retinal ganglion cells emerge from the back of the eye, acquire myelin sheath, and become grouped into bundles, thus forming the **optic nerve**. The two optic nerves cross bodily at the midline—a region known as chiasm—where they enter the skull to join the **tectal target in the brain** contralaterally, not ipsilaterally as in most other vertebrates. Thus, axons of retinal ganglion cells represent the only structure that is common to all three compartments, which are, nevertheless, distinguished by different types of astrocytes, or astroglia cells, which form the principal framework, locally adapted to serve the needs of the tissue, as described below.

Astrocytes in the Retina

The Muller cells are the principal glia (Latin: "glue") cells of the teleost retina. They form architectural support structures stretching radially across the thickness of the retina. At the turn of last century, Cajal (1) described the fine structure of Muller cells in several species using Golgi staining, a technique that bathes the tissue in silver

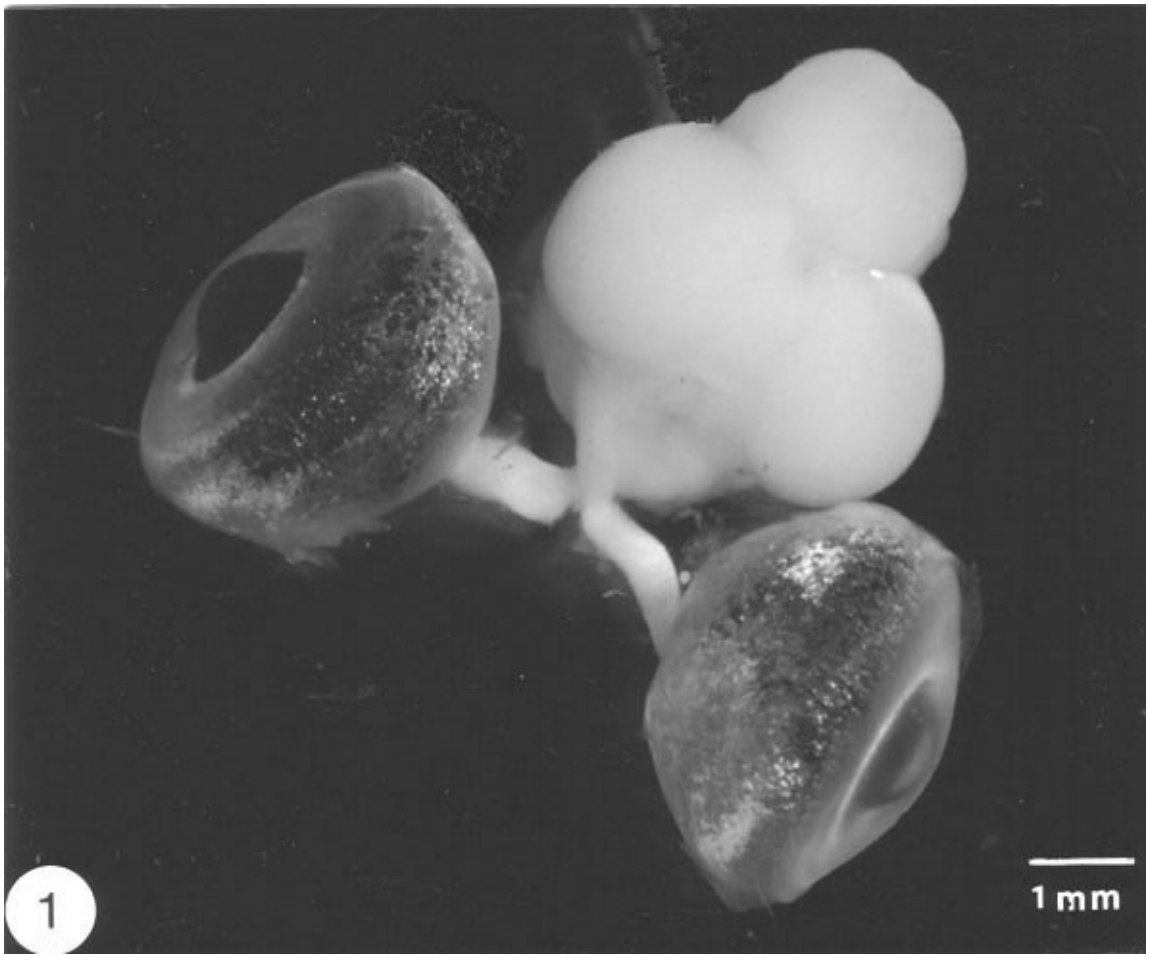

Figure 1. The visual system of the goldfish. Note the complete crossover of the two nerves at the chiasm. (Dissected by Carole Bartlett).

salts to reveal the fine details of individual cells. The Muller cell bodies lie in the inner nuclear layer of the retina and project thick and thin processes in either direction to the outer and inner limiting membranes. Muller cell processes insinuate themselves between cell bodies of neurons in the nuclear and plexiform layers and enwrap neuronal cell bodies (2). Through this extensive system of cell processes, Muller cells are believed to provide metabolic support to the retinal neurons, as well as remove their waste.

The Muller cells are considered to be a type of astrocyte because their processes are filled with intermediate filaments, so-called because their diameter is intermediate between myosin filaments (15 nm) and actin filaments (6 nm), that stain dramatically with antibodies to glial fibrillary acidic protein (GFAP), the subunit protein of the filaments found in astrocytes (reviewed by Traub (3). The GFAP subunit is well conserved across the vertebrate phylum, and in goldfish, as in rat, it has a molecular weight of 51,000, as determined by SDS-polyacrylamide elctrophoresis (4). The antiserum to goldfish GFAP, when applied to sections of goldfish retina, specifically recognizes Muller cells' radial processes, which at the basal end enwrap retinal ganglion cell perikarya and form end-feet at the vitreal surface of the retina, while at the other extremity, they elaborate a network of fine processes that terminate at the photoreceptors (Fig. 2). The Muller cells perikarya and lateral processes, both of which are readily seen by the Golgi method, are not revealed by anti-GFAP, possibly because these structures do not contain GFAP in detectable amounts. Nevertheless, the specificity of the antiserum is nicely demonstrated by the absence of staining elsewhere in the retina. In this context it is interesting that "free" astrocytes, of the type described in the nerve fiber layer of mammalian retina (5), are absent from the teleost retina.

Astrocytes in the Optic Nerve

The structure of the fish optic nerve has been described by several workers using various methodologies (6-8). This author intends to add another dimension to these reports, by describing the pattern of glial cells and optic fibers in the normal goldfish optic nerve as revealed by goldfish-specific antibodies to GFAP and neurofilament protein, respectively. These studies are complemented by ultrastructural studies to provide a detailed picture of the optic nerve structure and, therefore, a template with which to compare the structure of the repaired nerve following injury.

In the goldfish, the optic nerve is cylindrical in shape, measuring 0.5 mm in diameter and 2.5 mm in length (in a 5-cm long fish). The optic nerve is white in appearance because of the lipid-rich myelin sheath that enwraps its fibers (Fig. 1). For the purpose of this discussion, the optic nerve will be divided into two parts: 1) the intraocular optic nerve, and 2) the intraorbital optic nerve, through to the chiasm.

The Intraocular Optic Nerve

The tip of the optic nerve, which lies within the retina, has a conical shape. Axons of retinal ganglion cells converge onto the optic disc to be funneled into the optic nerve head by a resident population of GFAP-positive astrocytes whose radial orientation corresponds to the trajectories of the axons (Fig. 2). This arrangement implies that astrocytes at the optic nerve head direct the axons away from the rest of the retina and into the optic nerve head, perhaps through the expression of a combination of attractant and repellant molecules on their surface (9-11). Astrocytes, additionally, envelop the surface of the optic nerve head in a characteristic fashion

known as glia limitans, thus forming a tube-like structure through which the axons are funneled (Fig. 3). Running through the center of the optic nerve head is the central artery, which is also enwrapped by astrocyte processes. It is thus reasonable to assume that the manner with which the astrocytes envelop the vasculature and the axons signifies some primitive disposition of blood-brain barrier, as well as providing a nutritive service, much like the Muller cells in the retina.

The Intraorbital Optic Nerve

After the optic nerve leaves the retina and passes through the globe's outer layer, the sclera, its tightly packed fibers more than double in size as they enter the orbit. This transition is a landmark, for it signifies that the hitherto naked fiberes have acquired myelin sheath. Thereafter, the glial cells sculpt the optic nerve into an intricate pattern, the fine details of which are beautifully revealed by immunocytochemistry.

An unexpected finding, reported nearly simultaneously by several laboratories, revealed that astrocytes in the normal fish optic nerve do not contain an appreciable amount of GFAP (4), the universal marker for astrocytes (12). Rather, astrocytes of goldfish optic nerve (7, 13) and cichlid optic nerve (8) are composed largely of cytokeratin polypeptides—proteins that are normally found in epithelial tissue. This finding led some workers to propose that the absence of GFAP is a reflection of the immaturity of the tissue and is, therefore, the reason why fish optic nerve has the capacity for robust regeneration (13). However, this suggestion has been mooted by the author and his colleagues, who were the first to demonstrate that the attenuated level of GFAP in the goldfish optic nerve (14) is greatly enhanced following an injury to the visual system (Fig. 4).

Interestingly, the dramatic response of fish optic nerve astrocytes to injury, although in keeping with what is generally observed in all damaged CNS tissue, was to be followed by more dramatic cellular responses in the optic nerve that set this tissue apart from its mammalian counterpart, and offered an explanation for its spontaneous recovery after injury.

The response of the goldfish optic nerve to injury reveals a striking pattern underlying the tissue's framework: it shows that the first one-quarter of the optic nerve is made up of GFAP-positive astrocytes that are organized as a dense, lace-like pattern with no evidence of segmentation into discrete domains, an observation that is reflected in the organization of the fibers that appear closely bundled, with no discernible spaces between them (15). Further along the nerve, however, up to the nerve-tract boundary, myelinated axons are organized into discrete domains, known as fascicles (Fig. 5). In longitudinal profile, the fascicles appear as linear channels or tubes bound by parallel astrocyte processes (glia limitans), and each fascicle is separated from its neighbors by parallel rows of connective tissue septae. The pattern shows greater intricacy in transverse profile, with the astrocytes-bound fascicles being further divided into smaller compartments by fine processes (Fig. 6), a pattern that is also seen with an antibody to goldfish cytokeratin (7).

Ultrastuctural studies of the optic nerve are in complete agreement with these observations (6, 16). They show the optic nerve to be made up of bundles of myelinated axons enclosed by astrocyte processes, thus forming discrete fascicles that are separated from adjacent fascicles by septae, containing collagen, fibroblasts and capillaries. Furthermore, each fascicle is divided into smaller compartments by astrocyte processes that form characteristic desmosomal junctions. The close correspondence between ultrastructural and immunocytochemical findings is depicted in Fig. 6.

EM analyses additionally reveal that the optic nerve contains microglia, which equate to the macrophages normally found in the peripheral nervous system (PNS), and become phagocytic if the tissue is damaged, as well as a unique class of non-phagocytic granular cells that reside normally within the sheath/septae. A full complement of the cells and structures that make up the goldfish optic nerve is given in Fig. 7.

It is instructive to return briefly to the epithelioid characteristics of the fish optic nerve by referencing the cichlid optic nerves, which are formed as ribbons rather than discrete fascicles seen in the goldfish. The tissue pattern in

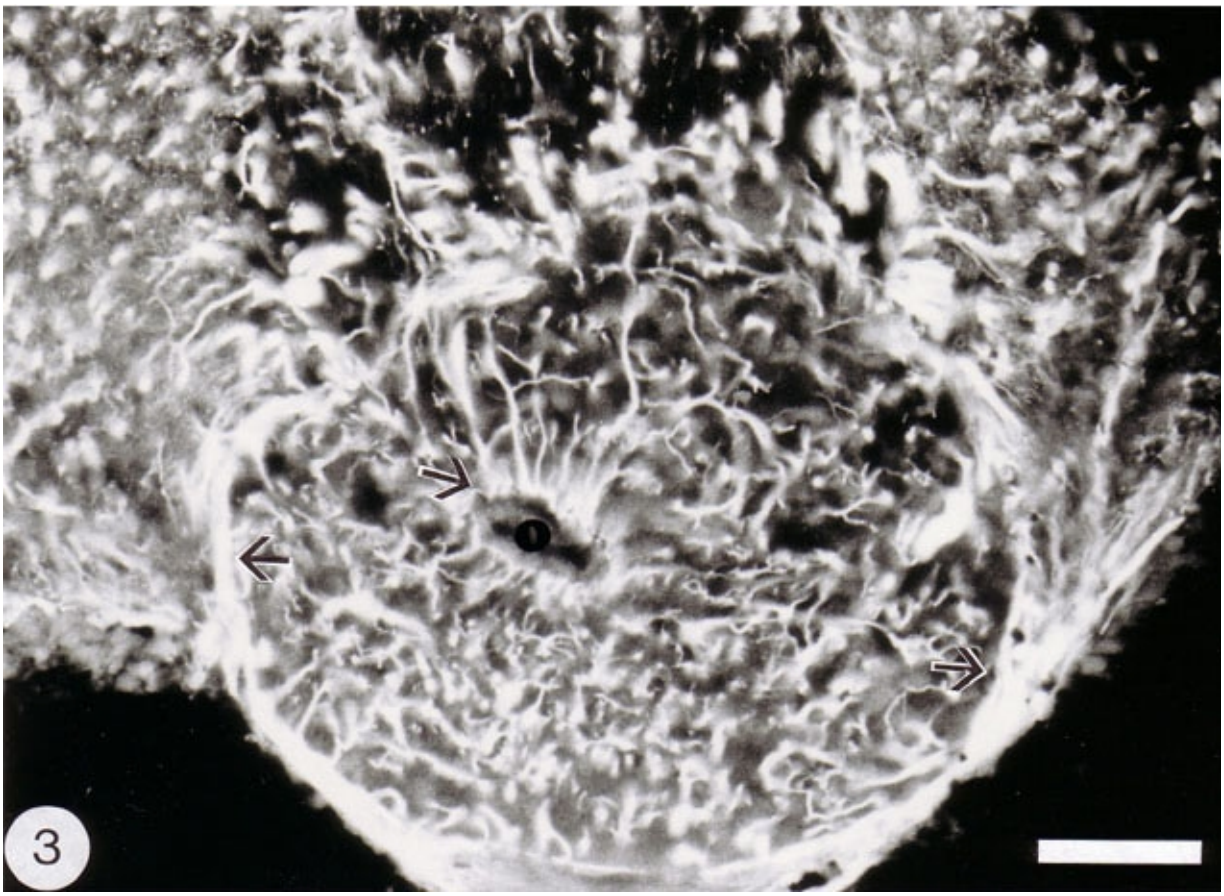

Figure 3. Cross-section of goldfish optic nerve head stained for GFAP. Astrocytes (→) enwrap the nerve head and the central artery (O). Bar = 50 μm.

the cichlid optic nerve appears to be more elaborate, with the longitudinally oriented astrocyte processes being connected at regular spacing by a lace-like network of finer astrocytes processes, laid out as sheets running at right angles to the optic fibers. Scholes and colleagues have proposed that this astrocytic pattern is linked throughout with desmosomal junction, thus providing the fish optic nerve with mechanical resilience needed during rapid eye movement. Astocytes in the cichlid optic nerves have been described as reticular astrocytes because they form a network pattern that complements the wavy pattern of the optic axons, enabling them to accommodate small stretches reversibly in a concertina-like action (17). And, as if to emphasize that eye movement in the fish can only be accommodated by a framework made up of an atypical phenotype (epithelioid) astroglia, both in terms of its organization and protein composition, the domain of the cytokeratin-expressing astrocytes in the optic nerves comes to an abrupt end at the nerve-tract boundary, beyond which, and throughout the brain, astrocytes are typically of radial morphology and express GFAP only (4).

Taken together, the above results demonstrate that astrocytes in the fish optic nerve express both cytokeratins and GFAP intermediate filaments, in contrast to the mammalian optic nerve astrocytes, which express GFAP only. One possible explanation is that astrocytes may have a relict evolutionary status (18). For example, the most primitive of extant vertebrates, the cyclostomes, have astroglia with similar cytology throughout the CNS, showing dense intermediate filaments linked with desmosomes (19). Scholes has suggested that fish optic nerve has retained elements of an ancient glial pattern that became outmoded as the CNS became armored in bone, but still appropriate in the orbit (17).

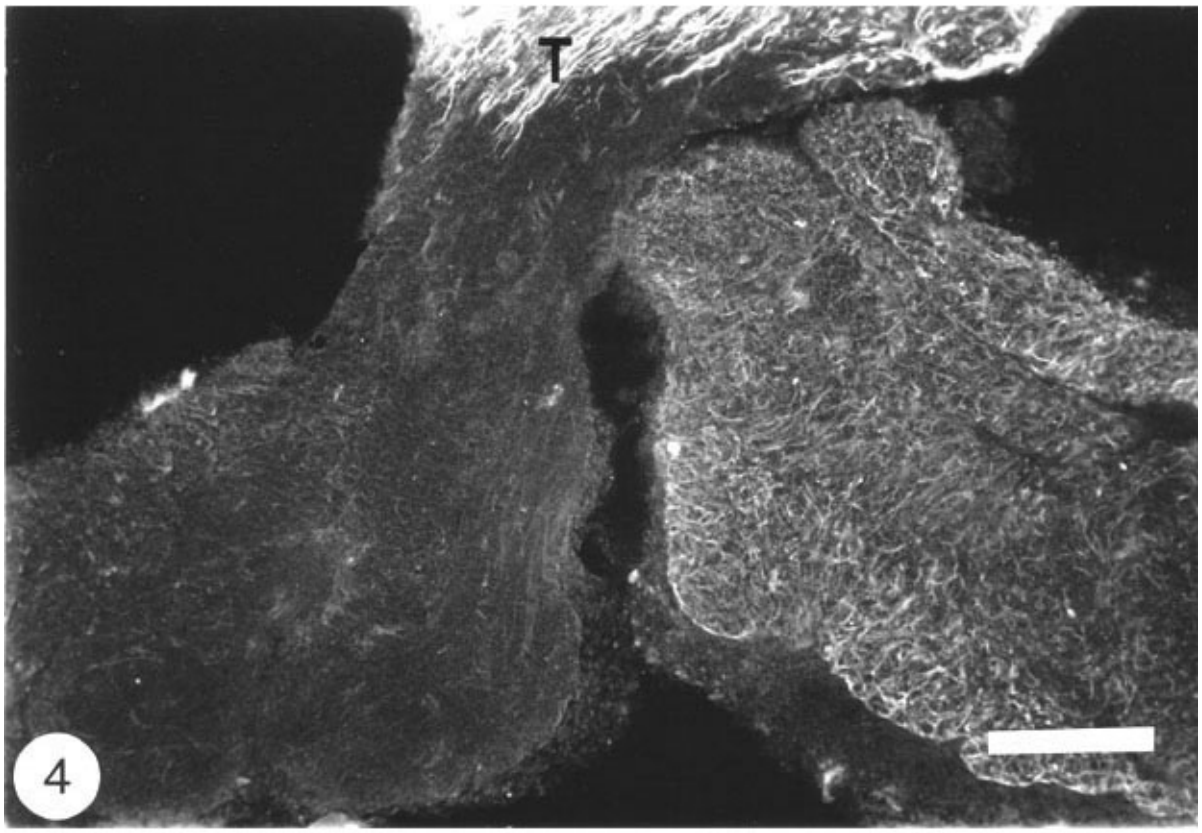

Figure 4. GFAP staining of normal (left) and injured (right) goldfish optic nerves at the chiasm. Astocytes are more prominent in the injured nerve. Astrocytes of the optic tract (T) are normally GFAP+. Bar = 50 µm.

Astrocytes in the Brain

Just beyond the chiasm, at the optic nerve-optic tract boundary, the astrocyte's phenotype changes abruptly in two respects. First, whereas before astrocytes were of reticular morphology, now they have a radial morphology. Second, whereas reticular astrocytes expressed strongly cytokeratin proteins and only faintly GFAP, radial astrocytes show a pronounced expression of GFAP, and there is an absence of cytokeratin expression (4, 7, 20).

Astrocytes in the Optic Tract

Astrocytes in the goldfish optic tract appear to arise from two sources. The radial astrocytes that are seen at the commencement of the tract arise from cells whose perikarya line the optic recess. Evidence for this comes from the staining pattern of two adjacent sections of the optic tract, with anti-GFAP and anti-S-100 protein, respectively. Although the former marker recognizes a profusion of radial processes, the latter additionally highlights a population of brightly stained round cell bodies at the nerve-tract boundary, extending into the optic recess (Fig. 8). The validity of S-100 protein as a marker for astrocytes has been documented for mammalian astrocytes (21, 22).

The second source of astrocytes in the optic tract are the cells that line the walls of the third ventricle, from where one subpopulation of radial astrocytes runs along the dorsal aspect of the tract, parallel to the optic fibers, while a second population of radial astrocytes traverses the tract to terminate as end-feet on its surface. Where the optic tract bifurcates, at the nucleus rotundus, before it joins the optic tectum, radial astrocytes are no longer discernible immunocytochemically (4).

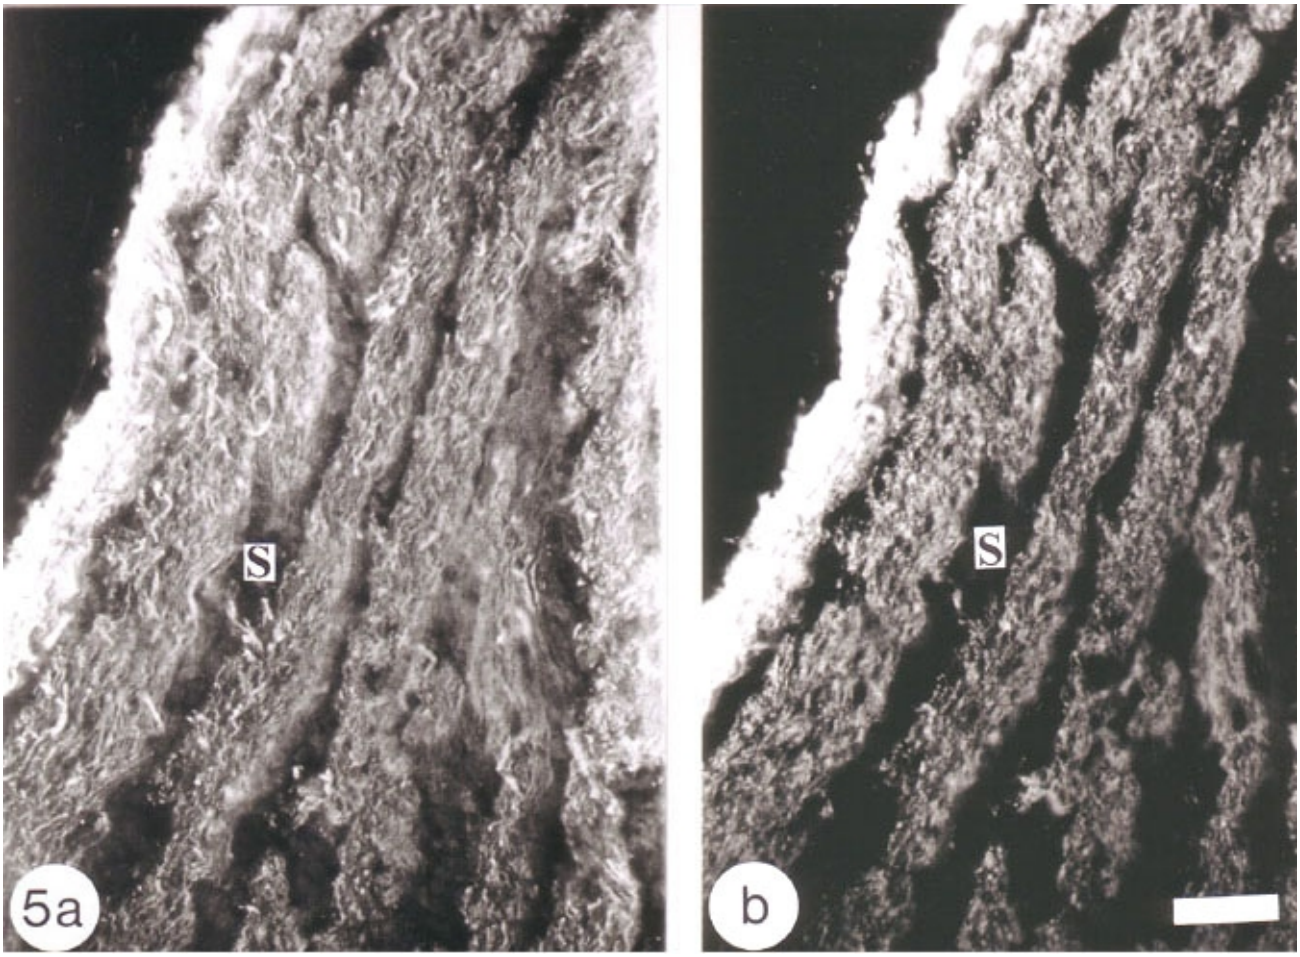

Figure 5. Longitudinal section of goldfish optic nerve stained with neurofilament marker IF145 (a) and myelin marker 6D2 (b). The optic fibers are contained within fascicles, separated by negatively stained septae (S). Bar = 50 μm.

Astrocytes in the Optic Tectum

In the optic tectum of the teleost, there are two distinct populations of GFAP-positive astrocytes. The ependymal region contains an extensive meshwork of astrocyte processes that border on the ventricular margin and extend dorsally toward the neuronal stratum periventricular layer (4). Arising prominently from this region and extending across all of the tectal layers is a well-organized system of radial processes that terminate as end-feet on the pia surface (Fig. 9). There has been much debate as to the source of these two astrocyte populations, with some authorities suggesting that they arise from a common cell body (23). However, studies conducted by the author, using anti-S-100 protein, have revealed two distinct populations of cell bodies: one that is scattered in the ependymal region, and another, one or two cells deep, that is interposed between the ependymal and the stratum periventricular regions. It is from this second population of perikarya that fine radial processes emerge to traverse the tectum (4, 24), a finding that is supported by EM studies (25). A curiosity is that in fish, neither the astrocytes in the brain nor those in the optic nerve conform to the classical description of astrocytes.

What Are Astrocytes?

Strictly speaking, astrocytes are the star shaped GFAP-positive glia cells (Fig. 10) (26) in the adult mammals and birds, which have end-feet on CNS blood vessels (for an excellent review, see Bignami (12). They lack desmosomes, and they appear late in development by proliferation of radial glia, following withdrawal of the pial and ependymal contacts (27). In the fish, on the other hand, GFAP-positive glia cells in the brain (4) and spinal

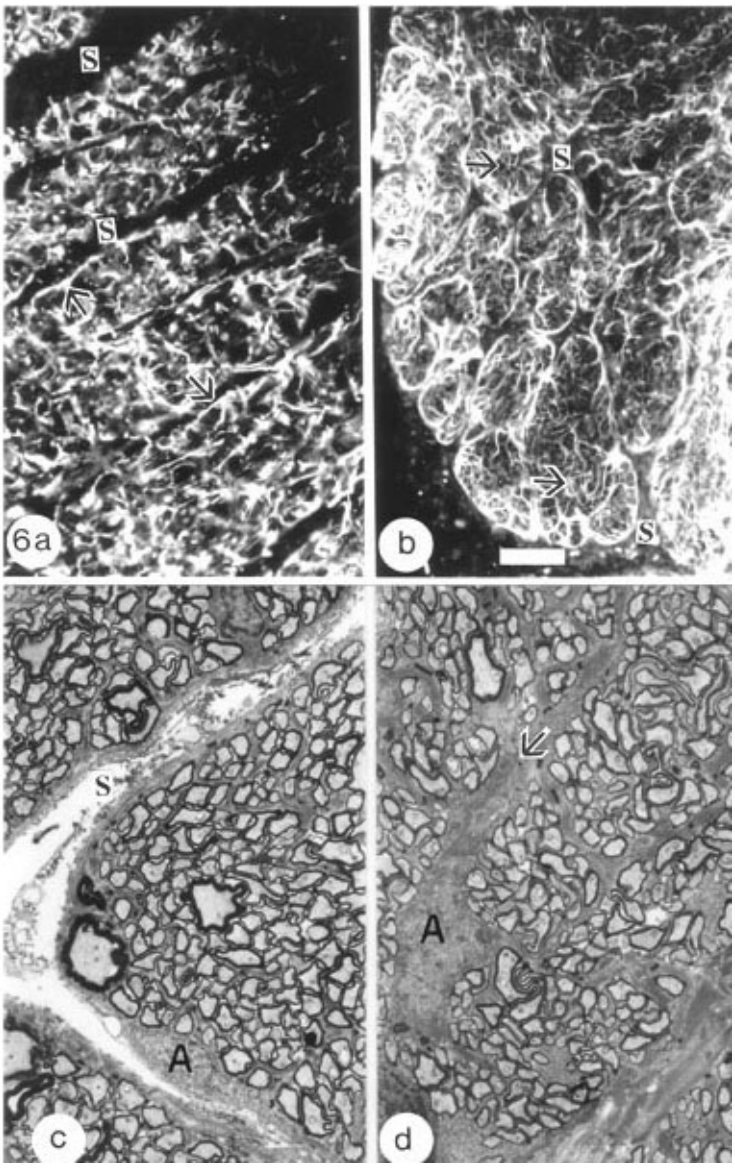

Figure 6. The fascicular pattern of the goldfish optic nerve is defined by the tissue's astrocytes. (a) and (b) show the pattern in longitudinal and transverse profiles, respectively, stained for GFAP. Note the fine details of each fascicle in (b). The pattern is nicely reproduced in EM sections (c) and (d), which correspond to (a) and (b), respectively. (S) septae, (→) astrocyte processes, (A) astrocytes cell body. Bar = 50 μm for (a) and (b). (c) ×3.5K; (d) 8K.

cord (28) retain their radial morphology in the adult. The persistence of radial astrocytes may signify some dependence on cell contact with the ependymal lining of the CNS ventricle. The absence of the ependymal structure from the optic nerve of the fish, therefore, explains nicely why astrocytes here differentiate as a specialized form—the reticular astrocytes (17).

Axon Regeneration in Injured Goldfish Optic Nerve

The literature abounds with studies that confirm an observation made by Ramon y Cajal (29) almost a century ago that, with a few exceptions, severed axons of the neurons in the mammalian CNS are capable only of abortive sprouting that provides little functional recovery. In contrast, neurons in the PNS have a greater capacity for regrowing their damaged axons, and under appropriate conditions, there is a recovery of function. It has not been possible to put forward a direct and simple explanation of this difference in regenerative capacity. Recent studies, however, give credence to Cajal's notion that the fault in CNS regeneration lies with the extrinsic

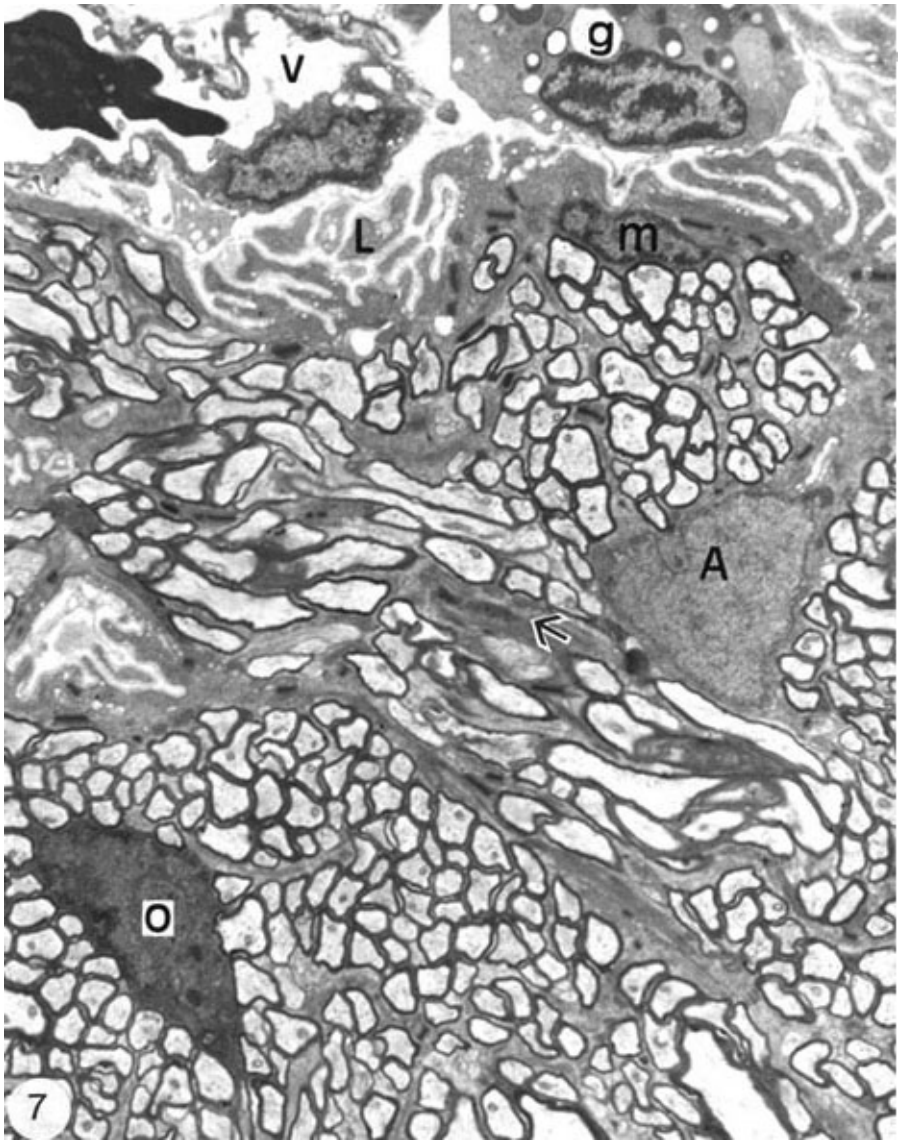

Figure 7. Composition of normal goldfish optic nerve as revealed by EM. Axons are myelinated and appear in transverse and longitudinal profiles due to the sinusoidal pattern of the fibers. Astrocyte processes (→), joined by desmosomes, arrange the fibers into bundles. Astrocytes also form a continuous limiting membrane (L) that excludes the septae contents from the interior of the CNS tissue. environment surrounding the neuron. Such explanation clearly does not encompass lower vertebrates, in particular the fish, whose CNS axons are endowed with a remarkable capacity for spontaneous repair after injury, despite having an extrinsic environment that shares many of the features found in mammalian CNS.

Set out below is a brief description of the components that make up the environment of the CNS and PNS in mammals and how their reaction to injury is perceived to impact upon the failure and success of axonal regeneration, respectively. This is followed by a detailed analysis of the events that accompany the repair process in the injured goldfish optic nerve, highlighting the environment of the lesion and distal nerve and how each region adapts over a period of several months to accommodate first axonal regrowth and later myelination. Immunocytochemical and ultrastructural evidence will be presented to show that regeneration in fish optic nerve is accompanied by several events that are common to regeneration in mammalian PNS, and that the CNS environment surrounding the regenerating axons actively supports, rather than inhibits, axonal outgrowth.

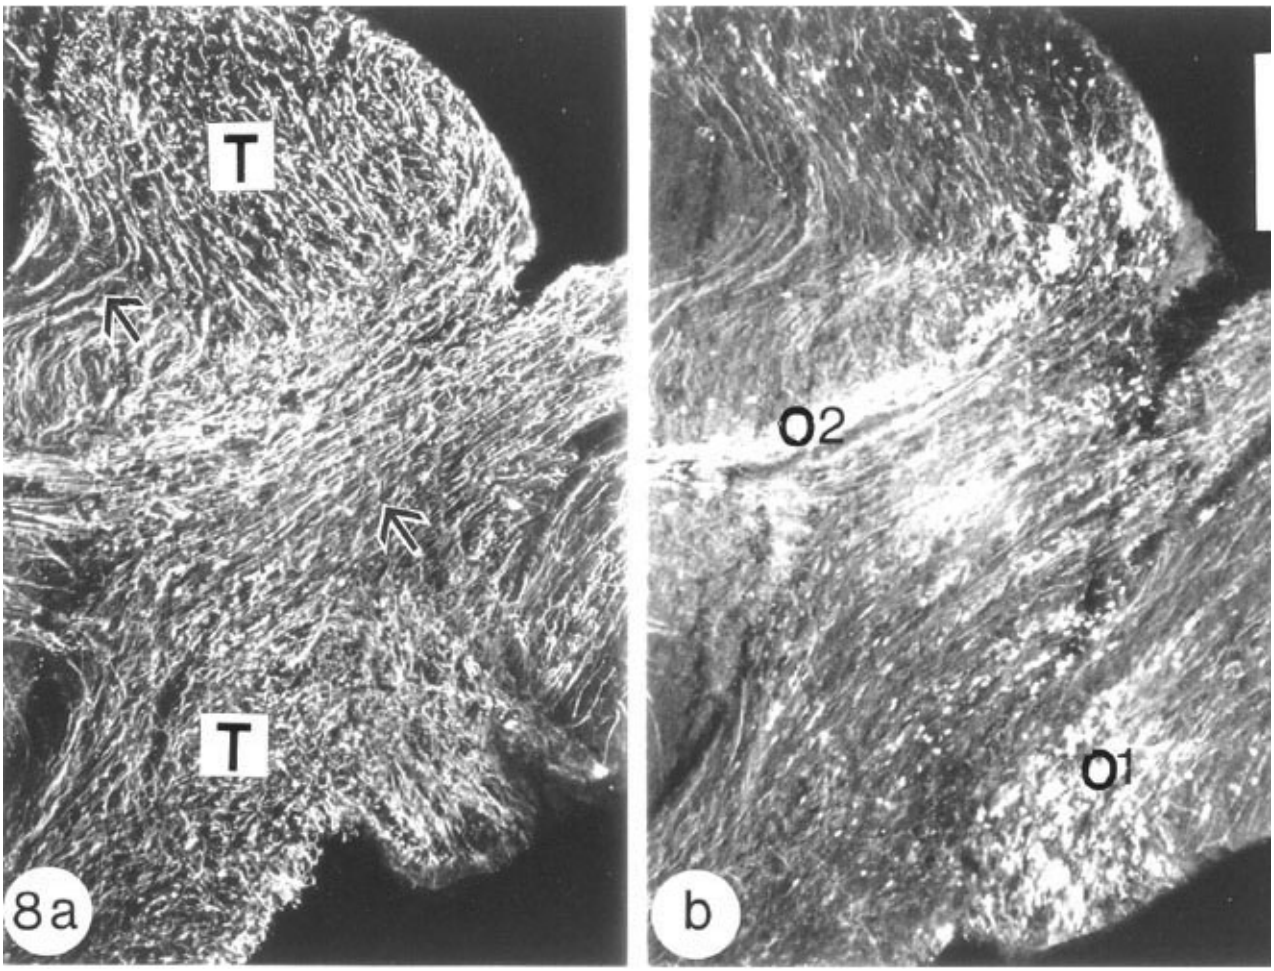

Figure 8. Astrocytes in goldfish optic tracts (T) stained for GFAP (a) and S100 protein (b). Astrocytes have a radial morphology (→) and arise from cells at the optic recess (O1) and the walls of third ventricle (O2). Bar = 100 μm.

Glial Environment of Axons in Mammalian CNS

One of the components of the milieu that surrounds an axon in the CNS is the astrocyte. During embryonic development, astrocytes act in guiding axon growth and neuronal development (30, 31). This capacity appears to be lost in the adult, with the consequence that an injury to the CNS induces tissue damage that creates barriers to regeneration. One of the main barriers is the glial scar, which consists primarily of hypertrophied (enlarged/reactive) astrocytes. Reactive astrocytes are perceived to form a physical wall that wards off any further damage to the tissue. The process leads, however, to the formation of the glial scar, beyond which axons cannot regenerate (32). Recent studies have sought to identify the molecular constituents of the glial scar that may play an additional role in inhibiting axon regeneration. It is recognized that although astrocytes can produce growth-promoting molecules, such as laminin, which aid in attachment and migration of neurons during development, it appears that adult astrocytes also produce a heterogeneous class of molecules known as proteoglycans—proteins to which are attached large sugar residues—whose expression increases in the glial scar, and as a result are thought to act as chemical barriers to axon regeneration in the CNS (33, 34).

A second protagonist in axon regeneration failure in the CNS appears to be myelin-producing oligodendrocytes, an idea first proposed by Berry (35). Studies based on tissue culture assays have shown that oligodendrocytes, and at least two different molecules that are associated with oligodendrocyte myelin, lead to the collapse of the growing axon tip, the growth cone (36). In molecular terms, growth cone arrest is attributed to the unfavorable interaction of growth cone receptors with ligands (myelin proteins) that are bound to oligodendrocyte

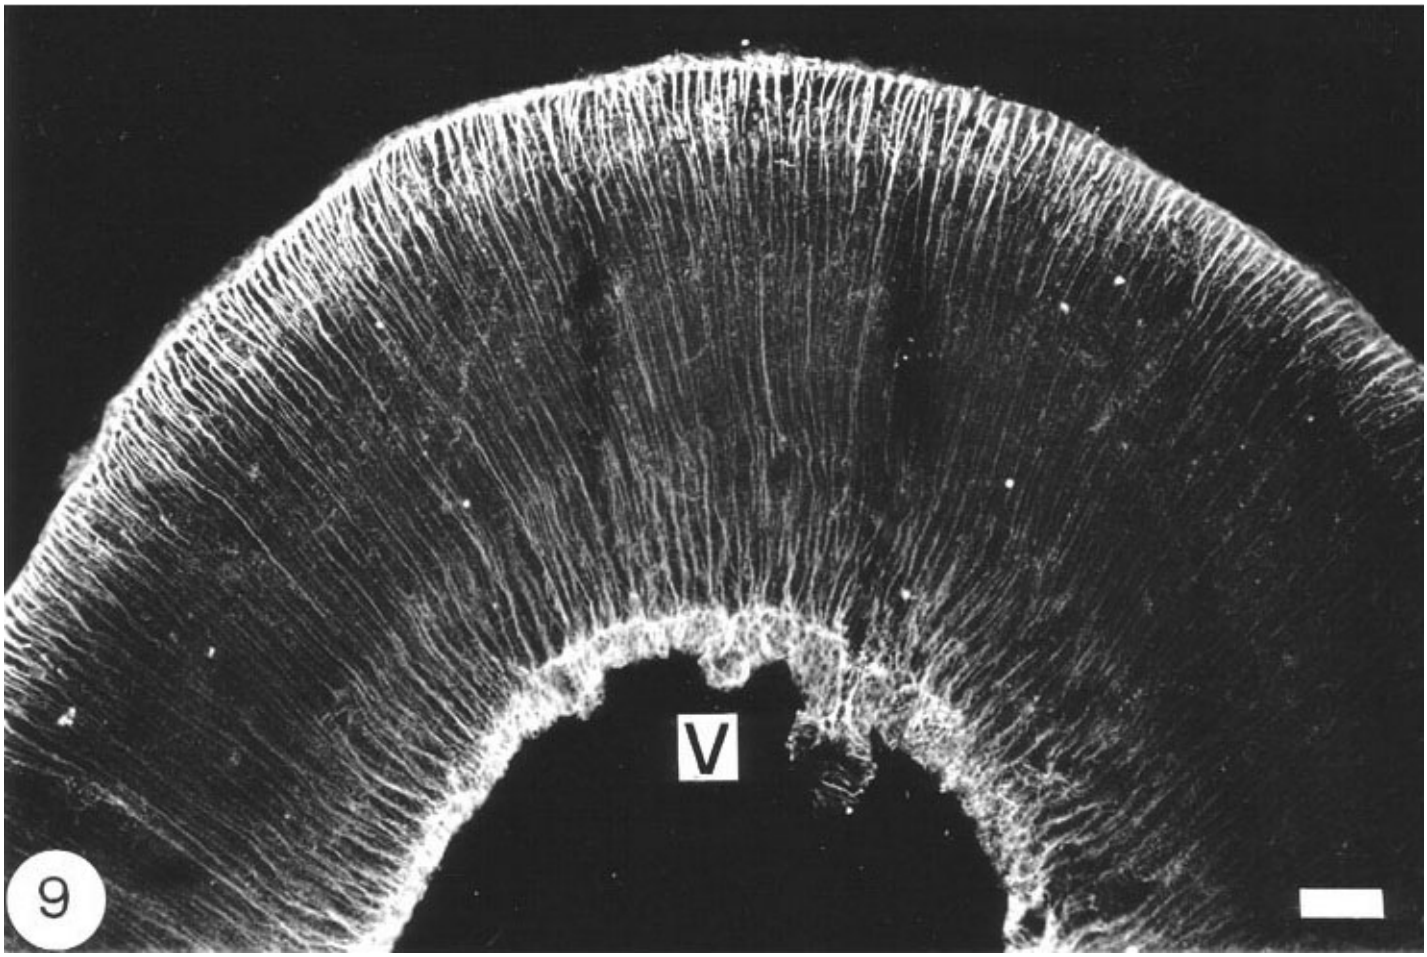

Figure 9. Sagittal section of fish tectum stained for GFAP. Radial astrocytes arising from near the ventricle (V) span the entire width of the tectum, terminating as end feet at the surface. Bar = 100 μm.

membrane, and that neutralization of the proteins promotes regeneration *in vivo* (37). From these and related observations, it is concluded that myelin-associated molecules are one of the principal causes of failure of regeneration of cut axons in the intact adult CNS (reviewed by Filbin (38).

Glial Environment of Axons in Mammalian PNS

The extrinsic environment of the PNS, on the other hand, contains neither astrocytes nor oligodendrocytes. Instead, one cell type, the Schwann cell, performs the dual task of axon guidance and myelination. The Schwann cell also produces basal lamina (cf. laminin in CNS), a protein-rich membrane that surrounds the Schwann cell-axon unit, forming a tubular structure along the entire length of the nerve. A substantial amount of additional matrix, particularly fibrous collagen that imparts tensile strength to the peripheral nerve, is deposited between these tubular structures. The Schwann cell is believed to impart trophic support to the regenerating axon, which extends to its target by adhering to the substrate made up of the matrix molecules, in a recapitulation of the events that take place during development. The cellular and extracellular components are retained during peripheral axon regeneration (reviewed by Martini (39)); their absence from the CNS has long been thought as the reason why this system lacks the regenerative capacity. To this end, a number of laboratories have recently reported that the usually abortive axonal sprouting near the lesion site in the injured rat optic nerve can be mobilized to trigger a limited axonal regeneration if an autologous peripheral nerve containing viable Schwann cells is anastomosed to the cut end of the optic nerve (40-42).

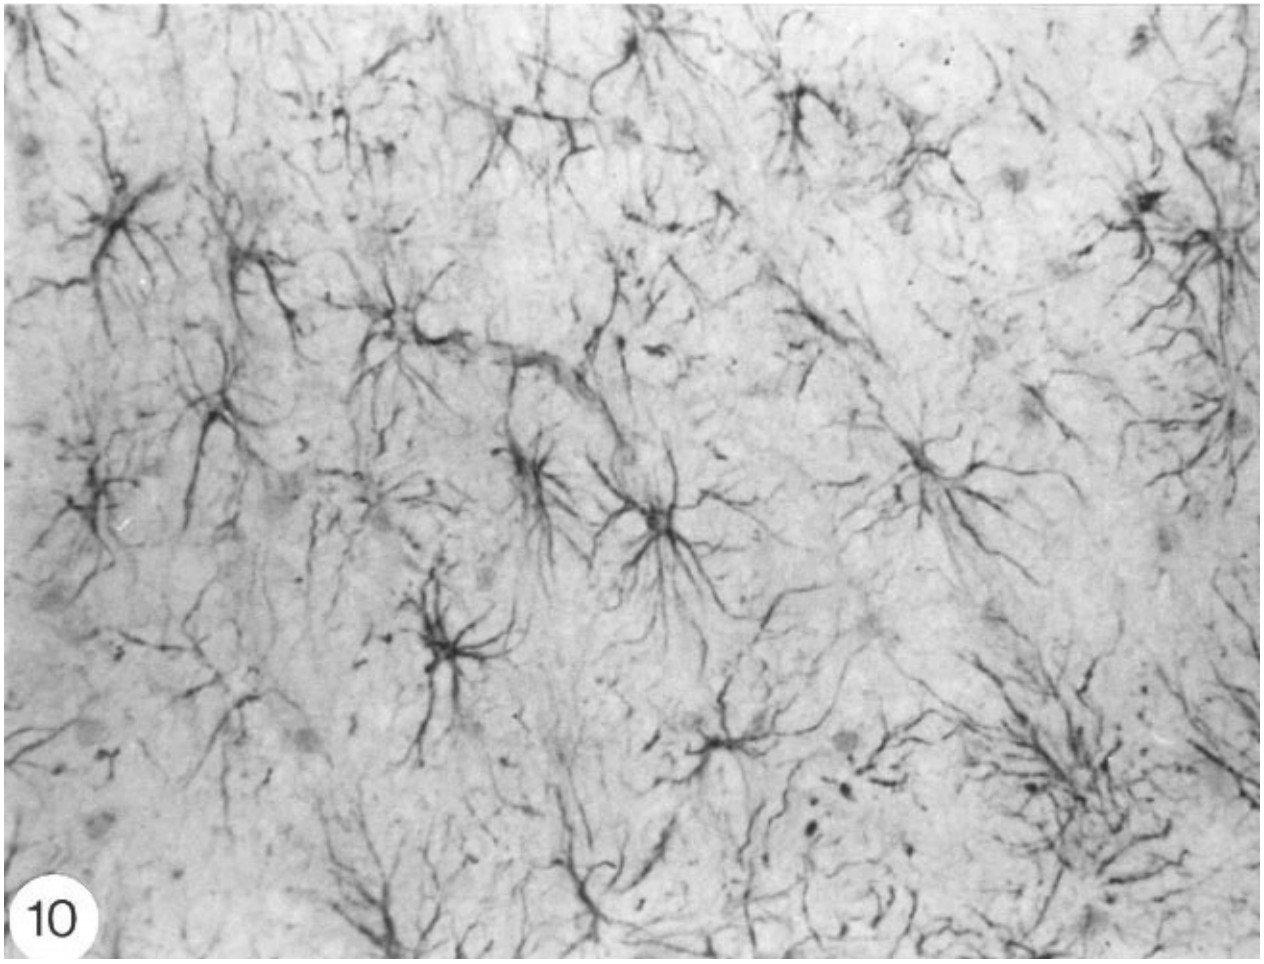

Figure 10. Astrocyte of stellate morphology in rat cerebellum stained with antibody to goldfish GFAP. ×100.

Glial Environment of Axons in Goldfish Optic Nerve

Interestingly, failure of axon regeneration in the CNS is not common to all vertebrates. In lower vertebrates, particularly the fish, axon regeneration in the CNS is the norm, and this is accompanied by the recovery of function. Much research has focused on the visual system of the goldfish in search of a direct explanation as to why it is endowed with the capacity for functional regeneration, especially because it appears that its glial environment is made up of the same agencies, namely astrocytes and oligodendrocytes, which are believed to be responsible for the inhibition of regeneration in adult mammalian CNS.

The Optic Nerve as a Model for Axon Regeneration Studies

The optic nerve has been a popular morphological model for the study of central nerve regeneration. It represents a circumscribed, unidirectional white matter tract, supported by astrocytes and oligodendrocytes, and composed almost entirely of fibers of one origin, namely optic axons arising from the retinal ganglion cells. In the goldfish, injury of the optic nerve induces an anabolic response in the ganglion cells that is the prelude to the regenerative response. The metabolic response, known as chromatolysis, is associated with increased biosynthesis of cytoskeletal proteins (43-45), so-called growth-associated or GAP proteins (46, 47) and lipid products in the cell body. GAPs and lipids are transported by the cytoskeletal proteins to the cut end of the axon, where they are incorporated into the membrane of the growth cone (48). Such a response by retinal ganglion cells to axotomy is crucial if the damaged axons are to traverse the lesion and reach the brain. In the goldfish,

this feat is accomplished through the survival of more than 90% of the axotomized retinal ganglion cells (49). In the frog, retinal ganglion cells also undergo chromatolysis, but only around 50% of retinal ganglion cells survive axotomy and reach the brain; the remainder of the retinal ganglion cells attempt to regenerate, but their axons fail to cross the lesion and consequently die (50). Significantly, in mammals only a minimal number of damaged axons cross the lesion unaided; virtually all of the axotomized retinal ganglion cells undergo atrophy through programmed cell death or apoptosis (51, 52). The programmed cell death is caused by several factors, including absence of chromatolysis, excitotoxicity to glutamate transmitter (53) as well as loss of endogenous and target-derived neurotrophins. Furthermore, a significant number of retinal ganglion cells seem to die because their axons fail to overcome the lesion. The evidence for this comes from studies in which the cut end of rat optic nerve is grafted to a segment of peripheral nerve: axons are able to extend several millimeters beyond the junctional zone, i.e., the lesion, even in the absence of agents that prevent cell death (40, 42).

The above comparative studies, while highlighting the gradation of responses of retinal ganglion cells to axotomy across the vertebrate taxa, also offer a clear indication that survival of axotomized retinal ganglion cells is dependent to an appreciable degree on their axon overcoming a major hurdle—the site of lesion. Rather surprisingly, however, even in regeneration competent systems there has not been a systematic study of the site of lesion, possibly because the region is considered too disorganized for meaningful analyses. We have taken advantage of the recent availability of several specific antibodies (4, 15, 54) to examine the cellular composition of the lesion in the goldfish optic nerve, from shortly after optic nerve crush to several months after injury. Our aim has been to discover if endogenous glial cells, or cells arising from the sheath/septae, reoccupy the lesion shortly after injury, possibly serving as scaffolding for the regenerating axons to traverse the lesion. In the course of the study, it became apparent that instructive changes also take place as the regrowing axons extend beyond the lesion, through the CNS environment of the distal nerve, and these events will also be described. Throughout the study, the term proximal is used to denote that portion of the optic nerve between the eye and the lesion site, and the term distal to denote the nerve between the lesion and the brain.

Events That Follow a Crush to Goldfish Optic Nerve

Immediately after the optic nerve has been crushed, and for at least 4 days thereafter, the lesion appears as a gap between the two nerve stumps, which are held in position by the intact sheath. The tissue-free constriction at the center of the lesion becomes flanked by a region 200 μm wide that is devoid of astrocytes, as noted by the absence of GFAP, B7, and Pax-2 immunoreactivity, and contains only a tiny number of cells, most of which are mitotic (bromodeoxyuridine positive, BrdU+) and appear to be derived from the sheath/septae where similar cells are present. At this stage, myelin disruption is barely noticeable, either in the proximal stump or distally (55). It is important to recognize that a lesion of the type described in this study leads not only to the severance of axons but also to the destruction of local astrocytes. In other words, the continuity of the nerve's fascicular structure is disrupted as a result of crush injury (Fig. 11).

During the following 10 days, there is a large accumulation of mitotic cells in the sheath/septae extending into the core of the lesion (Fig. 12) which, nevertheless, remains devoid of astrocytes, unlike in the proximal and distal stumps (and the retina), where astrocytes express an elevated level of GFAP immunoreactivity compared with that in the uninjured nerve—a response that is indicative of injury to CNS tissue.

The appearance of mitotic cells in the lesion coincides with a strong regrowth of axons (IF145+) from the proximal stump into the lesion, apparently unperturbed by a sea of punctate myelin debris that is scattered throughout the area (Fig. 12). However, by 14 days after injury, debris is no longer present in the lesion, which takes on a translucent appearance, in contrast to the opacity of the two nerve stumps (55, 56).

An important question to address relates to the cellularity of the early lesion and the means by which the regenerating axons traverse the lesion. The cells in the astrocyte-free lesion stain strongly with isolectin IB4 (Fig. 13), which has been used as a general marker for microglia/macrophages in rat (57) and amphibians (58).

However, in the absence of a more specific marker, a careful study was conducted using EM, with the aim of identifying the cells in the lesion. The study revealed unequivocally that the majority of cells in the early lesion are phagocytic macrophages, as distinct from microglia residing in the distal stump, on account of their morphology as well as the substantial amount of myelin debris present within their cytoplasm (Fig. 14).

The phagocytes are first seen at 4 days after injury, peaking 3 days later, coincidental with the appearance of regenerating axons across the lesion. The number of BrdU+ cells also peaks at this time, indicating that the increase in the number of macrophages is attributable to proliferation as well as recruitment, possibly mediated by mitogenic signals from the necrotic tissue. Indeed, macrophages are confined to the lesion where CNS tissue has been destroyed and do not infiltrate the degenerating distal stump, where CNS environment prevails, an observation that has been confirmed by other workers (59). By week 3, the cellularity of the lesion is minimal, phagocytes loaded with myelin debris are noted only in the sheath/septae, and naked axons are the hallmark of the lesion. The cells found among the naked axons have several characteristics that are reminiscent of immature glia cells—a well-structured nucleolus and short cytoplasmic processes that extend into the axons domain (Fig. 15). The cells have since been identified as precursor Schwann cells, as will be shown later.

The early appearance of macrophages at the lesion may be important for the outgrowth of axons in several respects: 1) if myelin debris were inhibitory to axonal outgrowth in the fish optic nerve *in vivo*, as it is *in vitro* (60) (see also Bastmeyer et al. (9)), then macrophages are playing a crucial role by removing inhibitory molecules from the path of regrowing axons; 2) the outgrowth of the axons may be further enhanced by macrophages releasing growth-assisting molecules such as NGF, the expression of which is noted in all of the IB4+ cells in the lesion (Nona, unpublished results). NGF is known to promote regeneration in mammalian PNS (61, 62); 3) macrophages may be aiding axonal extension across the lesion in a more direct manner: clusters of regenerating axons ranging from a few to 100 or more per cluster, often associated with a growth cone, are seen abutting the perimeter of the macrophages, which appear to be acting as a bridging substrate or carpet for the growing axons, in a manner akin to that observed in the lesioned optic nerve of the frog (50). In other words, macrophages in the lesion, in addition to their phagocytic role, also present growth-promoting and physical substrate to assist the axons to overcome the lesion. Significantly, the absence of astrocytes from the lesion means that endogenous glial cells are not acting as bridges for regenerating axons, as noted also by other workers (63-65).

The above results appear to suggest functional parallels between fish optic nerve lesion site and the mammalian PNS, where an injury is characteristically followed by a rapid influx of phagocytic macrophages, as a prelude to successful regeneration (66-68). By contrast, only limited recruitment of macrophages, and by implication debris clearance, is noted in lesioned rat optic nerve (69), a phenomenon that has been attributed to inhibitory factors released by resident glial cells (67). To overcome this imbalance, Schwartz and colleagues have introduced monocytes, previously cultured in the presence of fragments of sciatic nerve, into transected optic nerve of rat, to assess the effect of efficient debris clearance by macrophages on axon regeneration. The study showed that 15 times as many retinal ganglion cell axons regenerated in the treated nerve compared with untreated control nerve, thus confirming the importance of macrophages in axon regeneration (70, 71). In the injured fish optic nerve, in addition to the phagocytic macrophages, the early lesion also contains non-phagocytic granular macrophages, a unique class of cells found in goldfish optic nerve (72, 73). As shown in Fig. 7, these cells normally reside in the sheath/septae; their appearance in the lesion is attributable to the local disruption of the nerve's fascicular pattern and, by implication the astrocytic integrity, and strongly suggests that the phagocytic macrophages too are derived from the sheath/septae (Fig. 14). Interestingly, the status of the early lesion as a tissue with PNS characteristics was placed beyond doubt when Schwann cells took up residence in older lesion (see later).

It is instructive to add that the prompt clearance of debris in injured goldfish CNS is not confined to the optic nerve but also takes place in the optic tract (20) and spinal cord (28). And as is the case in the injured optic

nerve, regenerating axons in the optic tract and spinal cord use phagocytic cells, not astrocytes, as scaffolding to traverse the lesion.

Fish Optic Nerve *versus* Rat Optic Nerve

The apparent ease with which injured axons in fish optic nerve traverse the site of lesion is in stark contrast to the events in injured rat optic nerve, where attempts by the damaged axons to cross the lesion invariably end in failure. As noted earlier, much emphasis has been placed on the role of myelin proteins as one of the principal causes of failure of regeneration of damaged axons in the adult CNS. However, several recent observations favor the contention that inhibition of axon growth by oligodendrocytes/CNS myelin is not the entire answer to the question of why mammalian CNS axons do not regenerate after injury. For example, the myelin inhibitory hypothesis does not explain why axons fail to regenerate through the gray matter, where there is no myelin. Similarly, optic fibers of BW mutant rat, in which both oligodendrocytes and CNS myelin are absent, fail to regenerate in an exclusively astrocytic environment (74). Several authorities have, therefore, reopened the "inhibitory" debate, by asserting that astrocytes rather than oligodendrocytes are the main cause of axon regeneration failure in the CNS (75, 76).

The meticulous studies of axon regeneration in rat optic nerve by Berry and colleagues have highlighted the fact that astrocytes and mesodermal elements (fibroblasts and collagen) become organized into an impenetrable glia limitans of the scar that envelops the proximal and distal stump ends, largely because injured axons appear unable to initiate an early attempt to regrow, generally within 5 days of injury (77). Furthermore, injured optic axons can be made to overcome the glial scar and extend into the environment of myelin debris, if provided with sufficient trophic support. By inserting segments of peripheral nerve containing viable Schwann cells as a source of trophic support into the vitreous and simultaneously crushing the optic nerve, Berry and colleagues have observed that 10% of the injured axons are able to cross the lesion and extend 4 mm into the distal segment (77). It is proposed that peripheral nerve implants secrete trophic factors into the vitreous that are then taken up by the retinal ganglion cells and transported to the axon tip, thus stimulating its rapid growth across the lesion before there is a build up of astroglial scar. Earlier studies, in which peripheral nerve containing viable Schwann cells was grafted to the cut end of rat optic nerve, yielded similar results in terms of retinal ganglion cell survival and axon regrowth beyond the site of anastomoses, that is, into the peripheral nerve (40, 42, 51). These results do not argue against the view that glial scarring may, in some way, curtail axonal outgrowth. They do, however, suggest that the effect of trophic influences derived from viable Schwann cells are capable of nullifying the inhibitory effects on axonal outgrowth exerted by a scar of limited dimension. Put another way, the ability of a cut axon to regrow is dependent on the balance between the intrinsic ability of the axon to regrow and the permissiveness of the environment surrounding it.

In the injured fish optic nerve, the conditions appear to favor retinal ganglion cell survival and vigorous axonal outgrowth in the absence of external manipulations. The clearance of myelin debris is entrusted to phagocytic macrophages whose presence stimulates an early and robust axonal regrowth, which ensures that astrocytes around the stump ends, although markedly hypertrophied and showing an elevated expression of proteoglycans (72), do not become organized into an impenetrable, limiting membrane. On the contrary, both at the edge of the proximal nerve and throughout the degenerating distal nerve, the disrupted fascicular pattern of the optic nerve is gradually restored, as the regenerating axons encounter the awaiting astrocytes, in a recapitulation of events occurring in normal development and growth of the fish optic nerve (cf. Scholes et al. (17)).

Regeneration in Goldfish Optic Nerve Distal to Lesion

By around 10 days after injury, regenerating axons begin to emerge from the lesion proper into the distal nerve to be confronted by an environment dominated by hypertrophied astrocytes, myelin, and axonal debris. The progress of the regenerating axons through this apparently chaotic environment is best followed using EM (55).

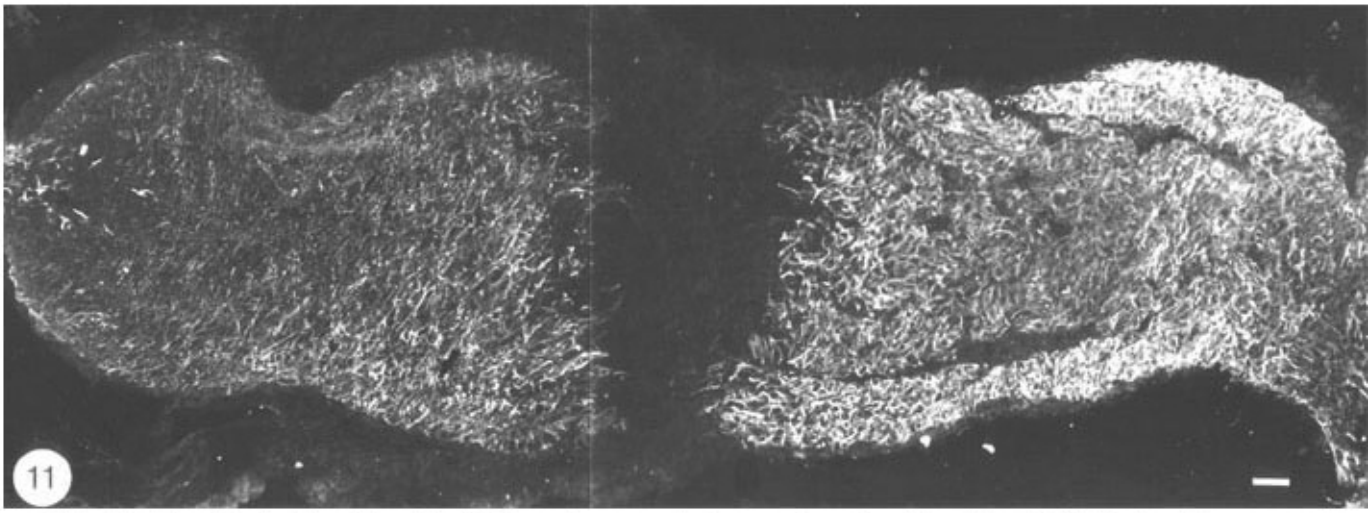

Figure 11. Longitudinal section of goldfish optic nerve 4 days after crushing, stained for GFAP. Astrocytes are nicely revealed along the length of the nerve, except at the site of lesion, where they are destroyed by the crush injury. Bar = 100 μm.

At first, small groups of new axons appear among radial processes of hypertrophied astrocytes where there is also a scatter of myelin debris. Astrocyte processes, connected by desmosomal junctions, form a myriad of irregular loops that enclose the newly arrived axons into loosely organised bundles (Fig. 16).

By 14 days, these have swollen into large bundles of tightly fasciculated axons, surrounded and separated from one another by cordons of lamellar astrocyte processes. Myelin debris, which was haphazardly distributed at earlier times, now is neatly confined to the periphery of these fascicles, alongside and within the astrocytic cordon (Fig. 17a).

Between 14 and 25 days after being crushed, the appearance of the distal edge of the nerve is reminiscent of the proximal edge at an earlier time after crushing: 1) astrocyte radial processes have enwrapped the axon bundles, thus demarcating the new fascicles; and 2) myelin debris is largely confined to the margins of the fascicles alongside the interposing astrocyte processes. More distally, the old fascicular structure is completely lost, and a substantial amount of debris still remains, present mostly within astrocyte processes, with surprisingly little debris seen in microglia, a finding that has been confirmed by other studies (59). The early axons that have reached the chiasm are invariably seen in debris-free areas or enveloped by astrocyte processes.

By around 43 days, little myelin debris remains, and the cytoarchitecture of the regenerated nerve begins to resemble that of the normal nerve, with astrocyte processes dividing the tissue into glial channels/compartments, thus restoring the fascicular pattern of the nerve. The patterning precedes axon remyelination (Fig. 17b)), which is known to be a protracted process, taking several weeks for near completion, and is rarely observed before around 40 days after nerve injury, that is, several weeks after the regenerating axons have crossed the lesion (16, 72, 73). In this study, there was little evidence of remyelination before around 50 days after the crushing injury. By 90 days, however, virtually all of the new axons in the distal nerve were myelinated by oligodendrocytes, much like the normal tissue (Fig. 21b), but in total contrast to remyelination in the lesion (see below).

It is important to emphasize that although there are structural similarities between the peripheral nerve and the optic nerve of the goldfish, in that both nerves consist of a multitude of cylindrical tubules or compartments, the mechanisms of axon regeneration in the two systems are quite different. In the regeneration of the peripheral nerve, growth cones are found exclusively in contact with the inner surface of the basal lamina of the Schwann tube (78). During regeneration of the optic nerve, however, new axons (this study), preceded by their growth cone (79) are only found deep within astrocyte fascicles, among other axons. This suggests that astrocytes, rather than basal lamina, support axonal growth during regeneration, and this pattern forming interaction with the

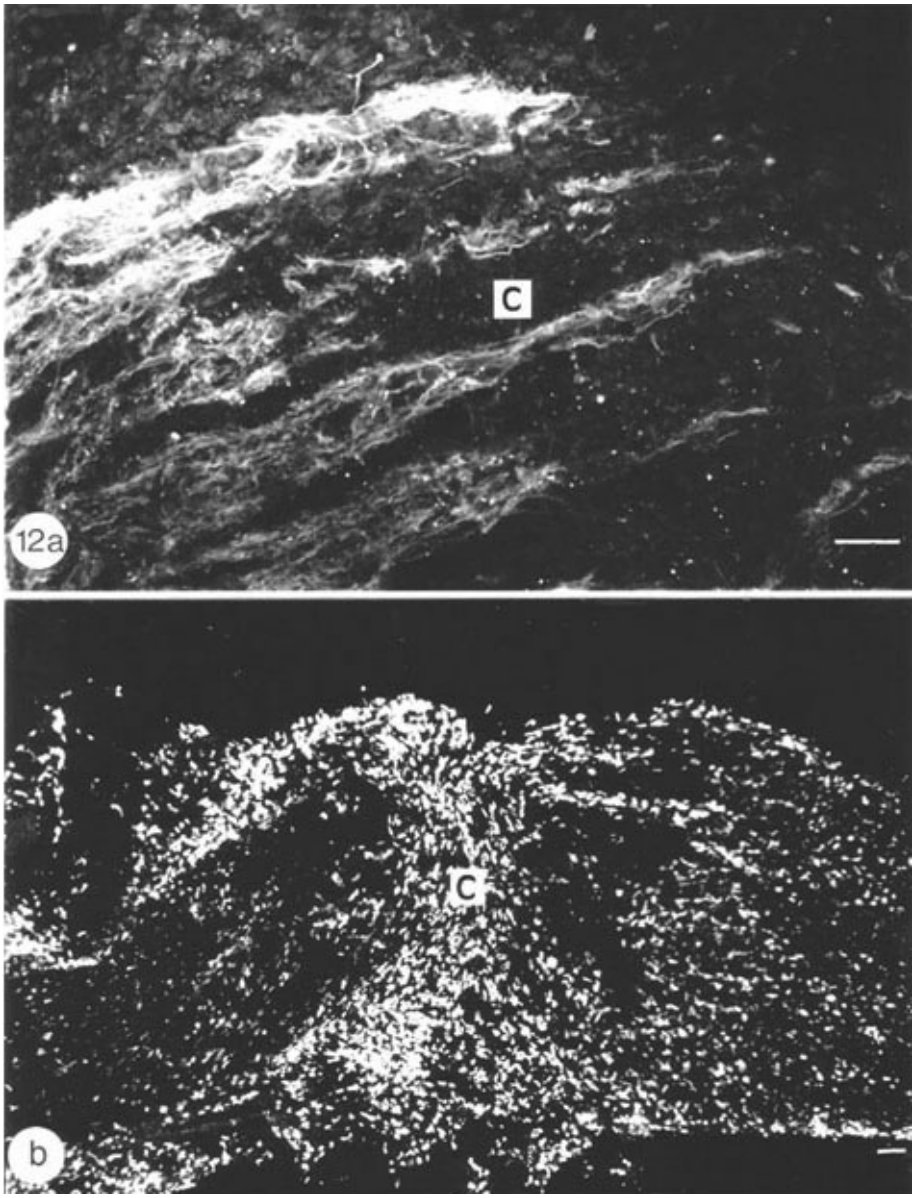

Figure 12. Seven days after the optic nerve crush, regenerating axons (a) extend into the crush site (C), coincidental with the arrival of mitotic cells from the sheath/septae (b). Bar = 40 μm. Compare with Fig. 13.

astrocytes, forming glial channels that exclude the degenerating myelin debris, may greatly facilitate the growth of the many axons that follow (55).

In this study, it is assumed that the pioneering axons emerging into the distal optic nerve will, in all probability, encounter not only astrocytes but also myelin debris. That this mixed environment appears not to disrupt the progress of regenerating axons owes much to the vigorous growth of the growth cone as well as, perhaps, myelin debris characteristics. In the trout, for example, CNS myelin lacks the mammalian protein PLP but contains two proteins, IP1 and IP2, which are immunologically related to PNS myelin protein P0 (80). On this basis, it may be argued that fish myelin proteins have similar properties to myelin proteins found in the PNS, which are known not to inhibit neurite extension *in vitro* (36). However, more recent studies have established that CNS myelin in fish does contain proteins that inhibit axonal extension *in vitro*, much like their mammalian counterparts (60).

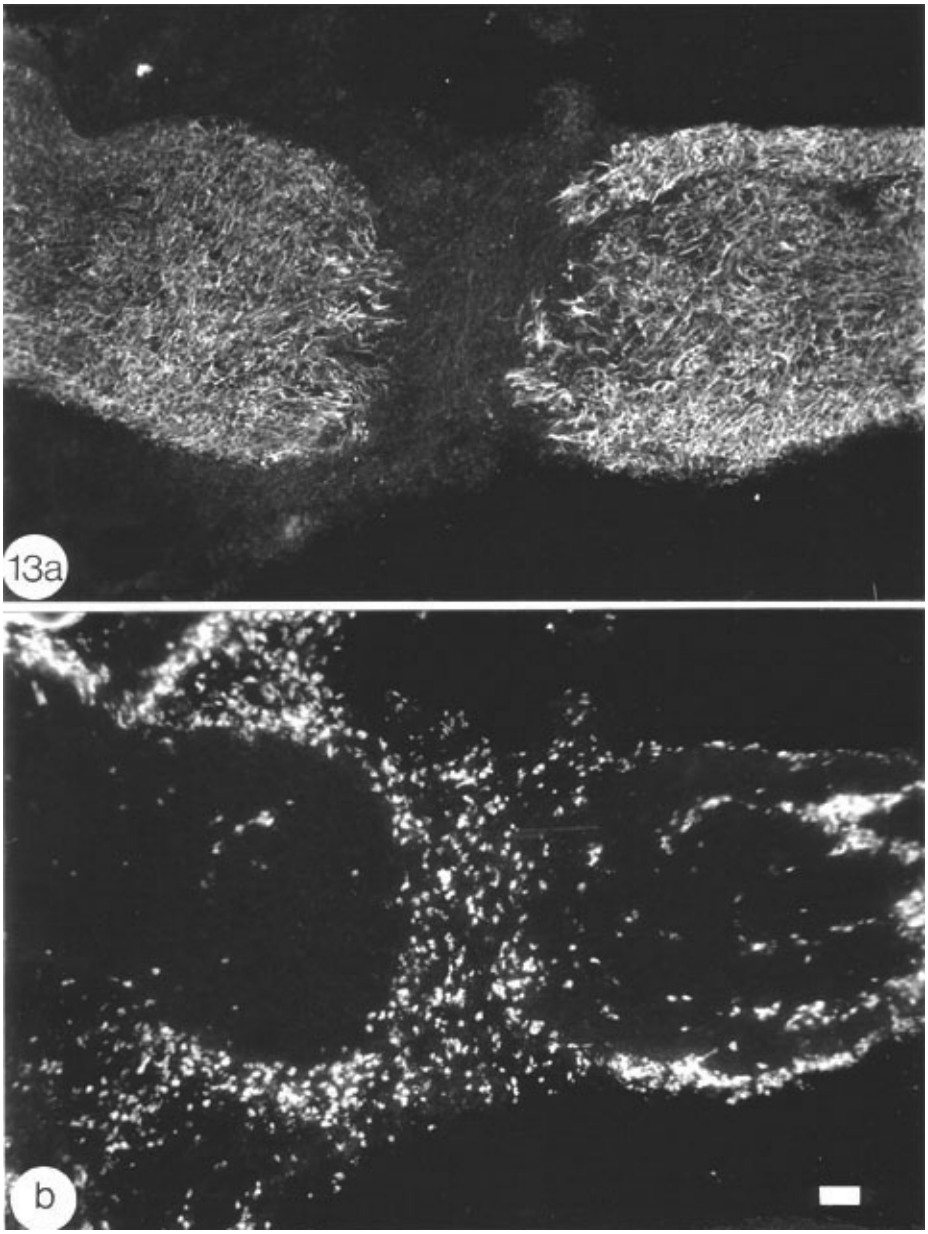

Figure 13. The absence of astrocytes (GFAP–) from the 7-day-old lesion (a) attracts IB4+ monocytes from the sheath (b). Bar = 100 μm.

Myelination of Regenerating Goldfish Optic Nerve Axons in the Lesion by Schwann Cells

Thus far, much emphasis has been placed on the paucity of cells in general, and that of astrocytes in particular, in the lesion. The substantial number of mitotic cells that accumulate in the lesion by day 7, and identified as macrophages, is much attenuated a week later, as the phagocytes quickly clear the debris and then disperse into the sheath/septae (see above). In the following weeks, the rate of division in the lesion is no greater than in the rest of the nerve.

Consistently, however, a second wave composed of large numbers of dividing BrdU+/S100– cells appear in the lesion at around 43 days after nerve injury (16, 56, 81). Over a period of several weeks, the number of dividing cells gradually decreases, to be replaced concomitantly by S100+ cells, whose spindly nuclei and bipolar

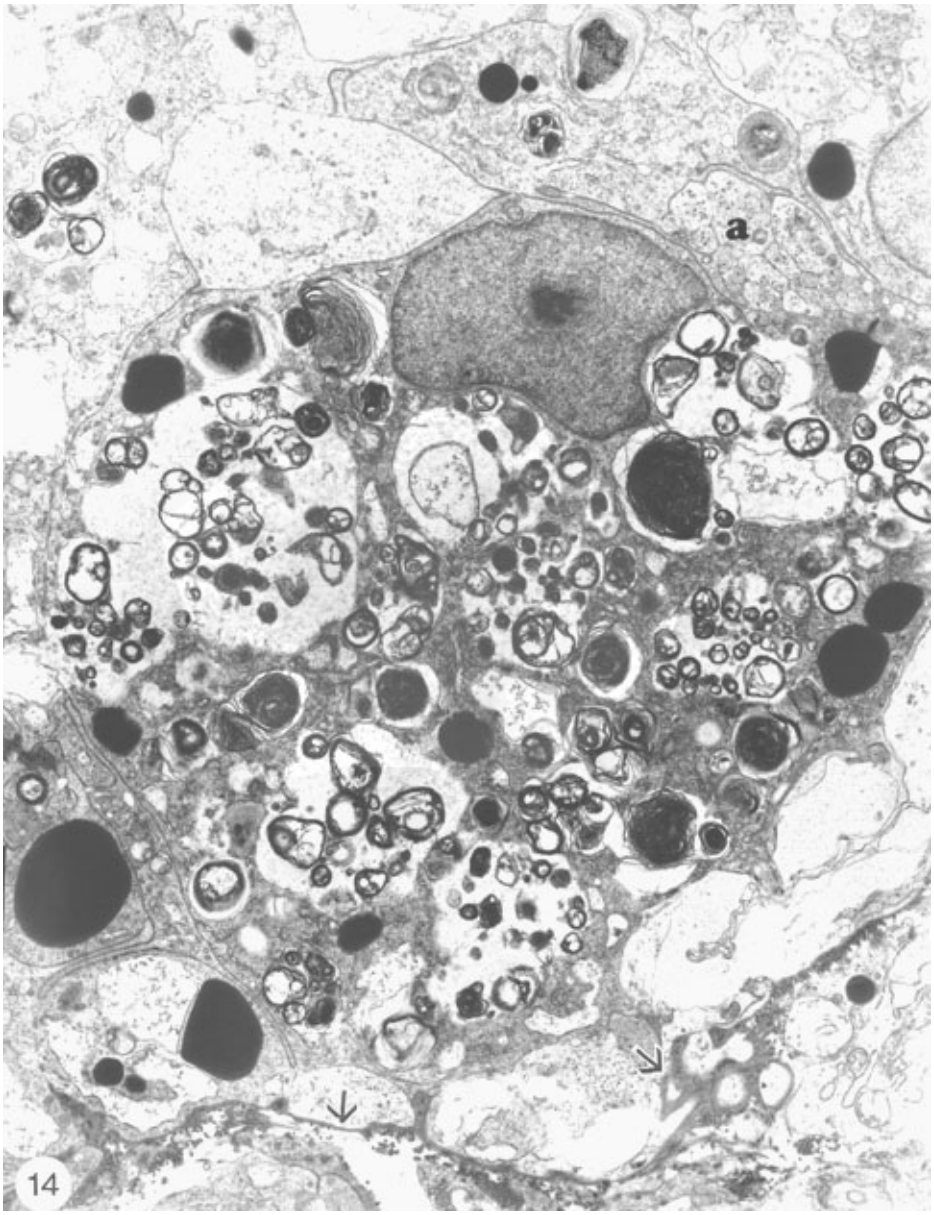

Figure 14. EM of a typical phagocytic macrophage in 7-day-old optic nerve lesion. Whorls of myelin as well as lipid droplets fill the phagocyte's cytoplasm. In the top right corner, a large group of regenerating axons (a) abut the phagocyte's membrane. The phagocyte lies close to a stretch of limiting membrane that is bruised and leaky (→). ×19K.

morphology match precisely that of Schwann cells in the peripheral nerve. By 90 days, BrdU+ cells are virtually absent from the lesion, which, nevertheless, is packed with S100+ cells (Fig. 18).

Antibodies to two fish-derived myelin proteins (central myelin 36K, and peripheral/central myelin 6D2) (82) have proved invaluable in confirming the identity of these previously unreported cells in the optic nerve lesion (16, 81). In sections from 90-day-old optic nerve, 36K antibody fails comprehensively to recognise myelin in the lesion, which is nevertheless flanked by bright central staining in both proximal and distal nerves. 6D2 antibody, on the other hand, recognizes myelin in the lesion and throughout the optic nerve. It is noteworthy that the appearance of S100+ cells coincided with the expression of 6D2 in the lesion, with a striking correspondence between the two labels. That the expression of 6D2 heralds the beginning of axonal remylination is supported by studies that show that the earliest expression of myelin-related antigens in dissociated cell populations of trout CNS coincides with the first appearance of myelinated fibers in defined brain regions (80). Our observations are

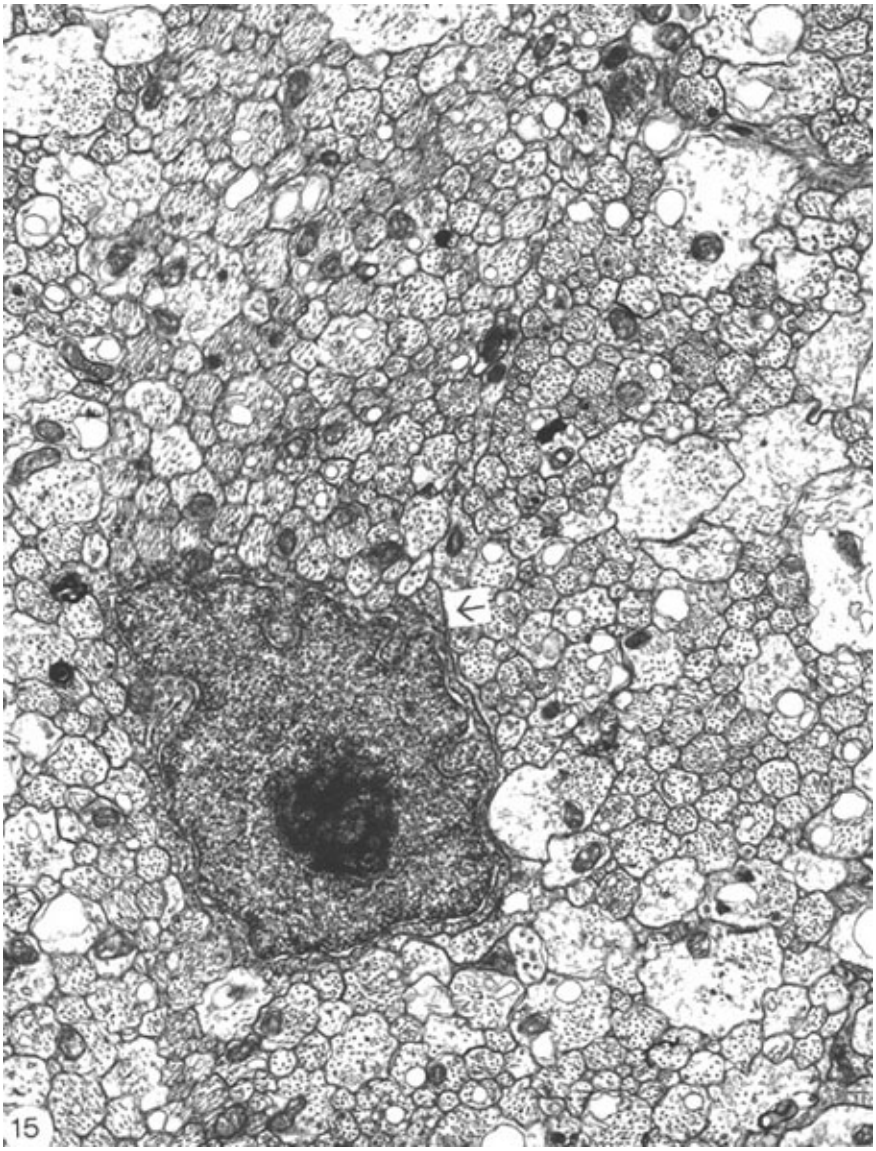

Figure 15. EM of 3-week-old lesion. Regenerating axons make up the bulk of the lesion, save for the presence of the odd cell with a well-structured nucleolus and short cytoplasmic processes (→). ×28K. Compare with Fig. 19.

also in agreement with those from the developing mammalian PNS, in which the expression of S100 marks the transition from precursor to mature Schwann cells and coincides with the commencement of myelination (83).

Further evidence in support of the identity of the cells in the lesion as Schwann cells comes from ultrastructural studies. First, the cells form a 1:1 association with myelinated axons, and each cell:axon unit is enclosed by basal lamina, thus resembling Schwann cells of the PNS. Second, in contrast to the compact arrangement of the tissue in proximal and distal stumps, the lesion contains considerable collagen and extracellular space, characteristic of PNS tissue. Third, the environment in the lesion contains none of the elements, namely astrocytes, that define a CNS environment elsewhere in the nerve (Fig. 21a).

Source of Schwann Cells in Regenerating Goldfish Optic Nerve

Although the appearance of Schwann cells in the lesion has been observed in every injured optic nerve studied by the author and his colleagues, the source of the Schwann cells and their arrival in the lesion have only recently been addressed. In normal CNS tissue, ectopic Schwann cells are rarely seen. They are excluded by astrocyte

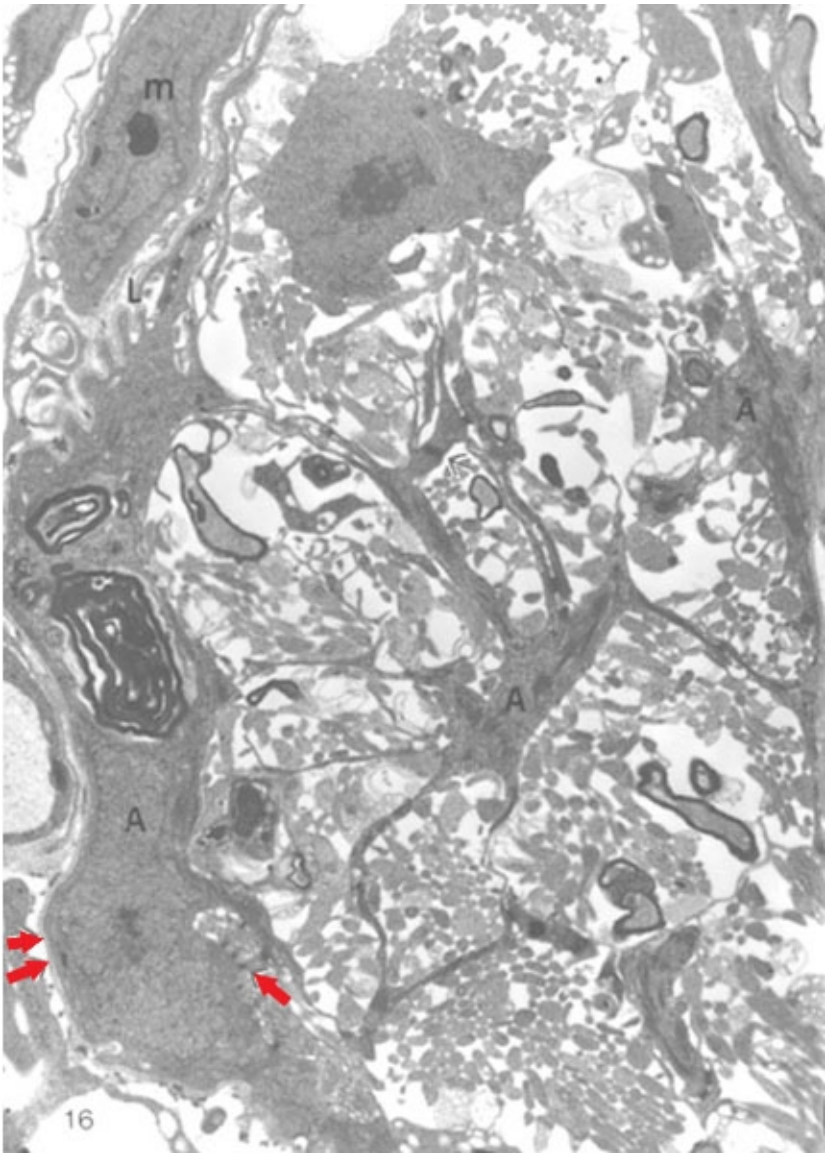

Figure 16. Processes of hypertophied astrocytes (A) at the tip of the distal nerve joined via desmosomes (→) to enclose the regenerating axons emerging from the lesion into discrete bundles. Astrocytes, not microglia (m), contain myelin whorls. Note the intactness (double→) of the limiting membrane (L). ×20K.

processes that are arranged as a glia limitans, forming a boundary between CNS and PNS. It is, therefore, not unreasonable to suggest that in the present study the colonization of the lesion by Schwann cells, much as its earlier colonization by macrophages, is the result of disruption of the astrocytic glia limitans (see Fig. 14). Support for this notion comes from studies of optic nerves that have received two or more adjacent lesions, which show that the larger the area over which astrocytes are destroyed, the greater is the Schwann cell invasion. Such correlation between Schwann cell invasion and the extent of astrocyte destruction has also been described in rat spinal cord following local injection of gliotoxic agents (84, 85).

As stated earlier, a characteristic feature of the goldfish optic nerve is that it is interleaved by connective tissue septae, which are an integral part of the nerve sheath. This arrangement brings a network of mesenchymal cells and capillaries within the outline of the fiber array. This poorly understood mix, elsewhere excluded from the interior of the CNS tissue, could well contain cells of neural crest origin and, in the event of glia limitans disruption, the pattern is well deployed to supply them locally as precursor Schwann cells (see Fig. 15). In this context, it is interesting that ectopic Schwann cells are never observed beyond the nerve-tract boundary, a line

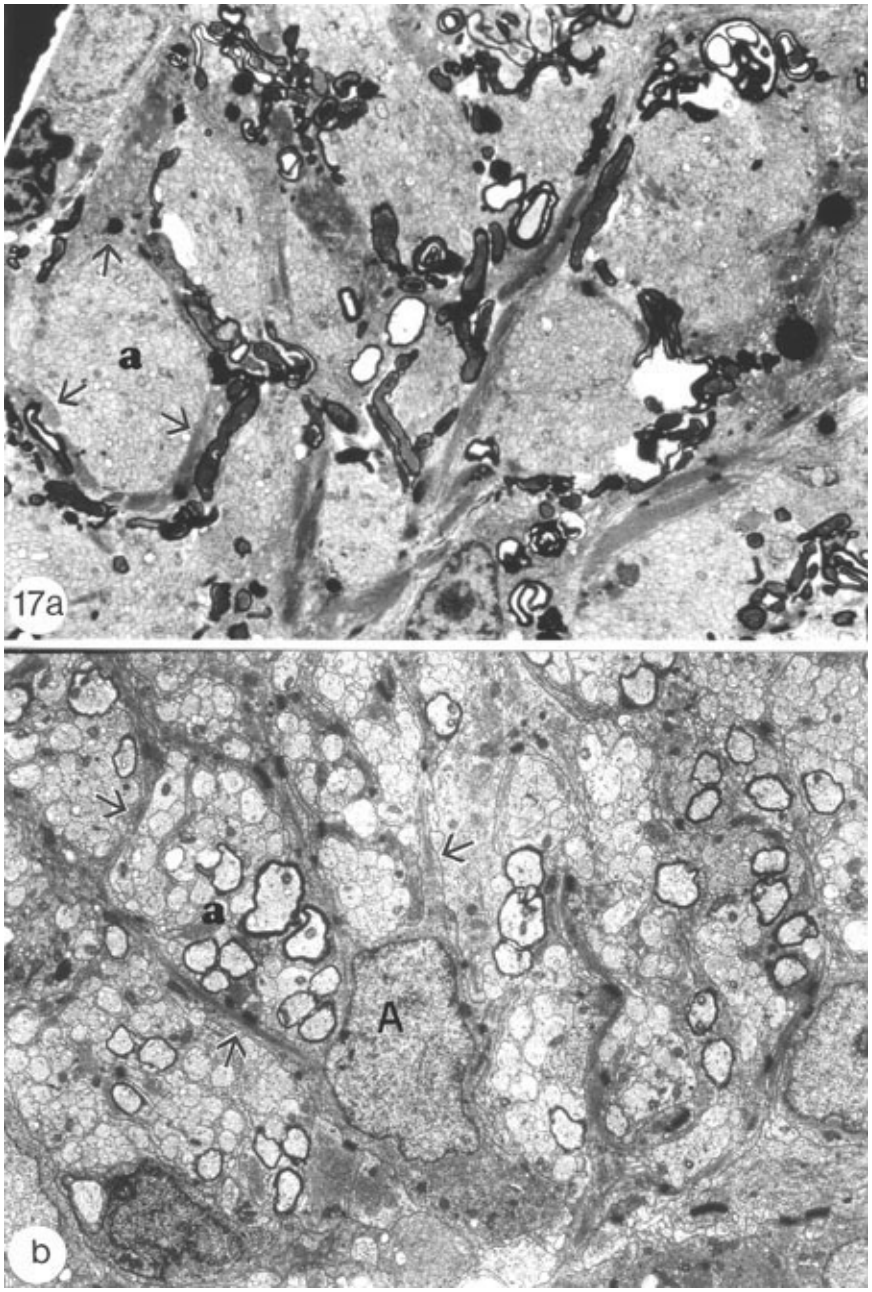

Figure 17. Reconstruction of the CNS envirnment in the distal optic nerve, 14 days (a) and 50 days (b) after the lesion. In (a), bundles of regenerating axons are enclosed by astrocytic cordons (→) that confine myelin debris to the periphery. In (b), the fascicular pattern defined by astrocyte processes (→) is the hallmark of the tissue, and myelination of the regenerated axons is commencing. a, ×5.4K; b, ×13.5K.

that also defines the limit of the reticular astrocytes in the optic nerve (20). We have carried out a detailed ultrastructural study of the lesion site to track down the precursor Schwann cell in the goldfish optic nerve.

Careful studies of the injured optic nerve, ranging from 14 days to 3 months of age, have confirmed that the younger lesions do indeed contain the occasional cell (Fig. 15) having several elongated cytoplasmic sheets that insinuate between the regenerated naked axons, which they enwrap communally (Fig. 19). In this respect, these cells have a striking resemblance to precursor Schwann cells found in the nerve of rat hind leg (see Fig. 1 in Jessen et al. (86). Connective tissue spaces and extracellular matrix are absent from the early lesion, and the tissue here remains compact because of the large number of axons it contains. In older lesions, individual cells

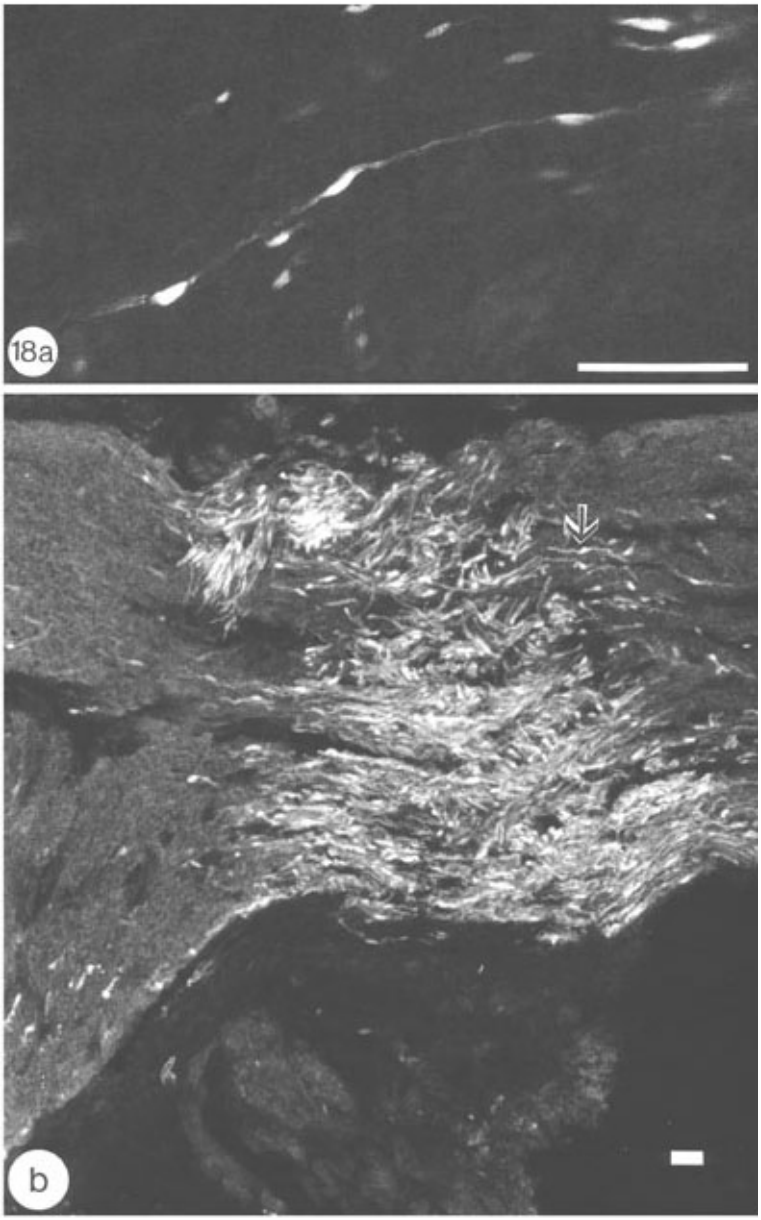

Figure 18. Appearance of Schwann cells at the site of lesion in goldfish optic nerve. Staining for S100 showing that at around 45 days after the injury, several weeks after regenerating axons cross the lesion, cells in a head-to-tail arrangement (a) appear in the lesion. The number of cells increases gradually, so that by 90 days after the injury (b), the lesion is colonized by a solid band of Schwann cells (→). Bar = 40 μm.

are noted in a unitary relationship with an axon, but such encounters are rare prior to around 40 days after lesioning.

Consistently, however, the lesions around 50 days of age begin to take on characteristics that are unmistakably those of peripheral nerve tissue. Axons in a 1:1 association with cells begin to acquire myelin, and these units are invariably surrounded by collagen matrix that form "rivers" through the tissue (Fig. 20).

The delayed differentiation of precursor Schwann cells into myelinating cells corresponds nicely with the late appearance of S100+/6D2+ immunoreactivity in the lesion, which means that both central (discussed earlier) and peripheral myelination commence synchronously. Furthermore, as already described for the distal nerve, myelination in the lesion is also a protracted process. By 90 days, however, myelinating Schwann cells colonize

the lesion (15, 16), building a perfect segment of peripheral nerve tissue intercalated into the regenerated visual pathway (Fig. 21).

Thoughts on Delayed Remyelination in Goldfish Optic Nerve

We interpret the observations relating to myelin formation in the regenerated fish optic nerve as follows. Schwann cells arise from a small number of continually dividing founder cells that colonize the lesion inconspicuously at an early stage, rather than by massive expansion at a late stage in regeneration. To distinguish between the two possibilities, established Schwann cells were challenged with renewed axonal regrowth from a second optic nerve injury, but again they only began to divide immediately before the onset of myelin formation, around 45 days, in synchrony with the peak of Schwann cell division in the new lesion (16). The failure of Schwann cells to respond to axotomy is, therefore, in contrast to the prompt response of injured axons in mammalian PNS, which show division at the first appearance of the regenerating axons (87). The observations in fish optic nerve, therefore, firmly identify a delayed wave of mitogenic signals occurring several weeks after initial axon outgrowth through the lesion.

The ectopic Schwann cells in the fish optic nerve thus conform to a schedule for myelin formation that is characteristic of CNS in general, whereby oligodendrocyte myelination begins late in development at widely different times in different pathways (88). The lengthy period over which myelination is taking place corresponds with the critical period in optic nerve regeneration when the initial disorderly pattern of axon terminals in the tectum is refined into an accurate point-to-point map (89).

Presumably, myelin formation is triggered by target-related changes in individual optic axons that occur at some stage during refinement. During the disorderly process of re-innervating the optic tectum, some axons may be better placed from the outset than others to retract their initial widespread branches into focused retinotopic arbors: these could be the axons that are myelinated first, whereas the less well-placed axons take longer (90). In other words, myelination proceeds on a fiber-to-fiber basis, and each fiber is continually myelinated throughout its length (16). The goldfish visual pathway is well suited to test this hypothesis (Fig. 22).

Conclusions

In this commentary, we have demonstrated the robustness of the fish visual system to manipulations. Severed retinal ganglion cells axons can initiate more than one round of regrowth through a glial environment that shares many of the physical and molecular properties of its counterpart in mammals, but with totally different outcome.

Neither astrocytes nor myelin, both of which are thought to contribute to axon regeneration failure in mammals, impede axonal regeneration in fish optic nerve. On the contrary, astrocytes show much plasticity in response to injury, not by forming a swathe of contiguous impenetrable membrane, but by enwrapping the new axons intimately into bundles and in the process consigning myelin debris to the periphery, where it is phagocytosed, not by microglia, but by astrocytes.

However, none of this would be possible were it not for an early and robust response by the damaged axons, aided by invading macrophages, which clear the site of injury of debris and act as scaffolding for the regrowing axons. The versatility of fish optic fibers to accommodate more than one type of environment is further demonstrated in older lesions, which Schwann cells colonize to form a perfect PNS tissue intercalated within the CNS tissue. Thus, severed fish CNS axons make use of glial cells derived from CNS as well as PNS environments for their repair.

The findings may have implications for axonal regeneration in mammals. It is now recognized that by boosting the rate of phagocytosis in lesioned rat optic nerve, through implantation of reactive macrophages, there is a

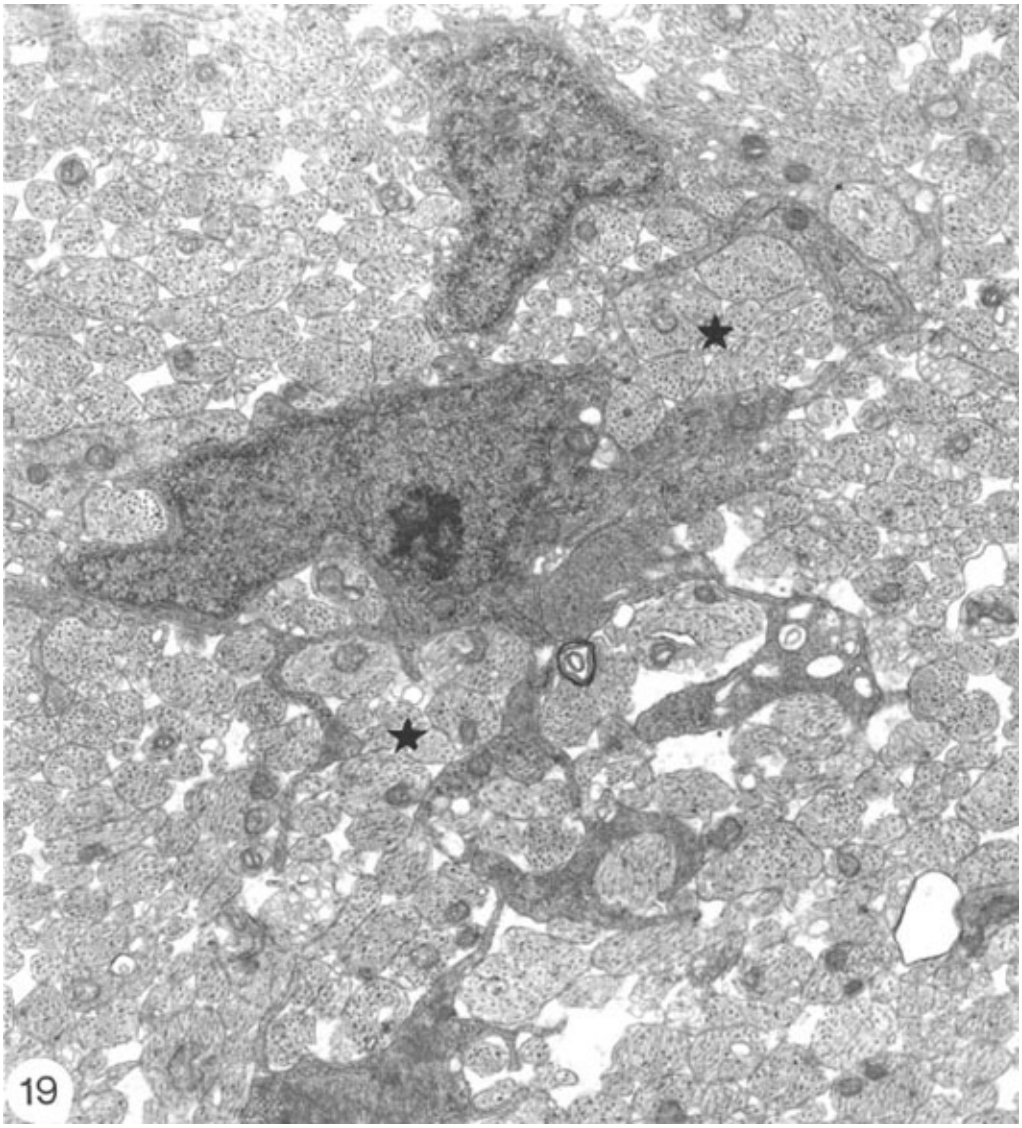

Figure 19. EM of the site of lesion 28 days after optic nerve injury. Precursor Schwann cells extend cytoplasmic processes that engulf the regenerating naked axons unitarily as well as communally. ×19.8K.

substantial increase in the number of regenerating axons beyond the lesion. A similar response in noted through the provision of factors derived from Schwann cells that are supplied either to the retinal ganglion cells or applied as implants to the cut end of the axons. Thus, insights from the fish and other regenerating species can provide strategies to overcome the many obstacles of regrowth in mammals and ultimately lead to successful optic nerve repair in humans.

A major unresolved problem in the regrowth of retinal ganglion cell axons is that the initial axotomy results in the death of 90% of retinal ganglion cells. Clearly, substantially more cells must be rescued if a meaningful retinotopic map is to be formed (91). Evolution has already conducted an experiment along these lines, with results of great interest. The optic nerve of reptilians regenerates efficiently, but for some reason refinement of the tectal map fails to occur: the axon terminals persist indefinitely in a diffused array over the tectal surface and the animal never recovers sight (92).

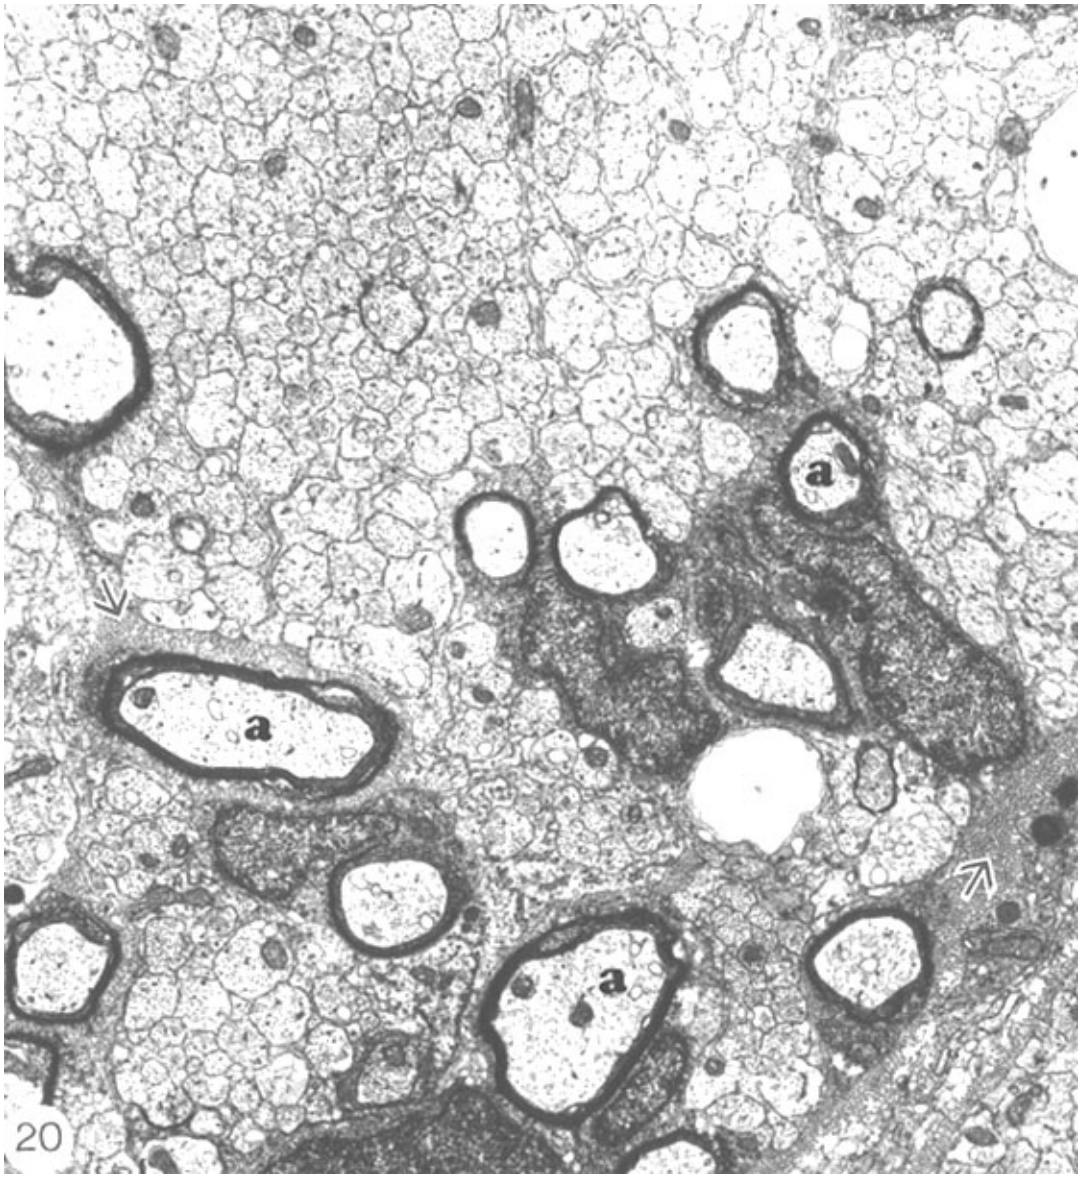

Figure 20. The site of lesion 50 days after optic nerve injury. Commencement of myelination by Schwann cells, some in a 1:1 association with their axon (a). Note the abundance of collagen (→) throughout. ×21.5K.

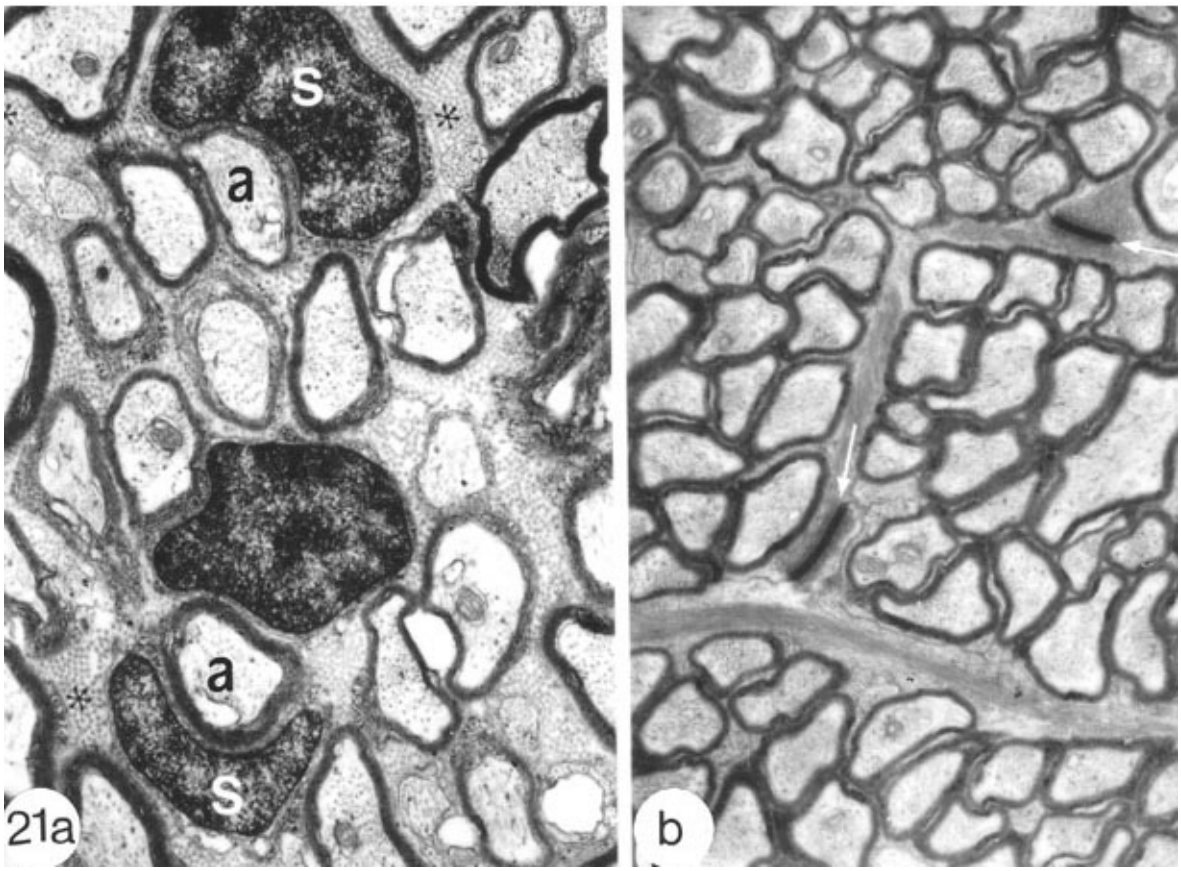

Figure 21. EM of the site of lesion (a) and distal nerve (b) 90 days after goldfish optic nerve crush. In (a), axons are myelinated by Schwann cells (S), and the tissue contains much collagen matrix (*). In (b), myelination is of central type, and astrocytes (→) are prevalent throughout the tissue. ×26K.

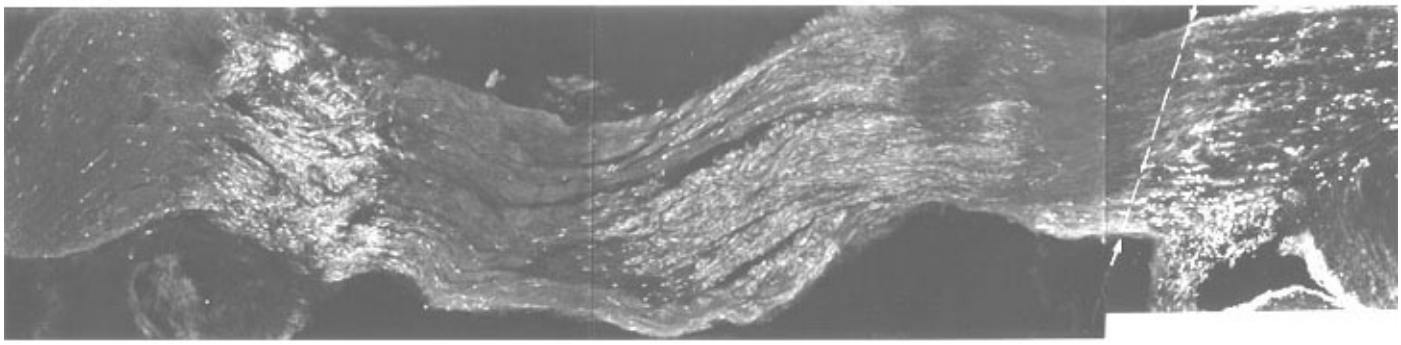

Figure 22. Montage of goldfish optic nerve from just behind the eye (extreme left) to optic tract recess (right), to illustrate the manipulability of the tissue. There are three distinct areas of cells stained for S100. The central area contains Schwann cells that are the result of a lesion 180 days old. To the left is a younger lesion, 90 days old, that is also packed with Schwann cells. On either side of the Schwann cells areas are regions of CNS. Remyelination commences synchronously throughout the nerve. Beyond the dashed line (→) are cell bodies of astrocytes at the optic tract recess.

About the Author

the age of 17, he gained a scholarship to study in England. He graduated with distinction from The Royal Institute of Chemistry in 1968 and went on to complete his PhD in Chemistry under the direction of Professor R.N. Haszeldine, FRS at the University of Manchester in 1971. After an enjoyable period of research in the field of organic fluorine chemistry, he was propelled into neuroscience when he joined Professor John Cronly-Dillon, whose group was studying the process of repair in the visual system of lower vertebrates. Dr. Nona and his colleagues have created a battery of goldfish-specific antibodies, which they have used with great effect to identify several important stages of axon regeneration in the goldfish visual system. He has enjoyed a fruitful collaboration with Dr. John Scholes of UCL, aimed at understanding the behavior of ectopic Schwann cells in CNS environment. Recently, Dr. Nona moved to Sydney and currently holds the position of Visiting Fellow in the School of Optometry and Vision Science at University of New South Wales, Australia.

Regeneration in the Visual System of Adult Mammals

Yves Sauve and Frederic Gaillard

Created: May 1, 2005; Updated: June 21, 2007.

Introduction

> "...once development was ended, the founts of growth and regeneration of the axons and dendrites dried up irrevocably. In adult centres the nerve paths are something fixed, ended, immutable. Everything may die, nothing may be regenerated. It is for the science of the future to change, if possible, this harsh decree. Inspired with high ideals, it must work to impede or moderate gradual decay of neurons, to overcome the almost invincible rigidity of their connections, and to re-establish normal nerve paths, when disease has severed centres that were intimately associated." (Santiago Ramon y Cajal, 1913-14).

Over 90 years after Ramon y Cajal's farsighted work (1) (Fig. 1), we are still unable to solve the great mystery of regeneration in the adult mammalian central nervous system (CNS). Retinal degeneration leading to loss of photoreceptors and retinal ganglion cells (RGCs) is still largely untreatable, although recent experimental work is beginning to provide possible solutions to these devastating conditions. Other untreatable pathologies leading to loss of sight involve lesions to the CNS visual centers or projection pathways. There are two fundamental experimental approaches presently used to tackle both these problems. One involves reconstructing lost circuitry by replacement with (usually fetal) neuronal tissue, and the other is attempting to slow the rate of the degeneration.

Reconstruction of Primary Visual Pathways

Without any experimental intervention, nerve lesions in the adult CNS of mammals produce only a limited and brief period of abortive sprouting and then to the death of axotomized neurons. In sharp contrast, the peripheral nervous system (PNS) and the immature CNS of mammals, as well as the mature CNS of cold-blooded vertebrates, all display varying levels of successful spontaneous regeneration after injury. The development of experimental repair strategies has relied on lessons learned from these systems. Combined with advances in anatomical tracing and immunohistochemical methods, these strategies have revealed the surprising capacity for regeneration and synapse formation in the adult mammalian CNS. For instance, Dr. Albert Aguayo and colleagues have used an experimental approach (2-4) based on the concept that regeneration in the PNS is dependent on the permissive environment provided by Schwann cells present in the nerve tube. They suggested that the absence of this permissive environment in the mature CNS was the reason for failure of regeneration. Thus, they postulate that damaged neurons from the mature CNS might be able to regenerate axons if placed in close proximity to Schwann cells. In fact, this hypothesis was suggested by Ramon y Cajal (1) over a century ago and was later tested by Tello in 1907 (5) (Fig. 2) in a series of experiments on rabbits. There was a suggestion that retinal axons could regenerate after axotomy if the cut optic nerve end was anastomosed to a sciatic nerve graft (5). The lack of anatomical tracers at that time did not allow us to see whether such regenerating axons were indeed of CNS origin, namely from RGCs. The indisputable proof that some CNS neurons do have this regenerative potential had to wait until specific axonal tracing techniques became available in the late 1970s (6, 7). Further work applied to primary visual pathways showed that if directed into the brain (Fig. 3), regenerating RGC axons were able to re-establish connections in visual centers of the brainstem (4). These connections appeared capable of transmitting visual information (8, 9).

The concept that neural regeneration depends on a permissive environment does not alone explain why most mature mammalian CNS neurons do not regenerate an axon. For instance, in the absence of axonal myelin-associated growth inhibitors such as Nogo, axonal sprouting itself is not improved (10). The role of axonal growth inhibitors in axonal regeneration remains a controversial issue (11). When developing experimental

Figure 1. Santiago Ramon y Cajal at work. From the Cajal Institute (http://www.cajal.csic.es/).

strategies, other factors have to be considered, such as axotomy-induced cell death and secondary degeneration (12), scar formation (13), and factors intrinsic to neurons themselves. We know that most CNS neurons loose their capacity for axonal regeneration at a specific point in early development, even before myelination (14-16).

The abundant and diverse experiments directed at reconstructing visual circuitry (several will be discussed below) have all uncovered a range of difficulties, such as: 1) establishing a permissive interface between sprouting and/or regenerating axons, or between graft and host; 2) providing the optimal conditions for appropriately directed axon outgrowth; 3) achieving sufficient amount of axon outgrowth for proper function; and 4) limiting or controlling the local neural responses to initial injury, such as cell death, which may in itself mitigate against effective recovery. A central point to all such work is that visual function should be used as the yardstick for success (see Generation of Action Potentials in Target Neurons).

Requirements for Recovery of Function following Lesions of CNS Pathways

The recovery of lost function following axonal interruption in any neuronal system depends on the fulfillment of the following prerequisites:

- survival of axotomized neurons and prevention of secondary degeneration
- axonal extension of the neurons surviving axotomy
- guidance of regenerating axons toward their appropriate target(s)
- target innervation and synapse formation onto recipient neurons
- supra-threshold activation in target neurons caused by regenerated afferents
- restoration of ordered functional connections
- preservation of local and downstream circuitry

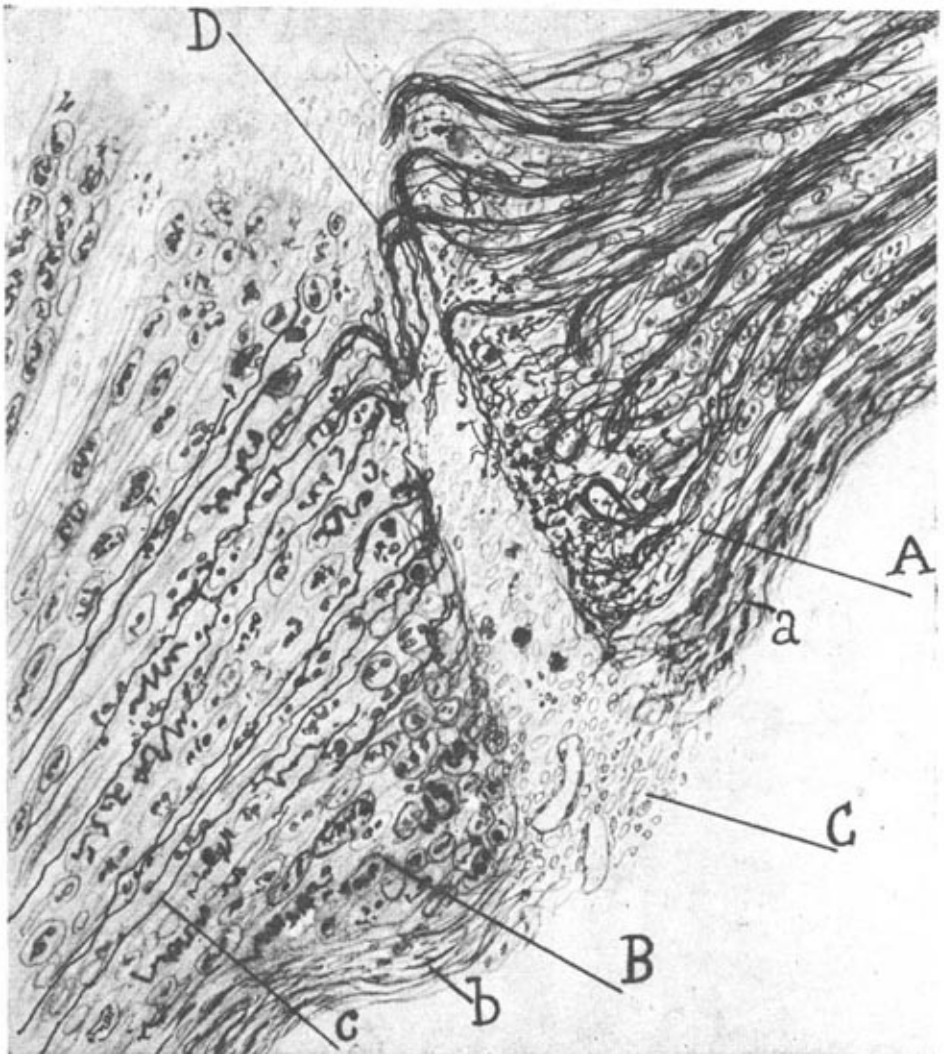

Figure 2. Sciatic nerve graft (B) anastomosed on the optic nerve stump (A) in an adult rabbit. Axons can be seen to cross the anastomosis site (D). A scar has formed at the anastomosis site (C). Letters in lowercase indicate a vein in the optic nerve (a), "neurilema" in the sciatic nerve graft (b), fibers that might correspond to RGC axons regenerated in the sciatic nerve graft (c). Taken from Tello (5).

The retinocollicular pathway is particularly suitable for addressing the above-mentioned points for at least three reasons: 1) RGC axons project to the superior colliculus (SC) through the optic nerve, which can be easily lesioned, replaced, and anatomically traced; 2) because RGCs are excited by light, they can be selectively stimulated in a physiological manner without the use of less selective electrical pulses, which would concomitantly excite other pathways; 3) intact RGC axons arborize preferentially in the superficial layers of the SC, onto which they form a point-to-point representation of the retina (17-19) and which allows comparison of the regenerated pathway with those intact, using either morphological or physiological approaches.

We will review the extent to which these requirements can be achieved by using the example of the interrupted retinocollicular pathway and attempts for reconstruction using PN grafts replacing the optic nerve. In brief, the potential for regeneration of optic axons after being damaged was first indicated by studying hamsters in which the optic nerve was cut and a peripheral nerve graft placed in association with the retinal optic fiber layer (3) (Fig. 3). Optic axons grew into this nerve graft, and studies in cat, in this instance, showed that the major classes characterized, both anatomically and physiologically, contribute to this regenerative growth (20). Subsequent experiments (21) refined the approach and were able to show that up to 10% or so of the normal optic projection was able to regenerate into the nerve graft. If the other end of the nerve graft was placed in an appropriate brain

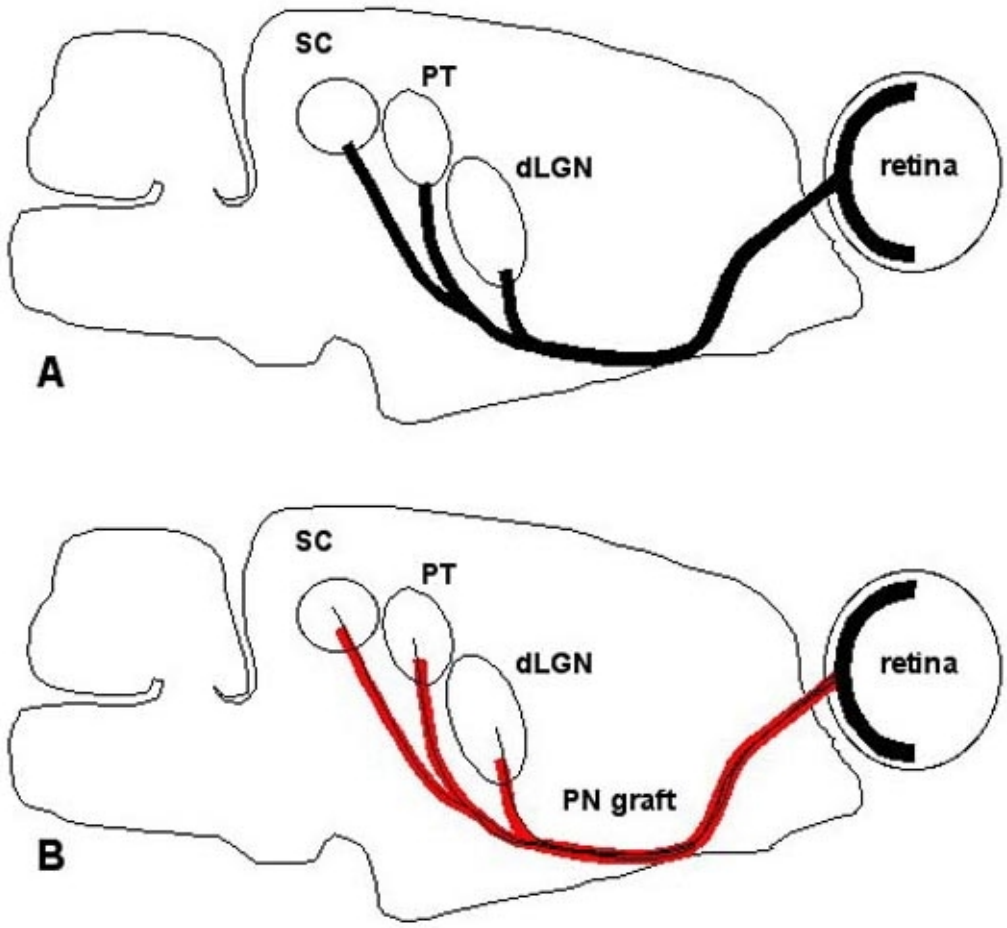

Figure 3. Schematic of peripheral nerve graft bridging the retinofugal pathways. A, normal optic pathway projecting to superior colliculus (SC), pretectum (PT), and dorsal lateral geniculate nucleus (dLGN). B, regeneration of optic axons through a peripheral nerve graft (red) to reach the various visual centers.

region, a proportion of these axons could reach regions normally innervated by them (4, 22). If the central stump was placed in close proximity to a visual center, the axons formed terminal ramifications and synapses within that region (23). If placed at a distance from a visual center, axons were able to grow as much as 6 mm through the brainstem to specific targets of optic input, ignoring in the process other brain regions, including ones that had lost their primary input during the surgical procedure (22). Although an anatomical study of topological representation of the regenerated axons has not been done, physiological experiments (24) have indicated that although the precise map encountered in the normal retinotectal projection was not seen, there was indication of a tendency for the naso-temporal representation of the visual field to be appropriately arrayed along the rostrocaudal SC axis. Whether this would be sufficient for an animal to be able to perform a behavior requiring topographically encoded information, such as head tracking, is not clear. The further possibility that some sort of training regimen might improve the tightness of the map has not been explored either, but this preparation does lend itself to such exploration.

Promoting the Survival of Axotomized RGCs

RGCs Die after Optic Nerve Transection

After a complete intraorbital lesion of the adult mammalian optic nerve, the majority of RGCs are lost within 2 weeks (21, 25-27). Axotomized RGCs start dying after 1 week post-lesion, via programmed cell death. This

process, known as apoptosis, is also responsible for the naturally occurring cell death of RGCs during development. Cells undergoing apoptosis, such as axotomized RGCs, are characterized by the condensation of their nucleus, DNA fragmentation, and the formation of apoptotic bodies (25, 28). The pathways responsible for the apoptotic death of axotomized RGCs involve the activation of caspases types 3, 8, 9, and CPP32-like (29-33), and the p38 mitogen-activated protein kinase p38MAPK (34). The inhibition of either or all of these caspases (30, 32, 35, 36) or of p38MAPK (34) enhances the survival of axotomized RGCs. Furthermore, optic nerve transection leads to the elevation of proapoptotic protein Bax and the decrease of the antiapoptotic proteins Bcl-2 and Bcl-X (37). The overexpression of Bcl-2 in transgenic mice has been shown to protect RGCs for axotomy-induced death (38, 39). Finally, transfection of RGCs with the X-linked inhibitor of apoptosis or with the caspase inhibitor p35 can both protect RGCs from axotomy-induced cell death (40). The conclusion from these findings is that axotomy-induced death of RGCs involves the activation of not only one but several apoptotic pathways. Therefore, strategies aimed at preventing the death of axotomized RGCs would have to target multiple pathways.

Strategies to Prevent the Death of Axotomized RGCs

Most strategies developed to prevent RGC death involve the supply of various trophic factors either exogenously, through cell-based therapy, or via gene transfection (for reviews, see Yip and So (41), Cui et al (42), Weishaupt and Bahr (43), and Koeberle and Bahr (44)). The rationale for supplying neurotrophins to axotomized RGCs is that their death might be related to the loss of retrogradely supplied trophic factors, such as brain-derived neurotrophic factor (BDNF), from their targets in the SC (45-47). Axotomized RGCs can be rescued by experimentally supplying the retina with BDNF, either via intravitreal injections (26, 48-50) or via gene transfection of retinal cells (51). Furthermore, transfection of retinal cells with the high-affinity BDNF receptor TrkB also enhances the survival of axotomized RGCs (52). Axotomized RGCs have also been rescued by the experimental addition of several other neurotrophic factors (some of which having additive effects with each other): neurotrophin NT-4/5 (26, 53); NGF (54); GDNF (55, 56); Neurturin (57); and CNTF (50, 58-60). Several growth factors mediate their action by binding to their specific receptors and activating the mitogen-activated protein kinase (MAPK) and phosphatidylinositide-3-kinase (PI3K) transduction cascade pathways. For details on secondary messengers and factors interfering with these cascades, see reviews by Kaplan and Miller (61), Patapoutian and Reichardt (62), and Koeberle and Bahr (44). In brief, neurotrophic factors may prevent axotomy-induced RGC death by interfering with caspase pathways and by promoting the expression of pro-survival genes.

The neurotrophic factors tested to date for their survival effect on axotomized RGCs all have only short-term effects, suggesting that trophic withdrawal is not the only trigger for the apoptosis of axotomized RGCs. Blockade of axonal transport (63) has minimal effects on the death of RGCs in neonatal rats. Other factors have been identified, among them, the up-regulation of inducible nitric oxide synthase (iNOS) by Muller cells after RGC axotomy (64). Inhibition of NOS has been shown to promote the survival of axotomized RGCs (64), and when done in combination with BDNF, it potentiates the effect of this neurotrophin (48). Modulation of microglial cells and macrophage activity has also been shown to have an effect on the survival of axotomized RGCs (65-67).

Finally, the prevention of axotomy-induced RGC death has been explored using a vaccination approach known as "protective autoimmunity" (for a review, see Schwartz (68)). Dr. Michal Schwartz and colleagues recently demonstrated that T cells specific to self-proteins residing in the site of the CNS insult can be neuroprotective. With the aim of boosting autoimmunity for neuroprotection without risking the induction of an autoimmune disease, Dr. Schwartz's group has developed the use of Cop-1 (an FDA-approved drug for the treatment of multiple sclerosis) as an active vaccination for neuroprotection. This approach is currently under investigation as a potential preventive treatment for glaucoma.

Promoting the Growth of Axotomized RGC Axons

Anastomosis of a PN graft onto the optic nerve stump has been shown to have a survival effect on RGCs (21, 69) as well as acting as an environment permissive to RGC axonal regeneration (3, 4). A maximum of 10% of the total RGC population in rodents (10,000 of 100,000 in rats and hamsters) (Fig. 4a, Fig. 4b, Fig. 4c) can regenerate an axon as far as the distal end of an autologous PN graft, covering a distance of up to 2.5 cm. This allows them to reach areas of the primary visual targets, such as the contralateral superior colliculus. The RGCs that have regenerated an axon along the PN graft appear to survive longer than the RGCs that have failed to do so (21). Whether some RGCs have intrinsic survival or axonal regenerative capacities or whether some RGCs simply randomly succeed to regenerate an axon by chance (for instance, proximity to the PN graft stump before retrograde degeneration beyond the optic disc) remains to be clarified.

The promotion of RGC axonal regeneration seems to involve different mechanisms than the ones promoting their axonal extension: most trophic factors shown to promote RGC survival fail to promote their axonal regeneration. The discovery of new candidate molecules promoting axonal extension comes in part from the observation that lens scratching induces the production of low molecular weight molecules that can promote both RGC survival and axonal regeneration within the intracranially lesioned optic nerve (70). Furthermore, macrophage stimulation, which is associated with the release of similarly acting molecules (71) can also promote RGC axonal extension within the lesioned optic nerve. The neutralization of myelin-associated growth inhibitors can promote RGC axonal regeneration within lesioned optic nerves, but only if RGCs are in an "active growth state", such as stimulated by the small molecules mentioned above (72).

The ability of RGCs to regenerate an axon does not only depend on their environment but also on their intrinsic state. As mentioned in the introduction, most CNS neurons such as RGCs appear to loose their capacity for axonal regeneration during maturation (15, 16). Some recent experimental manipulations have showed that it might be possible to reverse, at least to some extent, this state. Dr Lisa McKerracher and colleagues have shown that inactivation of the small GTPase Rho can promote RGC axonal regeneration after micro-lesions of the optic nerve in adult rats (for a review, see Ellezam et al. (73). Another approach, investigated by Dr. Mary Filbin and colleagues, involves elevating the intracellular level of cyclic AMP in neurons (74) (for a review, see Spencer and Filbin (75)).

Guidance of Regenerating RGC Axons Toward Their Appropriate Target

On the basis of what we know about developmental events, the challenges for regenerating RGC axons to successfully reach their appropriate targets are severe. First, as during development (for a review, see Oster et al. (76)), regenerating axons have to navigate within the retina, find their way to the optic disc, exit it, and finally enter into the optic nerve. After PN grafting (anastomosed on the intraorbitally cut optic nerve stump) combined with intravitreal BDNF (to increase the survival of axotomized RGCs), a minority of RGC axons do successfully regenerate an axon into a peripheral nerve graft. However, many regenerating RGC axons never actually exit the optic disc (77). Several axons from surviving RGCs appear to turn sharply just before the optic disc, growing in the opposite direction, forming numerous collateral branches and loops, with erratic growing patterns (Fig. 5).

A second challenge facing the regenerating RGC axon consists of navigating across the optic chiasma by crossing or not crossing the midline, again depending on the RGC type and/or location in the retina (for a review, see Williams et al. (78)). After which, regenerating RGC axons, again depending on their types, have to extend all the way into their appropriate target(s); some individual RGCs even have to send collaterals to multiple targets, such as both the SC and the dorsolateral geniculate nucleus (dLGN), and even more as shown in Fig. 6.

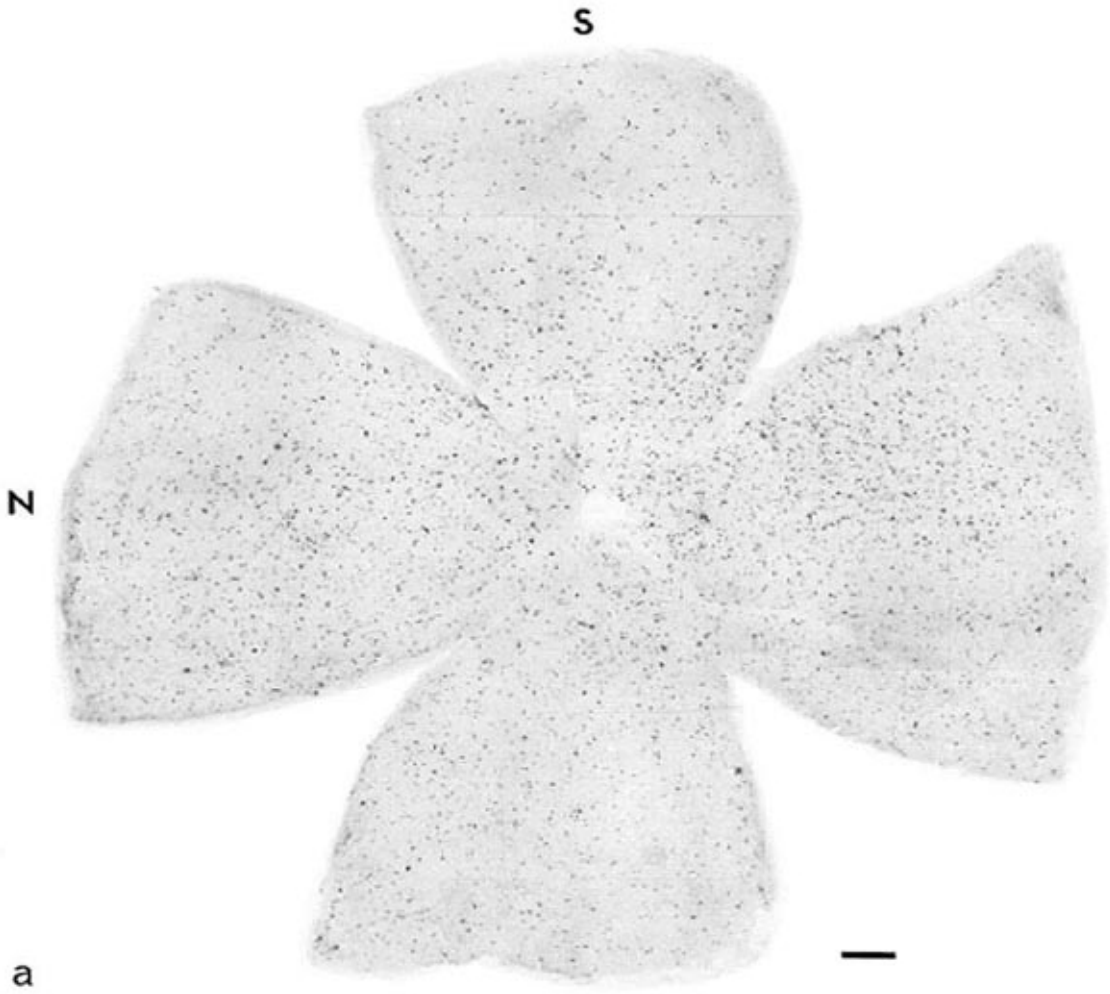

Figure 4a. Demonstration of hamster RGC axonal regeneration in PN grafts. Photomicrographic montage of a flattened retinal whole-mount from an animal with a PN graft attached to the ON. The montages were prepared from 24 overlapping photographs printed at a magnification of ×45. S, superior; N, nasal. Bars, 500 μm. The retina was reacted for peroxidase histochemistry 2 days after application of HRP to the distal end of the graft; this retina contains 12,385 ganglion cells that are retrogradely labeled with the tracer.

By using PN grafts, it has been possible to guide regenerating RGC axons into their appropriate targets such as the SC (4, 8, 9, 22, 24, 79), the dLGN (80), the pretectal nuclei (Fig. 7) (23), or deliberately into inappropriate targets such as the inferior colliculus or cerebellum (81).

However, in some animals following insertion of the distal end of the PN graft into a chosen target, only a minority or even none of the regenerating RGC axons can enter a target (23). In such cases, several RGC axons (anterogradely labeled with a tracer from the eye) are confined to a neuroma-like formation at the interface between the graft and the CNS target (Fig. 8).

The cause of the formation of the neuroma-like endings is unclear. Three main factors have to be considered: 1) glial reactions that might be associated with the lack of axonal penetration into the CNS target; 2) the presence of inhibitory molecules, which may also be responsible for the curtailed growth observed in CNS targets, and that are known to be expressed in the damaged CNS (82) and at the PNS-CNS interface (83-88); and 3) the perturbation, due to graft insertion procedure, of the tri-dimensional structure of the extracellular matrix that might act as "guiding railways" coated with molecules that have growth-inhibitory or -promoting properties such as laminin, vimentin, and chondroitin sulfate proteoglycans (CSPGs).

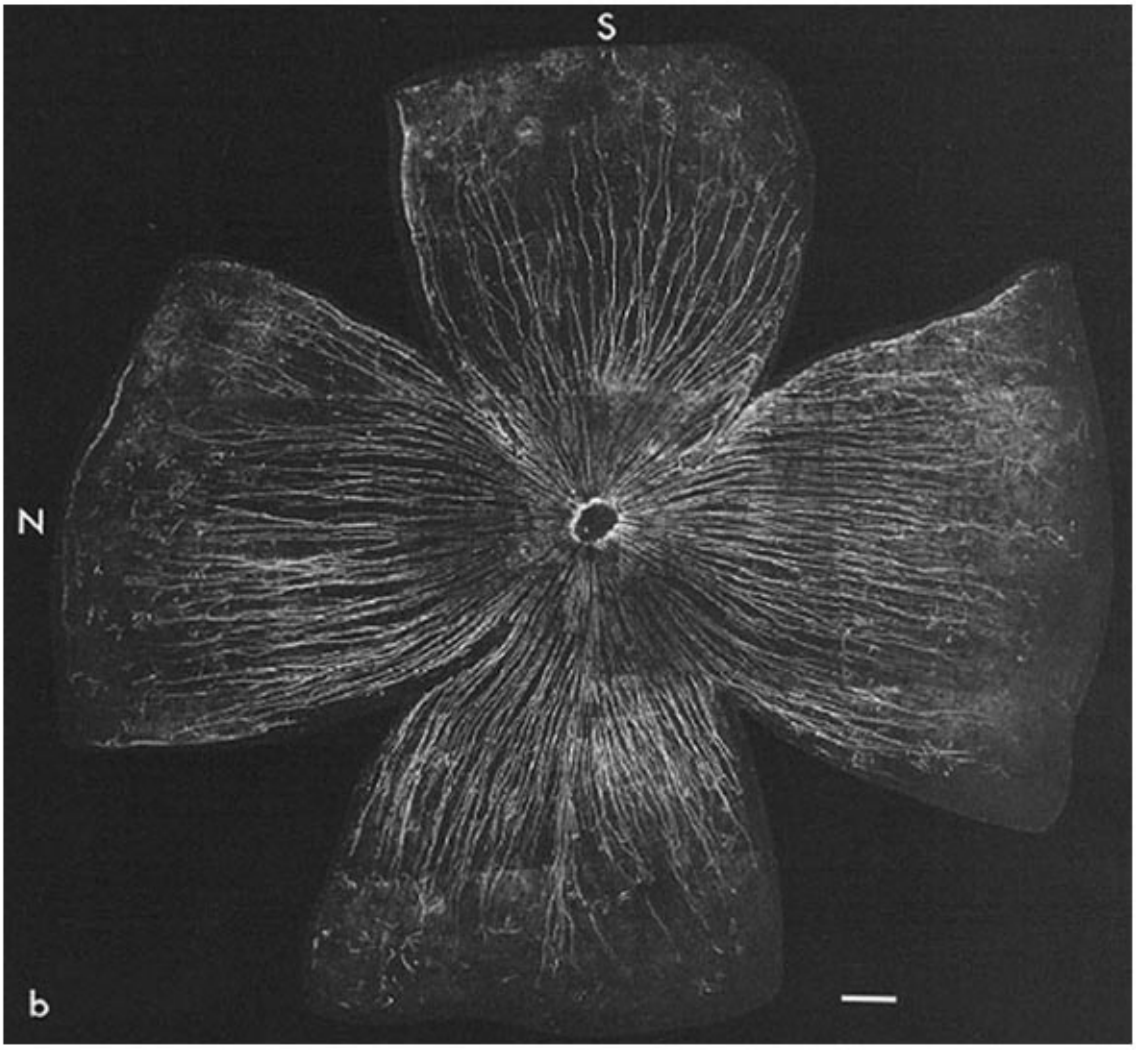

Figure 4b. Same retina as in A, incubated with the monoclonal antibody, RT 97, the immunofluorescent axons of retinal ganglion cells converge toward the central optic disk.

In some instances, PN grafts cannot be directly inserted into appropriate targets because of the small size of the nucleus. In the study of Aviles-Trigueros et al. (23), successful innervation of the olivary pretectal nucleus (OPN) and the nucleus of the optic tract (NOT) was achieved by inserting the distal end of a PN graft into the superficial aspect of the midbrain, between these two nuclei, by carefully avoiding touching them. Under such circumstances, some axons were seen crossing the midline to innervate the contralateral nuclei. This led the investigators to insert the nerves some distance further away from the nuclei. Axons, although coursing for long distances through the brainstem, still showed selectivity for optic target regions (Fig. 9, Fig. 10, Fig. 11). This occurred even though some nuclei within their trajectory were deafferented by the surgery associated with graft insertion.

The specificity of innervation of visual and non-visual targets would appear to be at odds with the observation of Zwimpfer et al. (81) showing innervation of the cerebellum by optic axons regenerating through PN grafts. There is, however, a significant difference in experimental design in that in the study of Aviles-Trigueros et al. (23), the axons have a "choice" of optic or non-optic targets, whereas in the cerebellum study, no choice is available. To complicate the issue, there is evidence that when two of the principal targets of retinofugal axons, the SC and dLGN, are ablated in newborn hamsters and the somatosensory (ventrobasal) or auditory (medial geniculate) thalamic nuclei are partially deafferented, the optic axons form permanent, abnormal connections in the latter

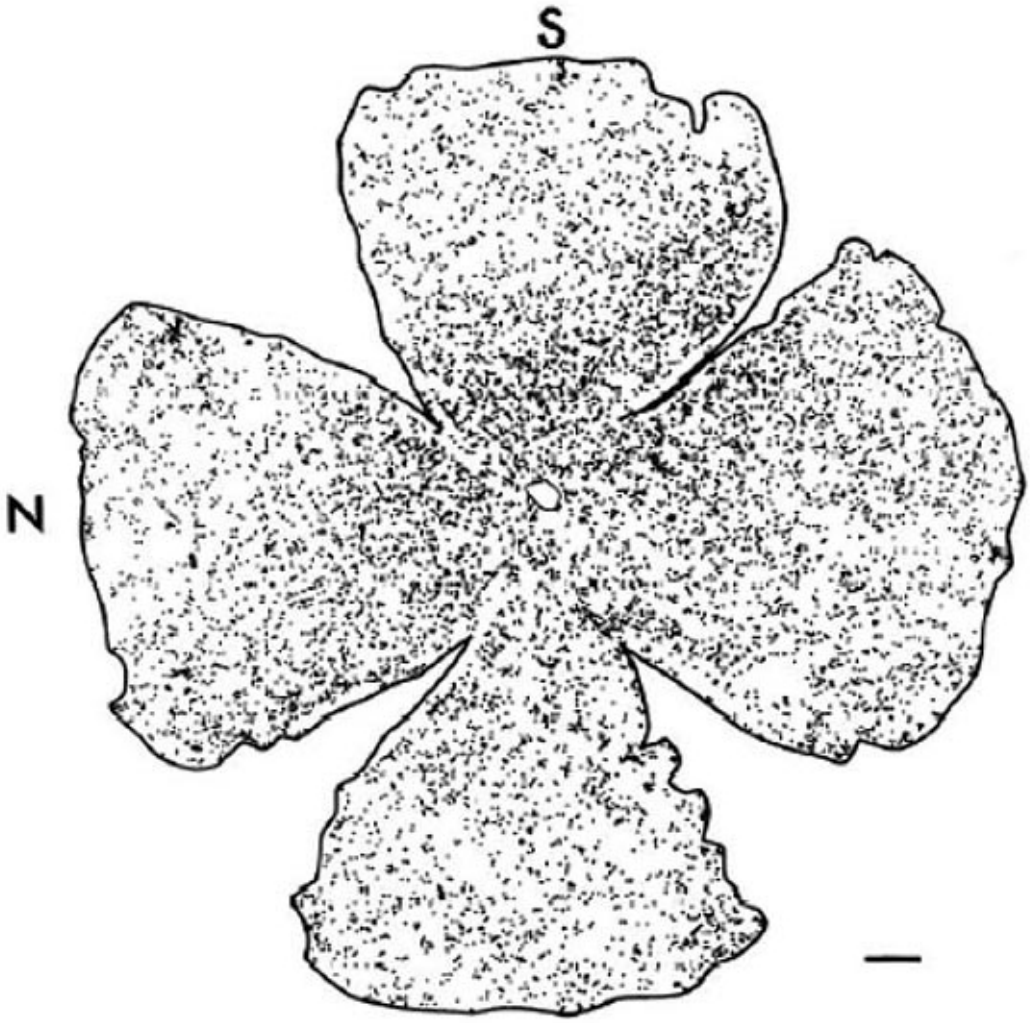

Figure 4c. Diagram, drawn from a photographic montage of a flattened retinal whole-mount from a different retina, indicating the location of 9451 neurons (dots) retrogradely labeled with HRP applied to the unconnected, extracranial end of the graft. The montage was prepared from 24 overlapping photographs printed at a magnification of ×45. S, superior; N, nasal. Bar, 500 μm. From Vidal-Sanz et al. (4).

nuclei (89). The mechanisms responsible for "apparent" preference of appropriate target in studies such as by Aviles-Trigueros et al. (23) are still unclear.

In addition to PN grafting, several studies have reported successful RGC axonal regeneration within the severed optic nerve (70, 73, 90-93). However, it remains unclear as to what is the growth pattern of individual regenerating RGC axons, especially at the level of the optic chiasm, and distally.

Arborization and Synapse Formation by RGC Axons Regenerating into Their CNS Targets

Studies involving PN grafting to bridge the retinofugal pathways have shown that regenerating RGC axons can form distinct arborizations in the target which they reinnervate (4, 23, 94, 95). The study of Aviles-Trigueros et al. (23) suggests that regenerated retinal axons adopt distinctive patterns of terminal arborizations, depending on the target they reinnervate. For instance, while axons entering the OPN show little ramification and swellings reminiscent of the typical retinal innervation of this nucleus, in the NOT axons tend to show more profuse ramifications and arborizations with terminal swellings (Fig. 12 and Fig. 13).

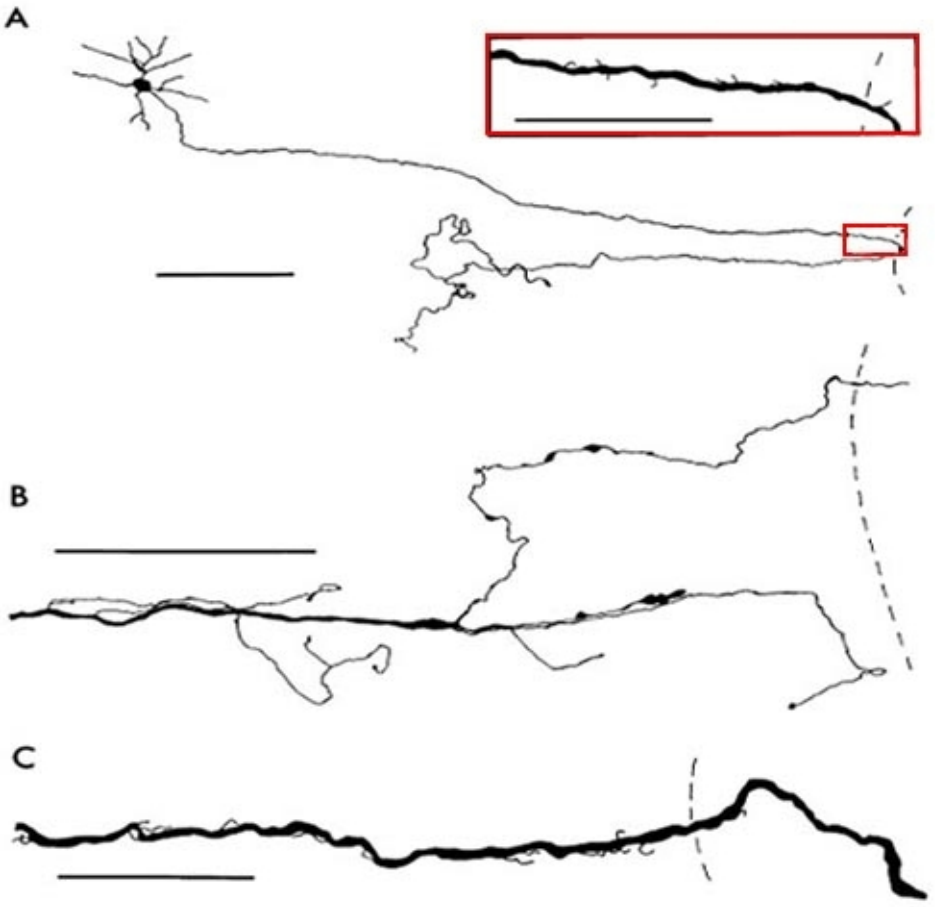

Figure 5. Camera lucida drawings of neurobiotin-labeled RGC axons in flat-mounted retinas 2 weeks after optic nerve (ON) transection alone (A) or with the intravitreal administration of BDNF (B) or NT-3 (C) at the time of transection. The broken lines indicate the edge of the ON head. A, an axon in an untreated retina turns at the edge of the ON head, grows toward the periphery of the retina for 824 μm, and then forms a branch that is 445 μm in length. The main axon then turns toward the ON head and ends as a growth cone. Scale bar, 200 μm. Inset, drawn at higher magnification, the axon shown in A also has numerous small branches near the ON head. Scale bar, 50 μm. B, an axon in a retina treated with 5 μg of BDNF at the time of ON transection has eight branches that range in length from 11 to 363 μm. Scale bar, 100 μm. C, an RGC axon in a retina treated with 5 μg of NT-3 ends over the ON head and has many short branches. Scale bar, 50 μm. From Sawai et al. (77).

These types of terminals are reminiscent of the terminals previously described for such retinorecipient nuclei in another rodent (96). In this context, what is also remarkable, is the similarity of the morphology of the elaborate arborizations found in the superficial layers of the superior colliculus (Fig. 14) with that described in normal animals (96). This indicates further specificity of terminal arborization within the retinorecipient reinnervated target. Thus, it appears that the morphology of the arborization is dictated by the recipient region, more than by the type of retinal fiber arriving to target (80), and that regenerating axons modify their arbors to adapt to the local conditions of the target nucleus.

In 1987, Vidal-Sanz et al. (4) provided experimental evidence that regenerating RGC axons were able to re-establish connections in visual centers of the brainstem (Fig. 15). These connections appear to persist for the life span of the rodent, i.e., up to 2 years of age (97). The type of synaptic contacts formed, the ratios of contacts to terminal perimeter, and the domains of the postsynaptic neurons contacted are similar to those of intact retinofugal pathways (22). Therefore, regenerated RGC axons can establish well-differentiated synapses with neurons in the SC. On the basis of their results, Carter et al. (22) concluded that, "The synaptic differentiation attained by such reformed retinocollicular projections suggests that regenerating CNS axons and their target

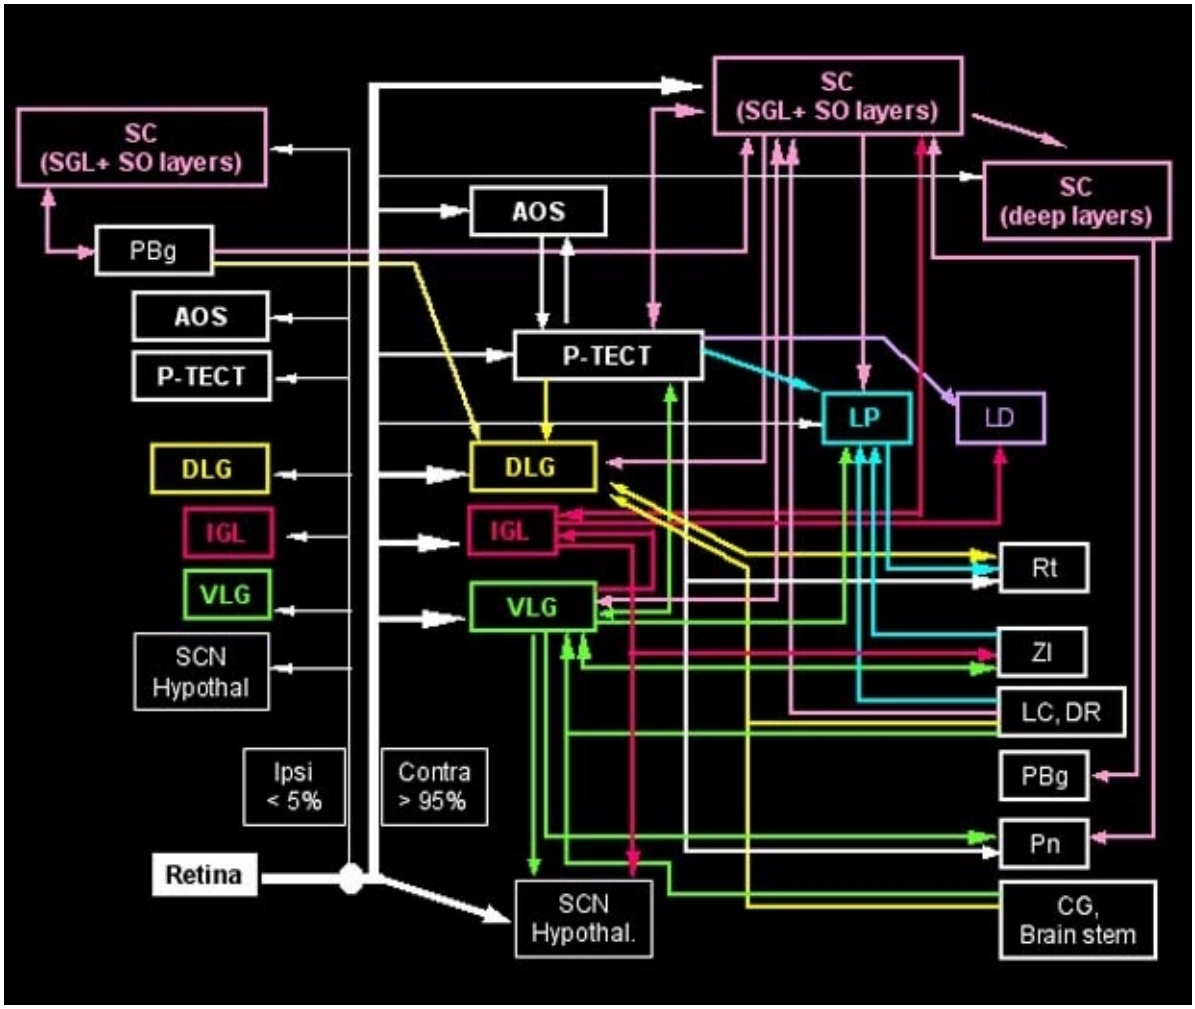

Figure 6. Retinal projections to the primary visual centers (white arrows) and their major links with homolateral secondary subcortical areas. Double arrows indicate reciprocal connectivity. For abbreviations, see later. Cortical connections are given in Fig. 28.

neurons in the adult mammalian brain may retain or reexpress certain molecular determinants of normal connectivity". There are, however, morphological differences between the regenerated and control synapses: 1) larger size of some regenerated terminals; 2) greater mean length of the regenerated synapses; and 3) higher proportion of contacts with dendrites that contain vesicles in regenerated *versus* intact synapses.

Generation of Action Potentials in Target Neurons

Dr. Sue Keirstead and colleagues (8) provided electrophysiological evidence that the synapses, such as the ones described at the electron-microscopic level by Vidal-Sanz et al. (4), could mediate the transynaptic activation of neurons in the superior colliculus of adult mammals. Extracellular recordings in the superior colliculus, 15 to 18 weeks after PN graft insertion into the SC, revealed excitatory and inhibitory postsynaptic responses to visual stimulation of the eye that had received PN anastomosis onto its completely cut optic nerve (Fig. 16). Specific stimulation protocols (involving paired electrical stimulation of the PN graft) were used to verify that postsynaptic activity could be elicited in the reinnervated SC.

Additional studies by Sauve et al. (9), using the same experimental preparation, indicated that each element of a typical bursting response to light (excitatory type of response; Fig. 17) consists of a terminal potential (TP) arising from a regenerated RGC axon terminal arborization, followed by a longer duration focal synaptic potential (FSP) that is selectively blocked by GABA. FSPs are extracellular changes in potential that reflect

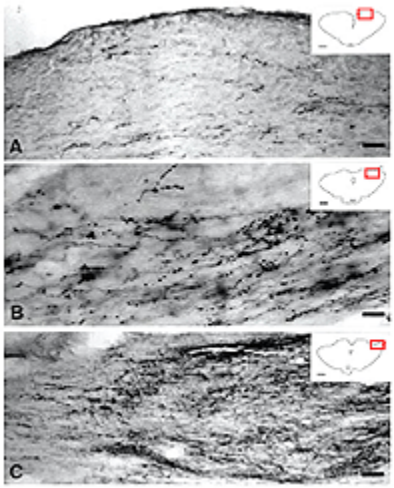

Figure 7. Light micrographs of 40-µm-thick cryostat coronal sections illustrating CTB-labeled retinal axons in the pretectum 16 weeks after grafting a segment of peripheral nerve between the left retina and the lateral side of the left diencephalon. A, CTB-labeled fibers extend through the dorsal aspect of the midbrain toward the midline. These fibers arborize within the NOT and OPN. Scale bar, 50 mm. B, CTB-labeled fibers show numerous varicosities within the NOT. Scale bar, 20 µm. C, PN graft entry zone lateral to the diencephalon. Note the interface between the PN graft and the midbrain and regenerated fibers crossing the interface. Scale bar, 50 µm. Insets in A-C are drawings of the respective section of the midbrain, and the red boxes indicate the region photographed. Scale bar, 1 mm. From Aviles-Trigueros et al. (23).

summation of excitatory postsynaptic potentials (EPSPs) in neurons within the terminal field of the regenerated RGC axon (Fig. 18). In some instances, superimposed on these FSPs are spikes (Fig. 19), which arise after three to four consecutive closely spaced impulses from RGS (as inferred from the TPs).

The results from Sauve et al. (9) indicate that terminal arborizations of individual regenerated RGC axons can synapse with multiple neurons in the SC and that convergence of inputs from regenerated RGC axons is not required for activation of SC neurons in response to light.

Finally, *in vitro* studies by Turner et al. (98) indicate that the deafferentation of the SC, caused by optic nerve cut, and a surgical approach to insert the PN graft into the SC together, lead to ultrastructural changes reflected functionally at the synaptic level in the target structure, even after potential RGC axonal regeneration. Such changes are likely to compromise the ability of the target structure to function normally during information processing. Therefore, although axons regenerating along peripheral nerve grafts can make functional synaptic connections, their efficacy in activating the target structure will probably be compromised by the local changes in synaptic connectivity.

Restoration of Retinotopy

Is Restoration of Retinotopy Needed for Recovery of Function?

Yes it is, for the appropriate execution of visually guided behaviors. We owe the proof to the 1981 Physiology Nobel Prize co-winner Dr. Roger W. Sperry (Fig. 20), who ingeniously took advantage of the spontaneous functional recovery of the retinotectal system in frogs (for a review, see Gaze (99)).

Sperry's impressive demonstration involved sectioning a frog's optic nerve and rotating the eye by 180° (100). After spontaneous regeneration of the retinotectal pathway, the frog's attempt to catch a prey resulted in an attack directed to the diametrically opposed direction (Fig. 21). The frog's behavior gave clues as to how the regenerating RGC axons had reconnected in the tectum. Note: the structure equivalent to SC is named "tectum" in lower vertebrates. Sperry inferred that the regenerating axons had returned to their original position in the

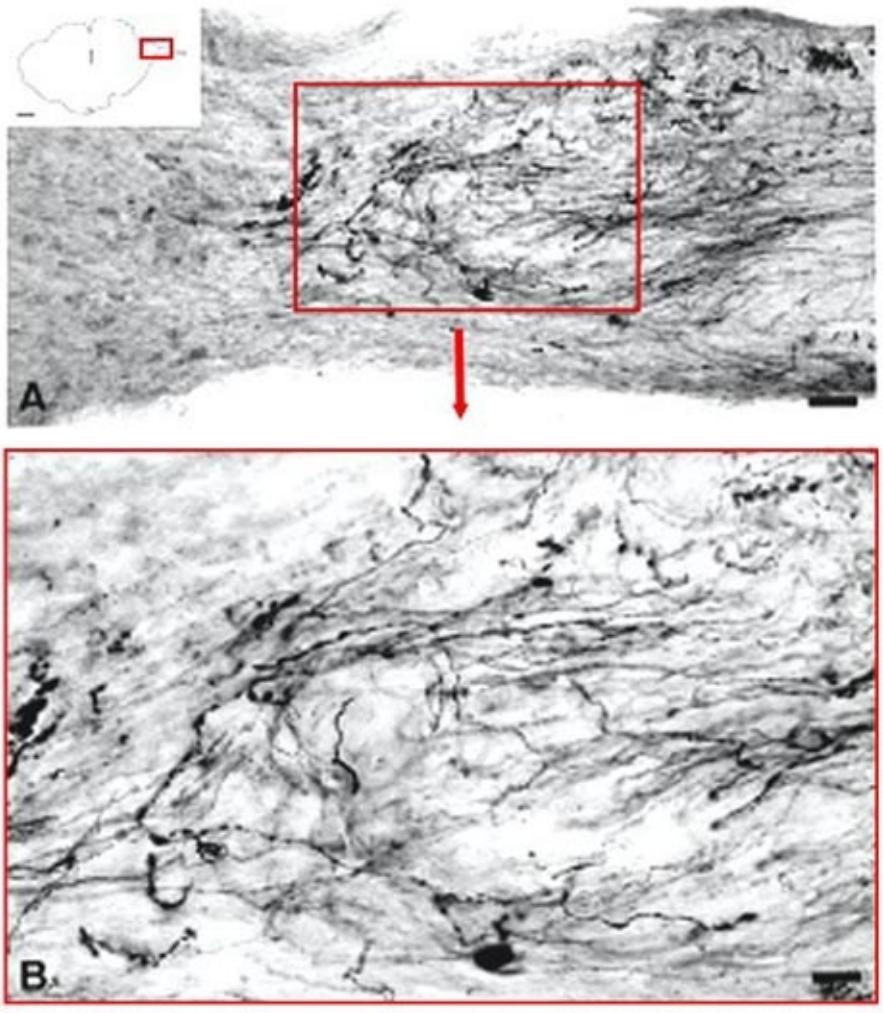

Figure 8. Light micrographs of a 40-µm-thick cryostat coronal section illustrating retinal axons 24 weeks after connecting the left eye and the ipsilateral brainstem with a segment of peripheral nerve and 5 days after intraocular injection of CTB. A, interface between PN graft and diencephalon. Most of the retinal axons do not exit the PN graft and appear within a neuroma-like formation. Scale bar, 47 µm. Inset is a drawing of the section, and the box indicates the region photographed. Scale bar, 1 mm. B, detail from box in A showing CTB-labeled axons that reach the distal end of the PN segment but turn around and do not enter the brainstem. Scale bar, 19 µm. From Aviles-Trigueros et al. (23).

tectum, regardless of the new position they occupied in the rotated eye. This gave experimental support for his chemo-specificity theory (100), which stipulates that "The connections are governed by intrinsic specificity of the advancing fibre tip plus that of the various cellular elements it encounters in its outgrowth" (101).

We can learn about the extent to which retinotopic projections have to be re-established to achieve behavioral recovery by comparing species that have various levels of regeneration of their retinotectal system and examining the level of visually guided behavior they can recover. The capacity for RGC axon regeneration in the vertebrate visual pathway is summarized in the study of Dunlop et al. (102). For instance, there is variability between various species of lizards. Some achieve a stable restoration of retinotectal organization (accompanied by restoration of visually guided behaviors), whereas others (*Ctenophorus ornatus*) fail to maintain a retinotopic ordering of the regenerated projection and lose their capacity to perform visually guided tasks (103). However, training on a visual task has been shown to improve the outcome of optic nerve regeneration in *Ctenophorus ornatus* lizards (104).

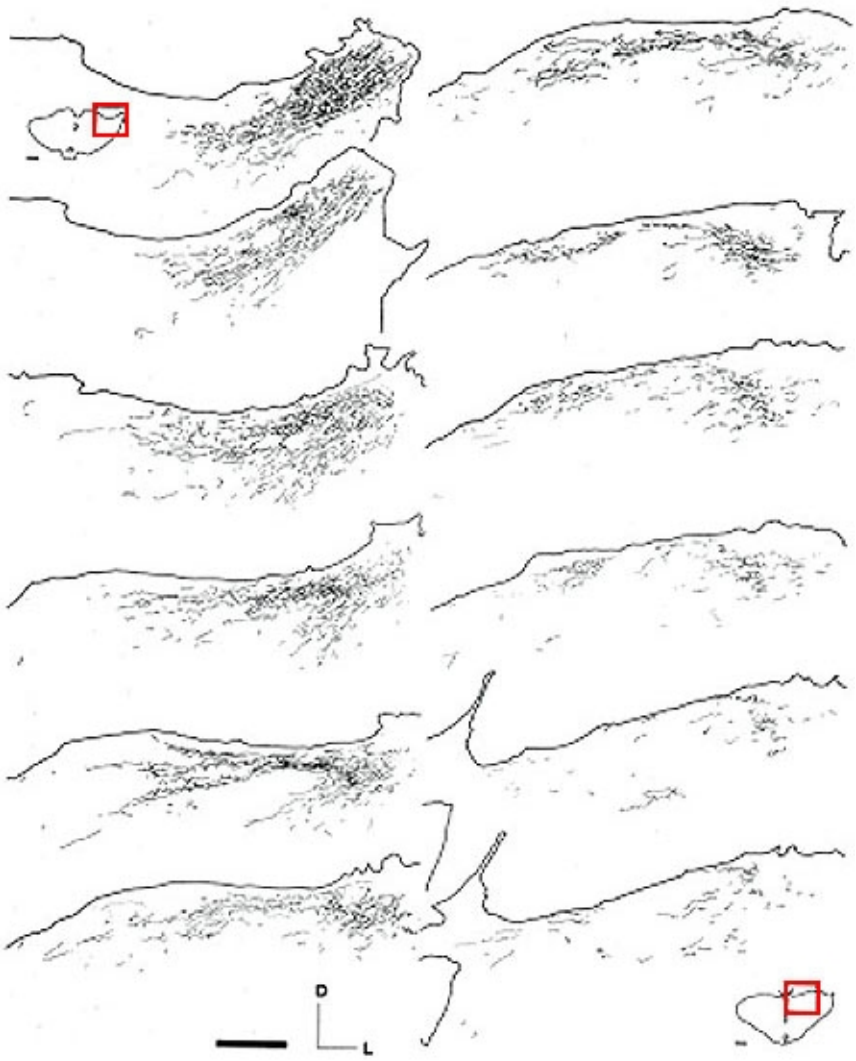

Figure 9. Drawings of alternate 40-µm-thick cryostat coronal sections through the brainstem, from caudal (top left) to rostral (bottom right), of a rat 16 weeks after grafting a peripheral nerve segment between the left retina and the lateral aspect of the left diencephalon. The drawings illustrate the distribution of regenerated retinal fibers orthogradely labeled with CTB injected 5 days earlier into the PN-grafted retina. Note the extensive reinnervation through the pretectum. Scale bar, 0.5 mm. The insets are drawings of the most caudal and rostral sections, respectively. Scale bar, 1 mm. From Aviles-Trigueros et al. (23).

Guidance Cues in the Injured Retinotectal Pathway

The retinotectal system is the model of choice for studying the mechanisms governing the formation of ordered connections in the CNS. In intact mature rodents, axons from RGCs located in the temporal retina project to the rostral (anterior) part of the contralateral SC, whereas axons from RGCs located in the nasal retina project to the caudal (posterior) contralateral SC (17-19). Ventral RGCs project axons medially and dorsal RGCs project axons laterally in the contralateral SC (Fig. 22).

To elucidate the mechanisms involved in axonal guidance, especially with regard to specificity of polarities in the tectum, Dr. Friedrich Bonhoeffer and colleagues developed an *in vitro* assay, known as the "stripe assay" (105, 106). The basis of this assay involves growing retinal explants on stripes made up of tissues alternating from rostral and caudal parts of the tectum. Results using tissues from developing chicks or rodents show that temporal RGC axons avoid stripes made up of caudal tectal tissue, whereas nasal RGC axons grow equally well

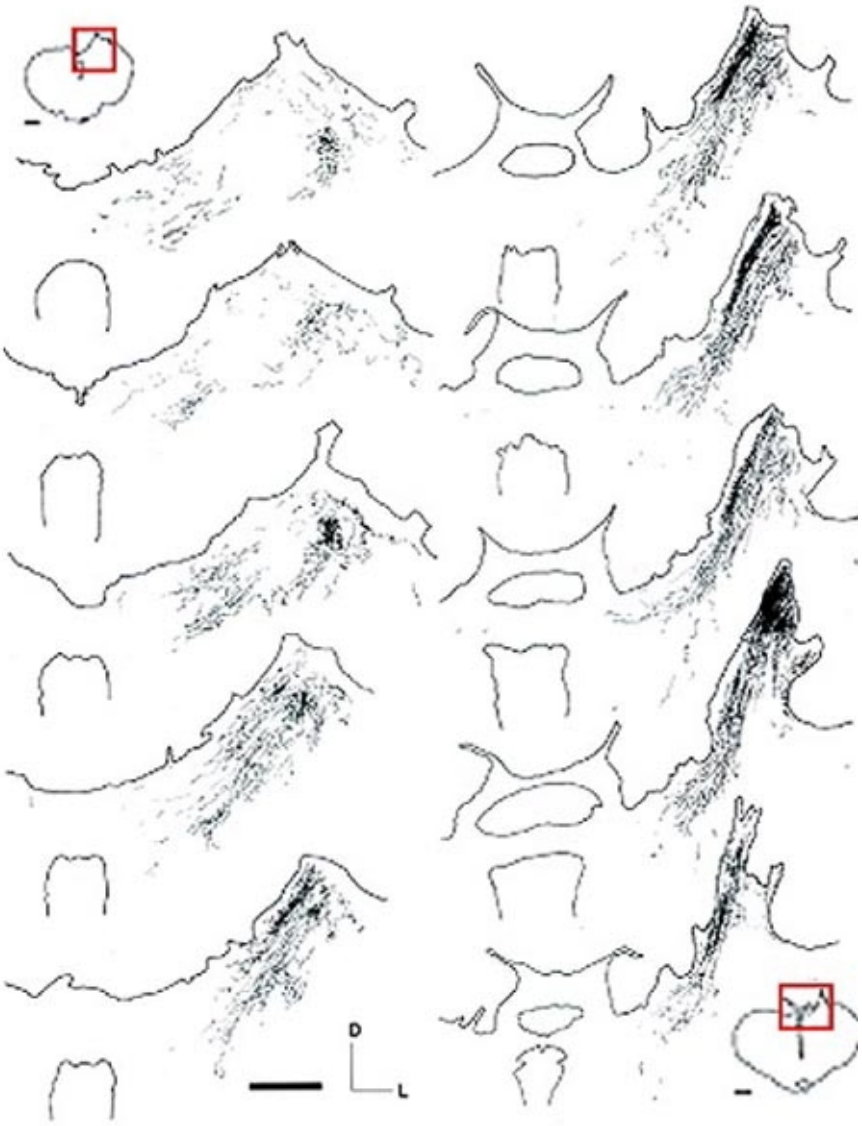

Figure 10. Drawings of consecutive 40-μm-thick cryostat coronal sections through the brainstem, from caudal (top left) to rostral (bottom right), of a rat 46 weeks after grafting a peripheral nerve segment between the left retina and the dorsal aspect of the left midbrain between the OPN and NOT. The drawings illustrate the distribution of regenerated retinal fibers orthogradely labeled with CTB injected 5 days earlier into the PN-grafted retina. Note the segregation of the retinal axons between OPN and NOT from the rostral to the caudal aspect. Scale bar, 0.5 mm. The insets are drawings of the most caudal and rostral sections, respectively. Scale bar, 1 mm. From Aviles-Trigueros et al. (23).

on either rostral or nasal tectal tissue stripes (105-108) or show a preference for nasal stripes providing specific pre-treatments (109). This preference appears to be developmentally regulated in a way that is lost in the mature system. However, Dr. Mathias Bahr and colleagues (110-112) showed that this capacity can be partially restored following optic nerve cut in adult rats. Their results indicate that guidance cues might be re-expressed in the deafferented retinotectal system of adult mammals, and that these cues might retain some level of function.

Several axonal guidance molecules and their respective receptors have been identified. Among them, the best studied compose these four classes: netrins, semaphorins, slits, and ephrins (for a review, see Koeberle and Bahr (44)). In the goldfish, in which spontaneous regeneration occurs, Eph/ephrins are upregulated as gradients at the time that topography is restored during optic nerve regeneration (113). Furthermore, the Eph/ephrin system is

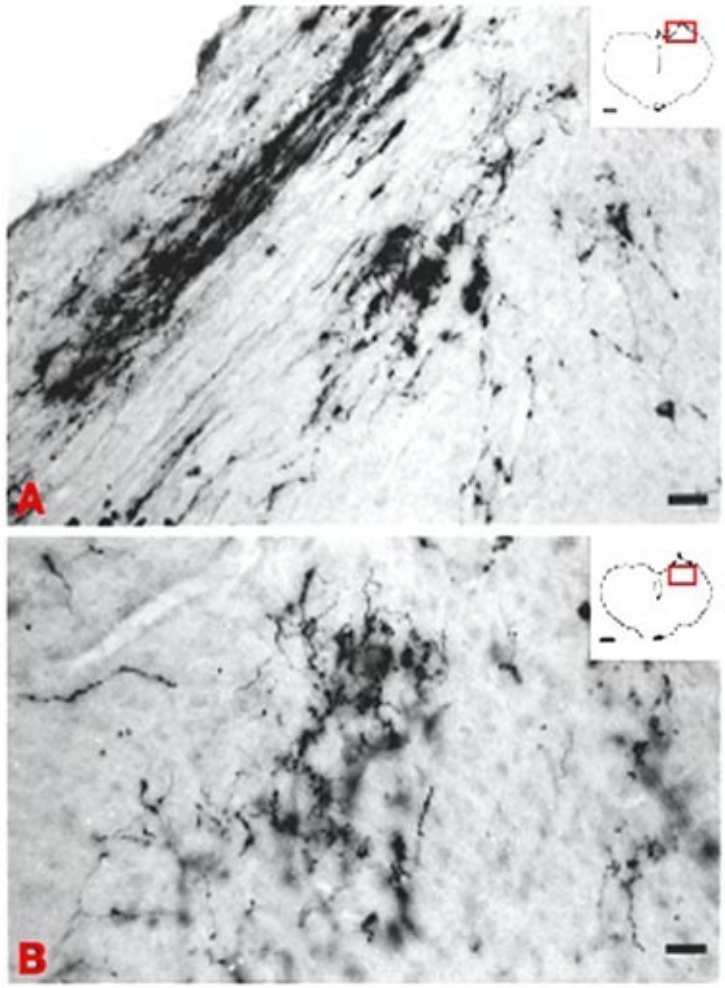

Figure 11. Light micrographs of 40-µm-thick cryostat coronal sections illustrating regenerated retinal fibers in the pretectum 46 weeks after grafting a segment of peripheral nerve between the left retina and the dorsal aspect of the left midbrain between the OPN and NOT and 5 days after intraocular injection of CTB. A, CTB-labeled retinal axons innervate the OPN extensively (toward the top left) and the rostral limit of the NOT (toward the middle and right). Scale bar, 35 µm. B, extensive innervation of the NOT area with numerous varicosities resembling bouton-like endings in a more caudal section. Scale bar, 28 µm. Insets in A and B are drawings of the respective section of the midbrain, and the red boxes indicate the region photographed. Scale bar, 1 mm. From Aviles-Trigueros et al. (23).

required to restore topography because blocking their interactions *in vivo* with fusion proteins results in abnormal topography (114). In rodents, in which spontaneous regeneration does not occur, most of the known guidance molecules have been shown to be modulated after deafferentation. However, although some molecules are up-regulated to levels similar to those achieved in development, some (such as the ephrin receptor EphA5 in the retina and the ephrin-B) are actually down-regulated. Therefore, it remains improbable that these various changes might actually recapitulate developmental events. How experimental manipulations might achieve such recapitulation of developmental events is, for now, a mind-boggling puzzle.

Can RGC axon regenerated through a PN graft resume topological specificity when reinnervating the superior colliculus? See an example from the study of Sauve et al. (24).

The study of Sauve et al. (24) indicates that regenerating mammalian RGC axon terminals do not form a precise retinotopic map (compared with normal intact animals; Fig. 23) when reinnervating the SC (Fig. 24).

However, superimposed on the apparent randomness of distribution of RGC terminals, there appears to be a small but nonetheless statistically significant tendency for these terminals to array themselves appropriately

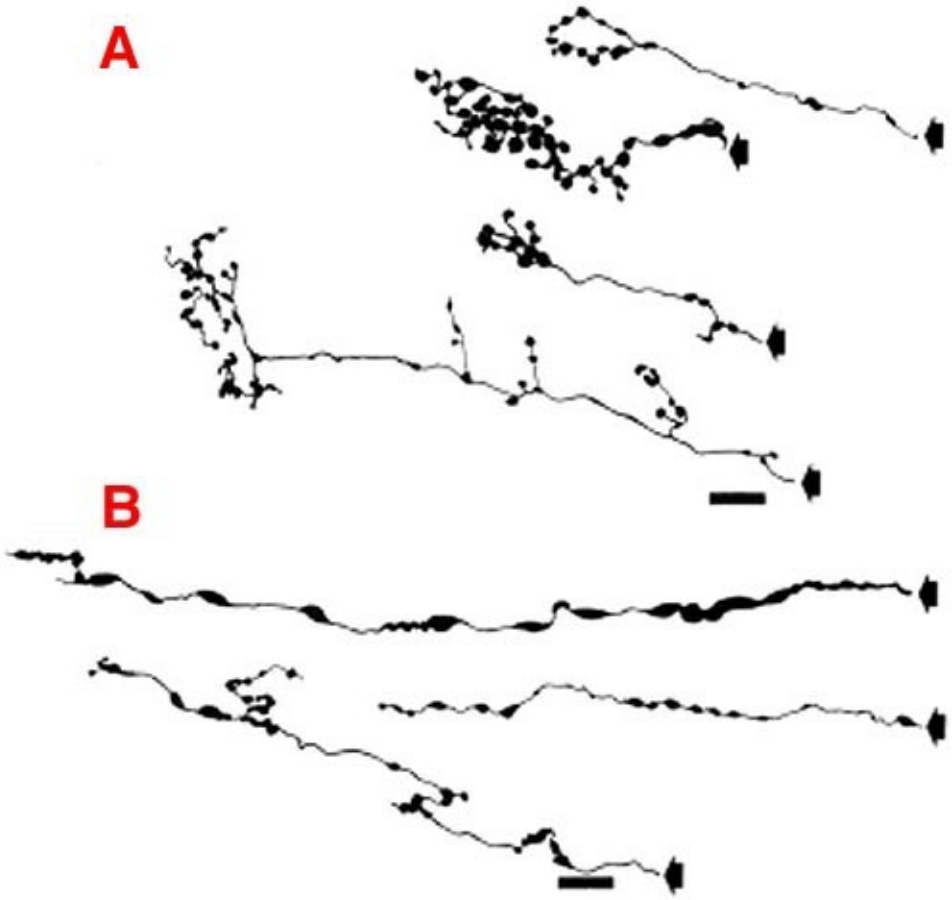

Figure 12. Drawings of retinal fibers 46 weeks after grafting a segment of peripheral nerve between the left retina and the dorsal aspect of the left midbrain between the OPN and NOT and 5 days after intraocular injection of CTB. A, retinal fibers divide into fine branches decorated with numerous medium and small varicosities and terminal swellings, frequently forming rosette-like clusters. These fibers predominate in the NOT area. Scale bar, 9 μm. B, retinal fibers with little branching decorated with large elliptical varicosities along the length of the axon and with terminal swellings of different sizes. These fibers predominate in the OPN area and resemble en passant fibers. Scale bar, 9 μm. The stem axons are indicated by arrows. From Aviles-Trigueros et al. (23).

within the rostrocaudal axis of the SC. Because the PN graft tip was placed at different locations in different animals, the assessment of topography was of necessity a comparison of the relative positions of reinnervating axon terminals for each animal rather than an identification of the absolute position of each terminal. It must also must be emphasized that the method used by Sauve et al. (24) assessed terminal positions but not trajectories of regenerating RGC axons. Nonetheless, these results suggest that factor(s) may be present in the reinnervated SC, as in the newly innervated SC, that can influence the direction of axonal growth and/or the area within which arborization and synapse formation occur.

Topographic ordering of projections during normal development of retinofugal pathways is thought to reflect at least two processes: 1) an initial pathfinding to the approximately correct area directed by spatially specific molecular cues as first suggested by Sperry (115); and 2) a subsequent phase of refinement of the projection due to activity-dependent processes in which near-simultaneous firing of neighboring RGCs (for a review, see Wong (116)) serves mutually to stabilize the connections of their shared target neurons in the LGN or tectum (117-121). Initial pathfinding of RGC axons in the tectum may be very precise, as in frogs and fish (122, 123), or more exuberant and diffuse, as in rodents (166, 167). Computer simulations suggest that a combination of positional cues and activity-dependent mechanisms gives rise to a very precise retinotectal topology in a variety

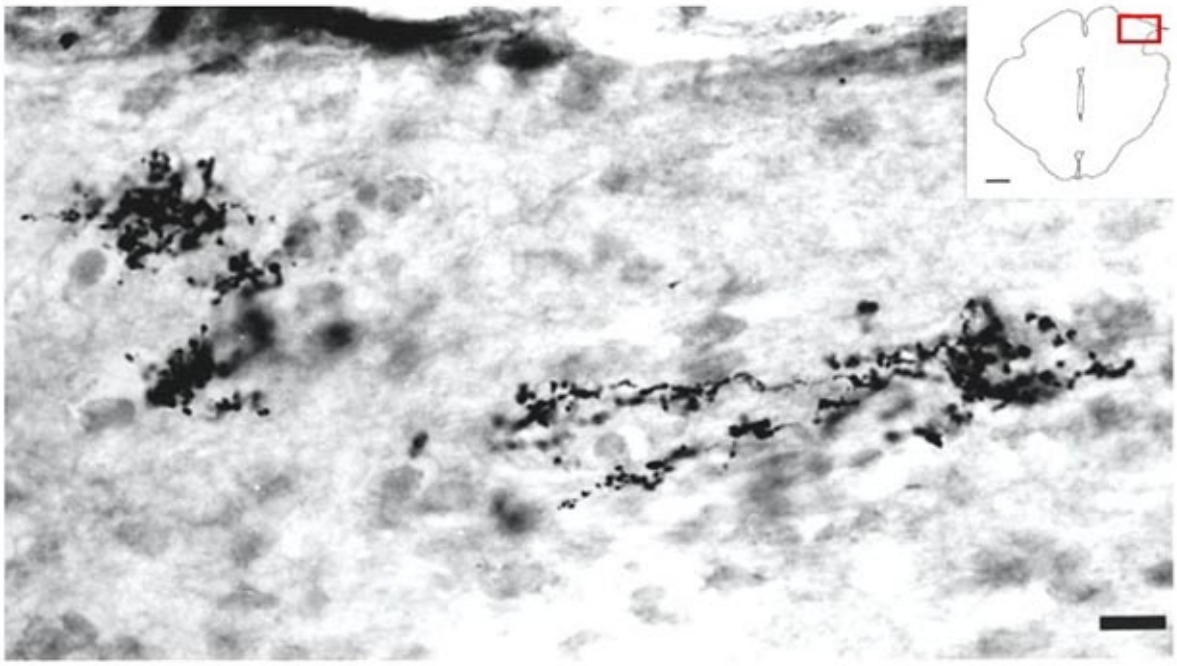

Figure 13. Light micrograph of a 40-µm-thick cryostat coronal section of the midbrain illustrating retinal fibers in the superficial gray 40 weeks after grafting a peripheral nerve segment between the left eye and the lateral aspect of the ipsilateral SC and 5 days after intraocular injection of CTB. Near the site of the PN graft entry, orthogradely labeled axons extend through the superficial layers of the SC forming typical arborizations. Note the high density of varicosities and terminal swellings resembling bouton-like endings on branching fibers. Scale bar, 17 µm. Inset illustrates a drawing of the section and indicates the region photographed. Scale bar, 1 mm. From Aviles-Trigueros et al. (23).

of experimental situations (124, 125), for example even if a molecular gradient is only transiently expressed during the initiation of innervation of the tectum (126).

During regeneration of the retinotectal pathway in frogs and fish, the initial topography is only roughly organized. Functional synapses are formed indiscriminately by regenerating goldfish RGC axons as they enter the tectum. These may be unstable if inappropriately located (127, 128). Projections become refined into a more precise retinotopic map over a period of several weeks by mechanisms that depend upon ongoing activity in neighboring RGC axons (117, 129).

In vitro experiments have shown that molecules with topological specificity with respect to the rostral and caudal tectum or SC are transiently expressed in the neonatal mammalian SC (105). These topologically specific markers disappear after the retinocollicular pathway is laid down but reappear about 2 weeks after denervation of the SC (112). Such positionally specific markers may be more strongly expressed in deafferented SC than in embryonic SC (130). The experimental results of Sauve et al. (24, 131) are consistent with the possibility that a gradient of such positionally specific markers could serve as an influence on the exploration of the SC by regenerating RGC axons (132-134), either by exerting a repulsive or tropic effect on their axonal growth cones (105, 106, 135-138), or by influencing their branching patterns (108). Positionally specific markers could also influence the deployment of regenerating RGC axons within the nerve graft as they approach the SC (139).

The question arises as to why the effects of these factor(s), if present, are so minimally expressed or so difficult to document in the reinnervated mammalian SC. In the reinnervated SC, the extent of exploration by a regenerated RGC axon is 1 mm or less (140). More extensive exploration of the SC is perhaps limited by the presence of factors inhibitory to axonal growth (141-144) that are present in the adult animal as well as by the developmental

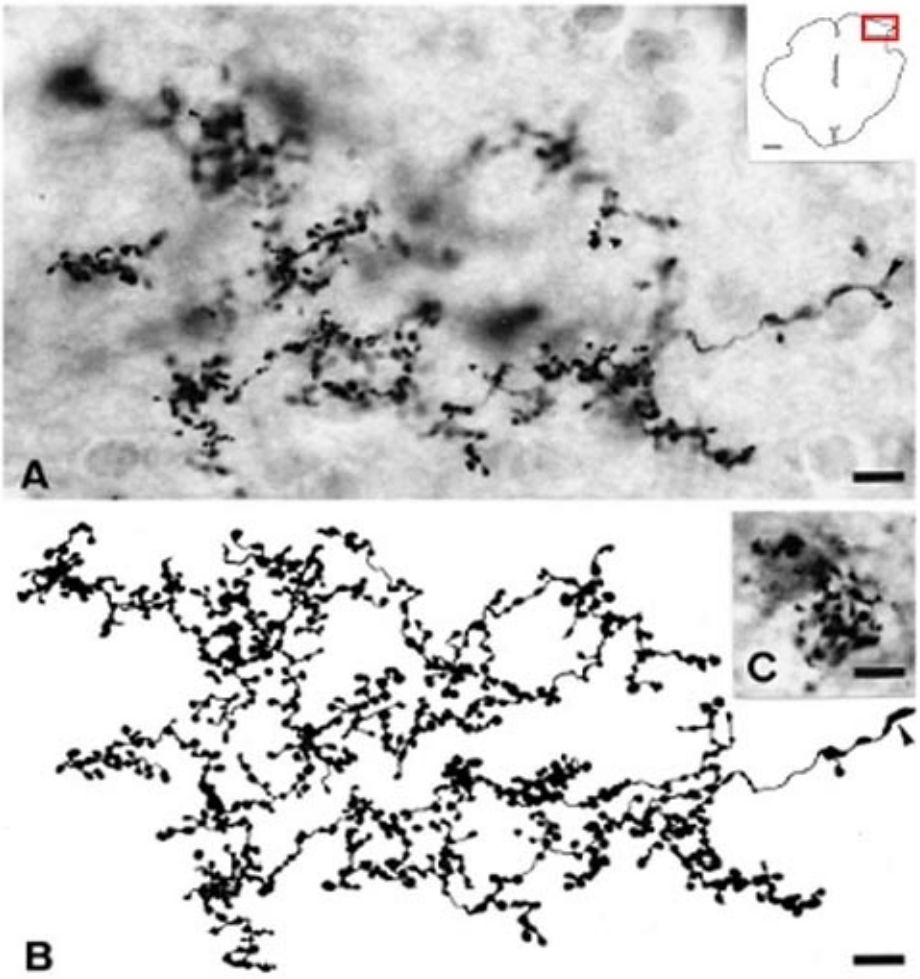

Figure 14. Light micrographs and drawing illustrating regenerated retinal fibers in the stratum griseum superficiale of 40-μm-thick cryostat sections of the midbrain 48 weeks after grafting a segment of PN between the left eye and the lateral side of the ipsilateral SC and 5 days after intraocular injection of CTB. A, single regenerated RGC axon in the SGS of the SC forming many branches that bear multiple varicosities of similar appearance and uniform size. Scale bar, 10 μm. Inset illustrates a drawing of the midbrain section and indicates the region photographed. Scale bar, 1 mm. The stem axon is indicated by an arrowhead. B, high-power reconstruction of the terminal arbor in A. Scale bar, 9 μm. C, close interrelation between terminal cluster of bouton-like endings of regenerated retinal projections and SC neurons. Scale bar, 8 μm. From Aviles-Trigueros et al. (23).

down-regulation of growth permissive molecules (145, 146) and receptors (147, 148). This is in contrast to the situation during normal development, where RGC axons from all portions of the retina initially innervate the entire SC (149, 150). In the PN graft regeneration paradigm, no more than 10% of the normal total number of RGCs usually regenerate their axons across the PN graft, and only a portion of these reinnervate the SC (4). Many axons terminate growth immediately after penetrating the CNS (23). One way to increase sprouting of regenerating RGC axons in the SC could be to provide BDNF and chondroitinase ABC (151). However, even in these conditions, with surviving RGCs widely separated in the retina and their axon terminals widely dispersed within the SC, the influence of activity-dependent mechanisms in shaping the topological pattern of innervation would be expected, *a priori*, to be much more limited than in normal development. Furthermore, with little competition among axons for synaptic sites, it is possible that inappropriately located synapses, once formed, would be much more stable than in the reinnervated frog or goldfish tectum. Such premature formation of synapses could in turn curtail the further exploration of the SC by regenerated RGC axons.

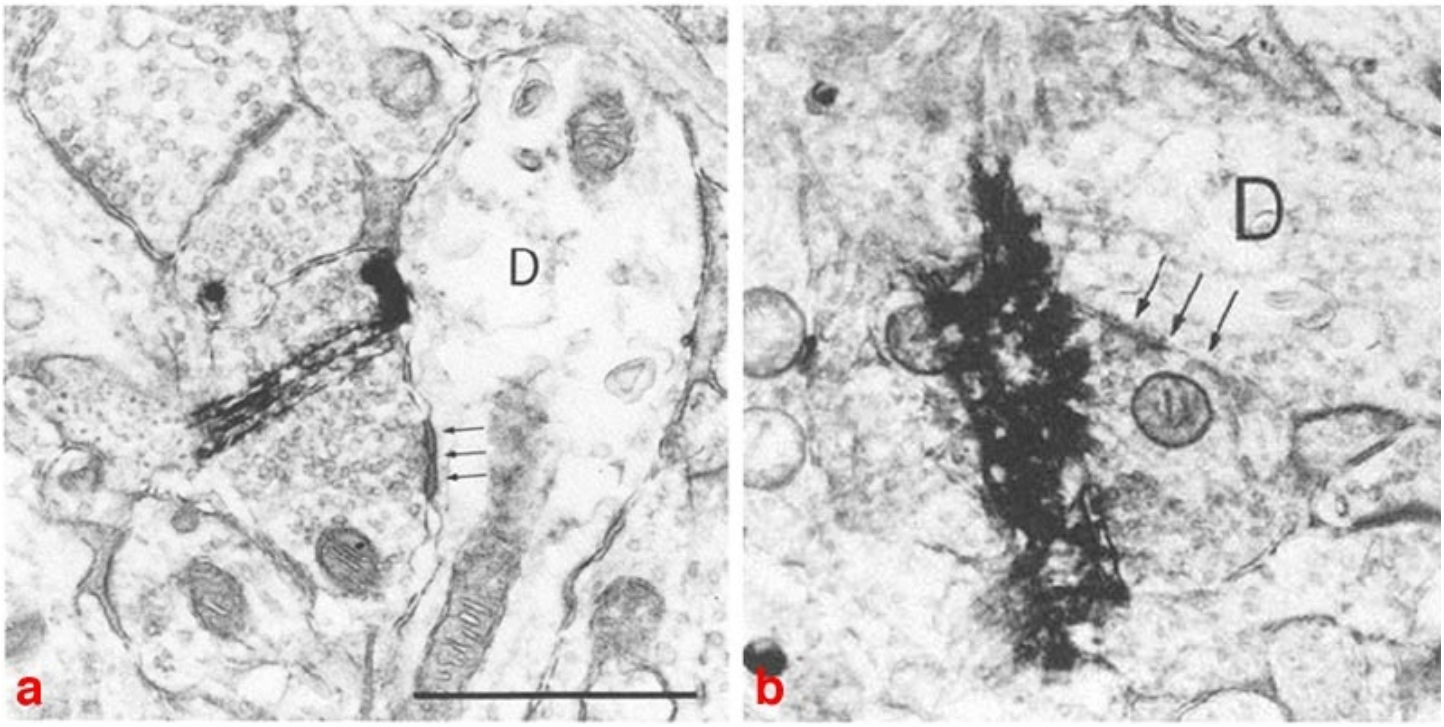

Figure 15. Electron micrographs of presynaptic profiles in the superficial SC (strata zonale and griseum superficiale) lightly labeled with HRP injected in the PN-grafted eyes of group IIb rats. D, dendrites. The presynaptic terminals contain vesicles that are predominantly round or spheroidal. The thickenings of the pre- and postsynaptic membranes at the synaptic contacts are indicated by arrows. a, characteristic DAB-Co-stabilized TMB reaction product (175) is confined to the presynaptic axon terminal. b, as occasionally occurs with this "technique", the reaction product extends beyond the boundary of the terminal. Bars, 1 µm. From Vidal-Sanz et al. (4).

Preservation of Local and Downstream Circuitry

In the study by Turner et al. (98), the local synaptic connectivity in the superficial gray layer of the SC was assessed after RGC axonal regeneration through a PN graft into the rat SC, using *in vitro* brain slice techniques. Repair was achieved between the ipsilateral eye and SC, after bilateral lesion of optic nerves and ablation of ipsilateral occipital cortex.

Impact of Deafferentation

The normal rat superficial gray layer (SGL) of the SC receives the majority (90%) of its excitatory input from the retina (152) (Fig. 25) and the remainder (10%) from the visual cortex (153).

Interconnectivity within the SGL appears to be mediated by local GABAergic interneurons (154, 155). Both the GABAergic processes of local circuit interneurons (152, 156) and the axon terminals of other projections proliferate (157, 158) after optic deafferentation. These new neural processes appear to form additional synapses or to take up positions apposed to the postsynaptic densities left vacant by the degenerating retinal afferents in the SC (152). As a result, the synapse-to-neuron ratio stays the same in the SC (159), although it is not known whether these synaptic contacts are functional. Because the subsequent repair of retinal afferents is also going to alter the balance between excitatory and inhibitory inputs, the connectivity between restored retinal afferents and target neurons is likely to be very different from that in the normal SGL (Fig. 26).

There is as yet no evidence for local excitatory connections in the SGL. Electrophysiological studies are consistent with the anatomical organization, in that retinal input to the SGL is monosynaptic and there is no evidence for local network-related activity, even when inhibition is blocked (160). In addition, contralateral

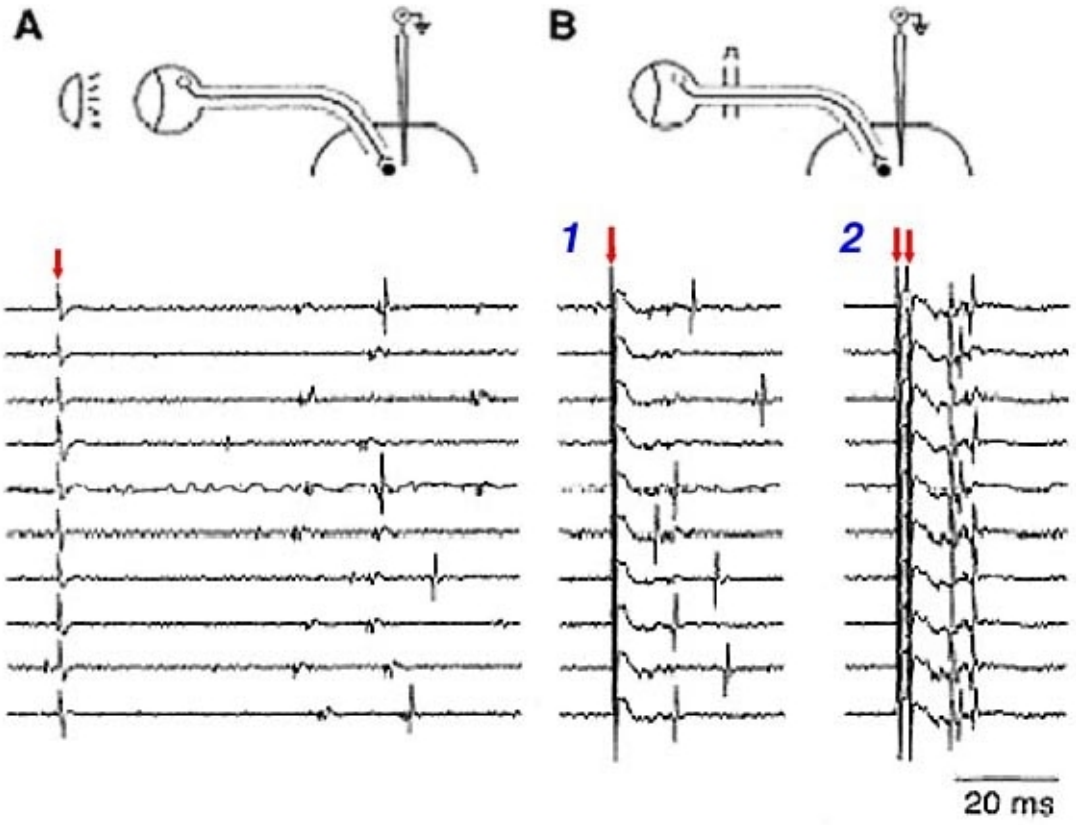

Figure 16. A, 10 successive responses to light flash (at arrow) recorded at a depth of 250 μm in the SC. The large unit responds with a single spike on 4 of 10 iterations. B, the same unit responds erratically with inconsistent latency to (traces 1) single electrical stimuli (arrow) delivered to the graft and responds at a more constant latency, often with multiple spikes, to (traces 2) paired electrical stimuli (arrows) of the same intensity. This pattern of response is inconsistent with that anticipated from an RGC axon and thus identifies this unit as an SC neuron. All recordings were filtered (band pass 500 Hz to 5 KHz) and stored on magnetic tape. From Keirstead et al. (8).

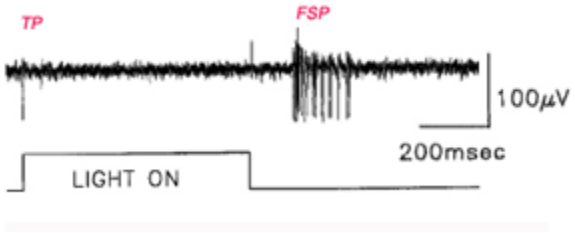

Figure 17. Unitary response to static illumination of a spot 4" in diameter recorded at a depth of 190 μm in a reinnervated SC 37 weeks after graft insertion. Bandpass 100 Hz to 5 kHz. From Sauve et al. (9).

enucleation 14 days before recording is sufficient to result in a complete loss of excitatory inputs to the SGL *in vitro* after intracollicular stimulation (161). However, the study by Turner et al. (98) suggests that this is not always the case: optic tract stimulation 3–9 months after optic nerve transection leads to excitation in the SC, and this is likely attributable to the recruitment of corticocollicular projections, which run close to the optic tract (162). Indeed, anatomical studies have shown that 30–45 days after contralateral enucleation, there is a reactive synaptogenesis of corticocollicular terminals (157). The nature of this responsiveness also suggests that this cortical input recruits local recurrent excitatory connections that have been formed as part of the reactive process to retinal deafferentation.

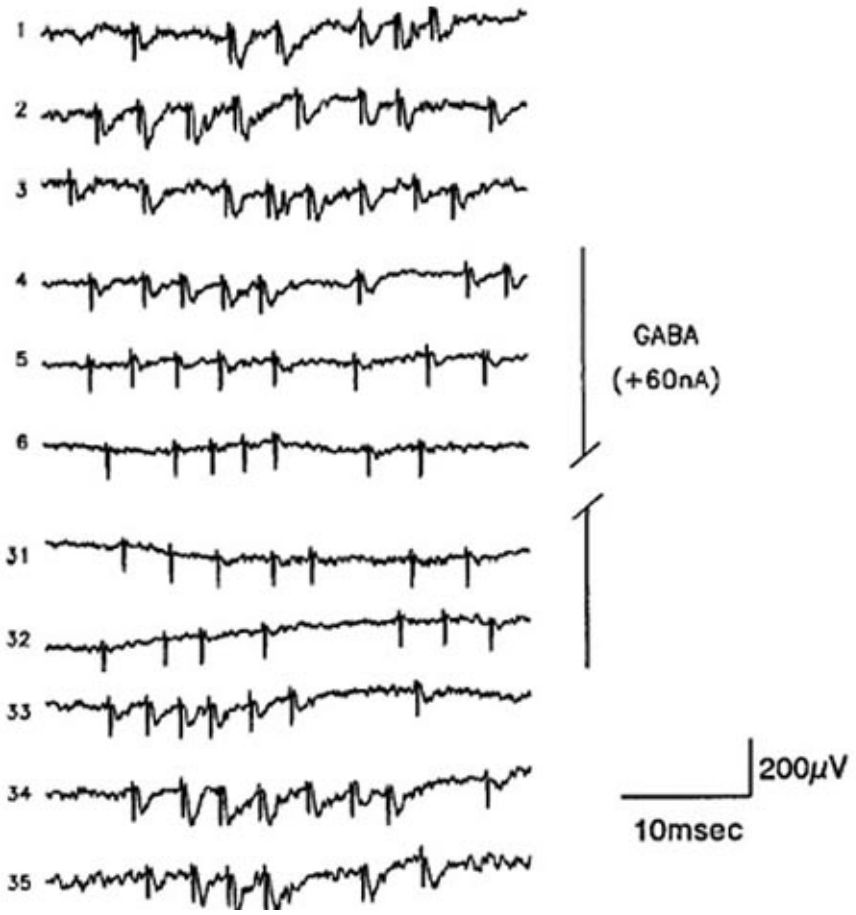

Figure 18. Successive OFF responses to repetitive light stimuli every 3.1 sec from the same unit as in Fig. 1. Traces begin 125 msec after offset of light. Band pass 10 Hz to 5 kHz. After application of GABA between traces 3 and 4, the second component of each unitary response is attenuated (traces 4 and 5) and then disappears on subsequent traces. When GABA application is discontinued after approximately 90 sec, the second component of each unitary response gradually recovers, becoming larger between traces 33 and 34. The gradual attenuation and recovery of the second component indicates that the effect of iontophoretic administration of GABA is not a current effect. Traces 7 to 30, during which GABA was continuously applied, are omitted. From Sauve et al. (9).

Evidence of New Inputs after PN Graft Repair

After combined retinal and cortical deafferentation (as part of the surgery for PN bridging the retinocollicular pathway), all normal excitatory inputs to the SGL are abolished. However, there is evidence from the study by Turner et al. (98) for the presence of both spontaneous and evoked EPSP-like events in SC slices from the PN graft repair preparation. This suggests that excitatory inputs can form new synaptic contacts on neurons within the SGL. These connections are likely to be attributable to reactive sprouting of excitatory neurons, either in the SGL itself or the deeper layers of the SC, such as the intermediate gray layer (IGL). Because both the SGL and IGL contain neurons that have dendrites that extend across the SO, this could provide a substrate on which such reactive synaptogenesis could form a recurrent excitatory network. Certainly, the delay (20–30 ms) in the onset of the network depolarizations after electrical stimulation (reported by Turner et al. (98)) suggests that sprouted excitatory input is polysynaptic, resulting from the recruitment of a relatively remote population of neurons, as may be located in the IGL. Indeed, the structure of the IGL is conducive to bursting activity because IGL neurons form a recurrent collateral network in normal animals and produce long-lasting synaptic responses in the presence of bicuculline (160). The network reorganization in the PN graft preparation (recorded *in vitro* (98)) is not that surprising, in view of the impact of deafferentation in other structures, e.g., cerebral cortex (163) or the dentate gyrus of the hippocampus (164). In both cases, this process leads to sprouting of excitatory axons

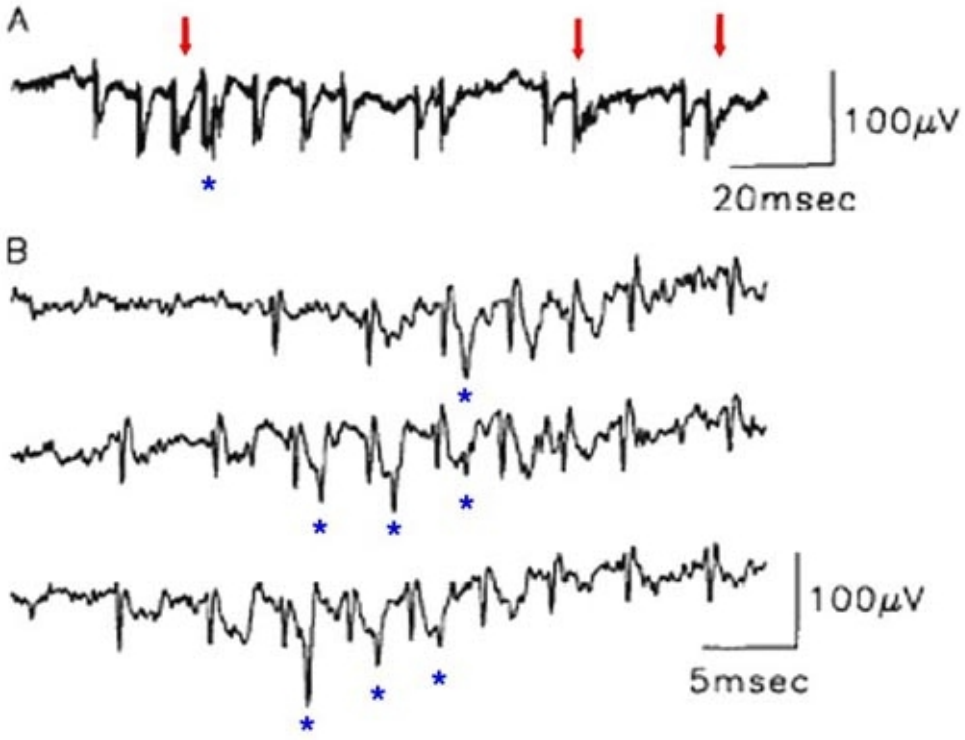

Figure 19. Spike-like activity arising from FSPs in single sweeps in response to static illumination of a spot. Recordings from units from two different animals. A, an OFF response. Depth, 200 μm. Note increase in baseline noise after closely spaced impulses in RGCs (arrows) and spike-like responses that are not TPs (asterisk). B, 3hree ON responses with multiple associated spike-like responses (asterisks) arising from FSPs. Depth, 100 μm. From Sauve et al. (9).

to form new recurrent excitatory connections. One consequence of the reactive events found in most SC slices (from PN graft repair preparation) is that they are likely to obscure efficacy of regenerated RGC axons that had established monosynaptic connections of retinorecipient neurons.

Impact of PN Graft Repair Surgery on the SGL Function: The Future for Repair Strategies

It is clear from the work of Turner et al. (98) that intrinsic changes in response patterns will impact the way the SGL will function during visual stimulation. Keirstead et al. (8) demonstrated that, in comparison with normal controls, restoration of functional retinal inputs into the SC, using the PN-graft method, had delays in the onset of post-synaptic action (165). This delay probably reflects the fact that the underlying synaptic responses involve the recruitment of recurrent excitatory connections. It may also reflect the profound impact that GABAergic inhibition has in controlling this network. The impact of visual deafferentation needs to be assessed throughout the SC to identify the locus/loci of the reactive changes that underlie(s) altered network behavior. In addition, for improvements in the current strategies of pathway repair, there is the need to limit or reverse these deafferentation-induced changes because: 1) this would allow a better assessment of the efficacy of new connections; and 2) it would probably improve system function.

In conclusion, axonal regeneration to a target alone clearly does not guarantee functional recovery. The study by Turner et al. (98) highlights the fact that the functional state of the target area is of fundamental importance for whether normal function can be restored, once axonal reinnervation has been achieved.

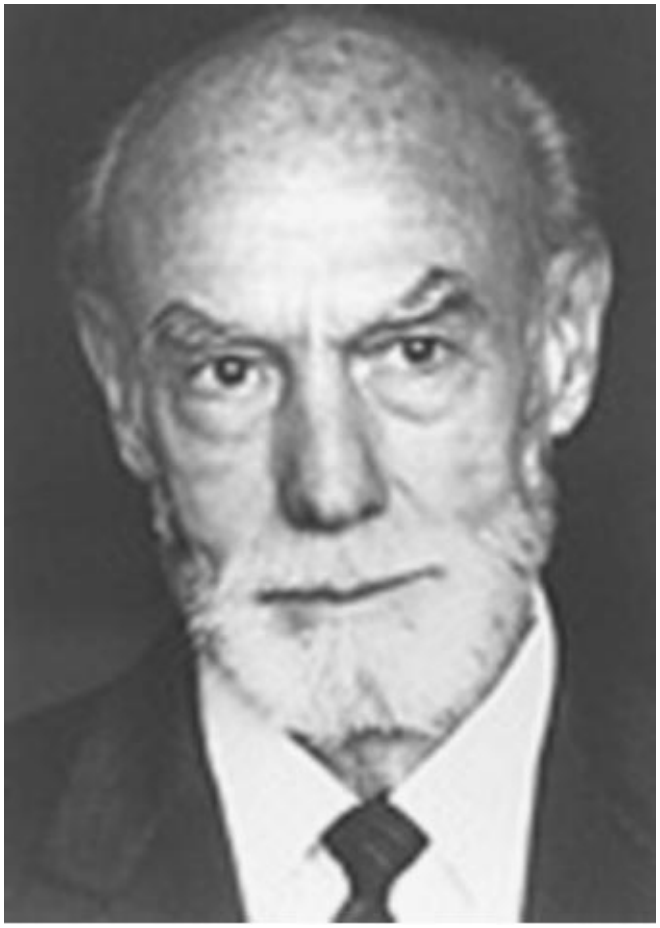

Figure 20. Photograph of Nobelist Roger Sperry.

Evidence for Some Level of Recovery of Function in the PN-bridged Retinofugal Pathways

The question of whether visual functions can be mediated by regenerated axons has been explored by looking at: 1) the pupillary light reflex, a conditioned response; 2) EEG desynchronization; and 3) behavioral arousal. It was found that the regenerated pathway could mediate pupillary constriction to light (166). Additional studies (167) showed that at best, the response amplitude and latency could be within normal range, but one noticeable difference was that although in normals, repetitive stimulation gave repeated responses of similar amplitude, regenerated pathways showed substantially reduced amplitudes with successive stimulation. The conditioned response studied, i.e., escape from a shuttle box in response to a light flash as a predictor of an electric shock, showed that this task could be performed in rats with regenerated optic input (168). Finally, animals were tested to demonstrate whether the regenerated pathways could mediate EEG desynchronization behavior to light (169). This depended on the fact that, under normal conditions, rats show a slow wave sleep pattern. A sensory stimulus, such as a flash of light or auditory signal, desynchronizes this high-amplitude slow wave activity, replacing it with low-amplitude, high-frequency activity. When presented with a light flash, blinded rats do not show this response, but animals with nerve grafts connected into the SC do. Associated with this, the rats also show a range of behavioral arousals.

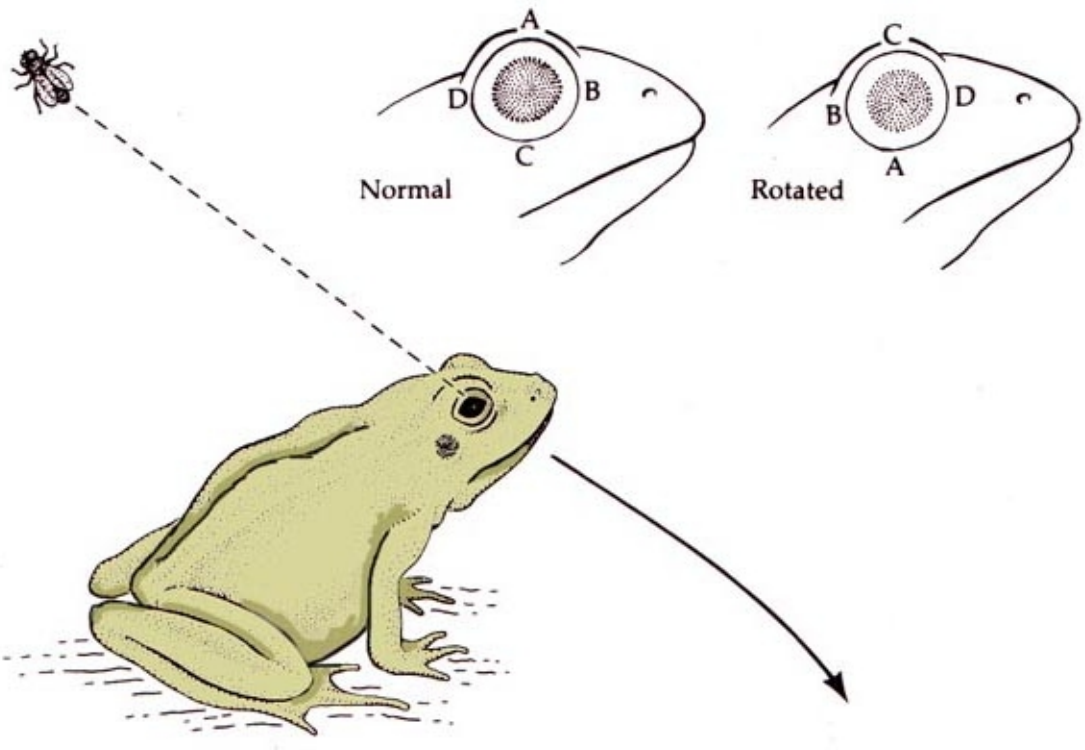

Figure 21. When the eye is rotated 180°, the frog's prey-catching behavior is inverted. After Sperry, 1956.

Visual Function Assessment

Visual function runs at many levels from unconscious responses to perception. These various functions are generally mediated through specific primary visual centers. Unconscious responses include driving circadian rhythms (relayed through the suprachiasmatic nucleus), photophobic responses (not specifically localized to any specific visual center), pupillary light reflex (mediated by the olivary pretectal nucleus), orienting responses (involving the SC), and head tracking to moving stripes (involving the SC also, but requiring cortical input for higher spatial frequencies). Perception requires elaborate decoding and integration of a set of visual signals to achieve a representational image at the level of the cortex.

For some visually driven functions, such as circadian rhythms and photophobia, all that is needed is to recognize a gradient, either temporal or spatial, of light and dark. For the pupillary light reflex, ability to encode the light intensity is also important, because the amount of pupillary constriction depends on brightness. For orienting responses and head tracking, some level of topographic encoding must be present. For perception, a much more elaborate degree of encoding must be achieved. In any attempt to reconstruct the damaged visual system, or indeed to limit its deterioration, the ideal is to recreate or preserve exactly the normal substrates of the various visually driven behaviors. This is rarely possible and indeed may not always be necessary. The CNS can sometimes adapt to an imperfect sensory input and demonstrate a level of adaptation sufficient to achieve a normal response (170-173): even in an intact animal, the system is able to operate over a wide range of luminance and contrast sensitivity (174). It is also apparent, especially in conditions involving re-establishment of connections, that specific visual responses can be modulated by associated events and may be interdependent.

To reconstruct a particular function, therefore, it is necessary for axons to innervate the appropriate brain region, subserving that function. Beyond this, it may also be necessary for a topological representation of the

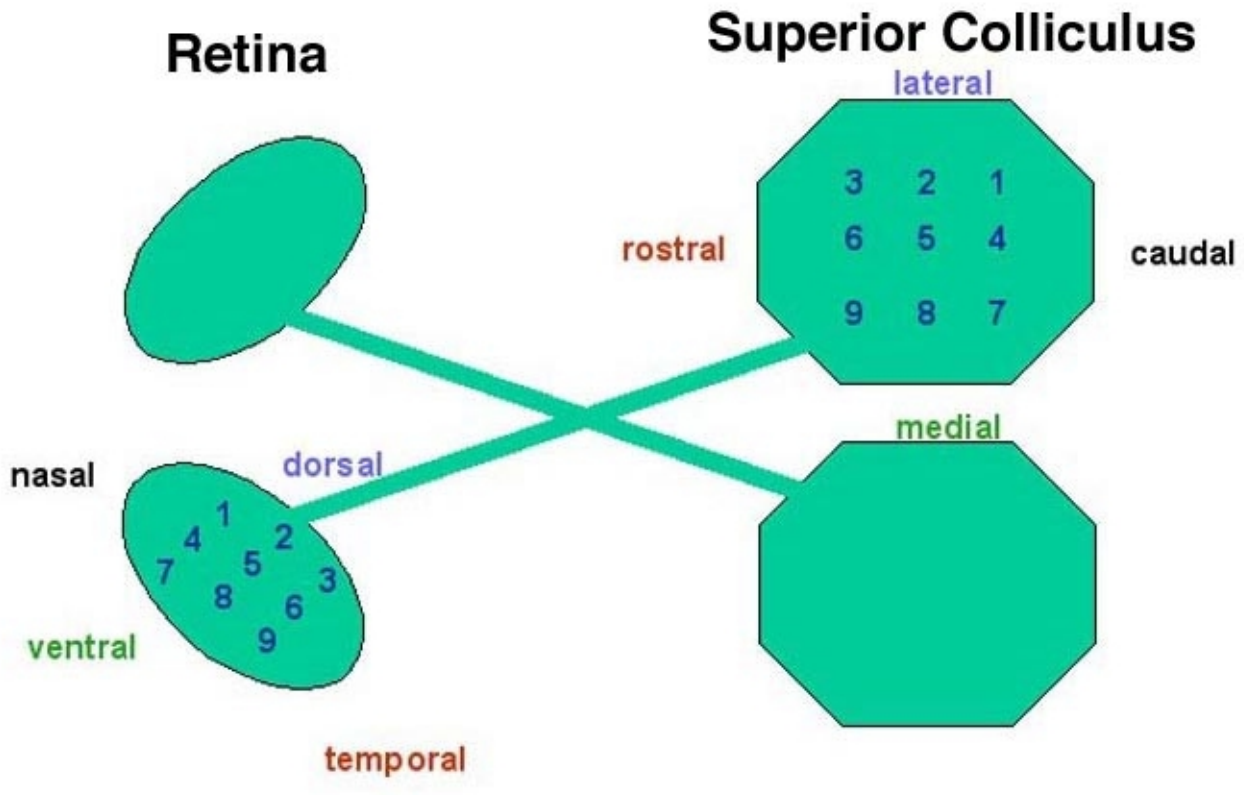

Figure 22. Ventral view schematic of retinotectal projections.

retina to be resumed within the region. Despite the likely neural circuit remodeling in a retinorecipient nucleus previously devoid of visual inputs, information processing within this particular nucleus should be relatively normal, and this becomes particularly important when cortical functions are involved. Finally, the information must have "significance" to the animal so that it can elaborate a suitable response strategy or develop a percept.

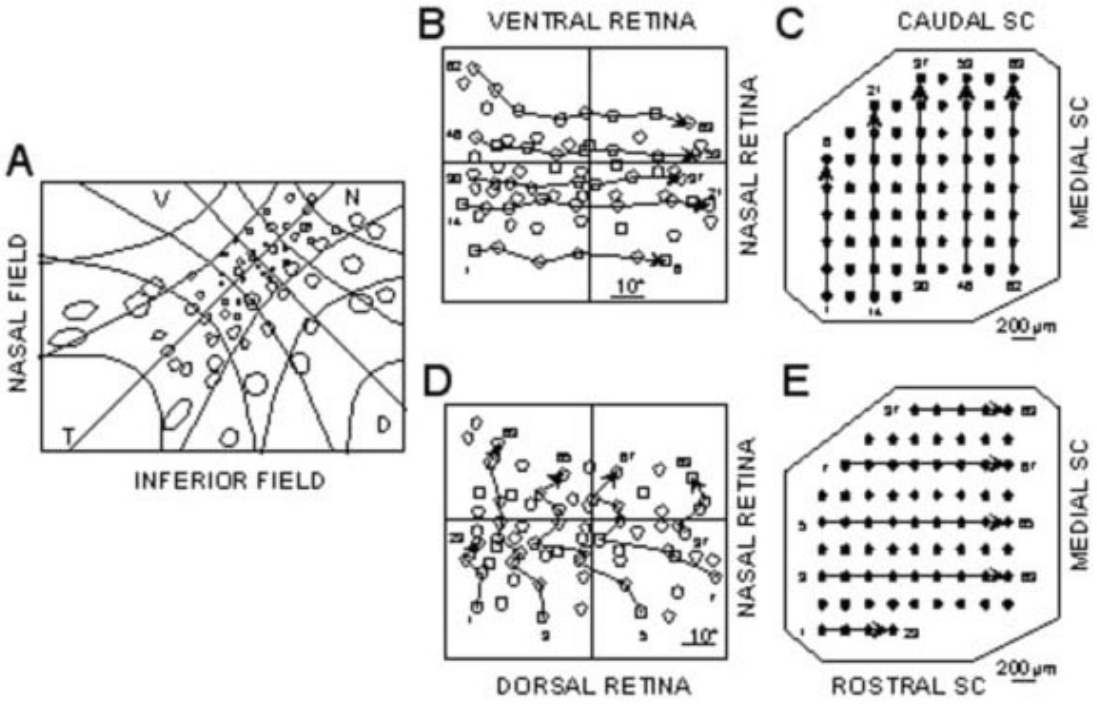

Figure 23. A, multiunit receptive fields were recorded from the left eye of a normal hamster, plotted on a tangent screen 20 cm from the eye, and viewed from the side of the screen opposite to the animal. The nasotemporal axis of the eye, defined by the position of the medial and lateral rectus muscles, is indicated by the line labeled NT. The projection of the optic disk is at the intersection with the orthogonal dorsoventral axis of the eye (line labeled DV). The calibration grids delineate 20°. B and D, the positions of these receptive fields are replotted as the corresponding positions on the retina with angular coordinates represented on a linear scale. C and E, the corresponding recording sites within the contralateral right SC are indicated. The numbers indicate the association of each receptive field with a recording site. Displacements from rostral to caudal of projection sites in the SC (C) are associated with parallel displacements from temporal to nasal of RGC positions in the retina (B), irrespective of the position in the retina or the SC. Displacements from lateral to medial of projection sites in the SC (E) are associated with less parallel displacements of RGC positions from dorsal to ventral in the retina (D). From Sauve et al. (24).

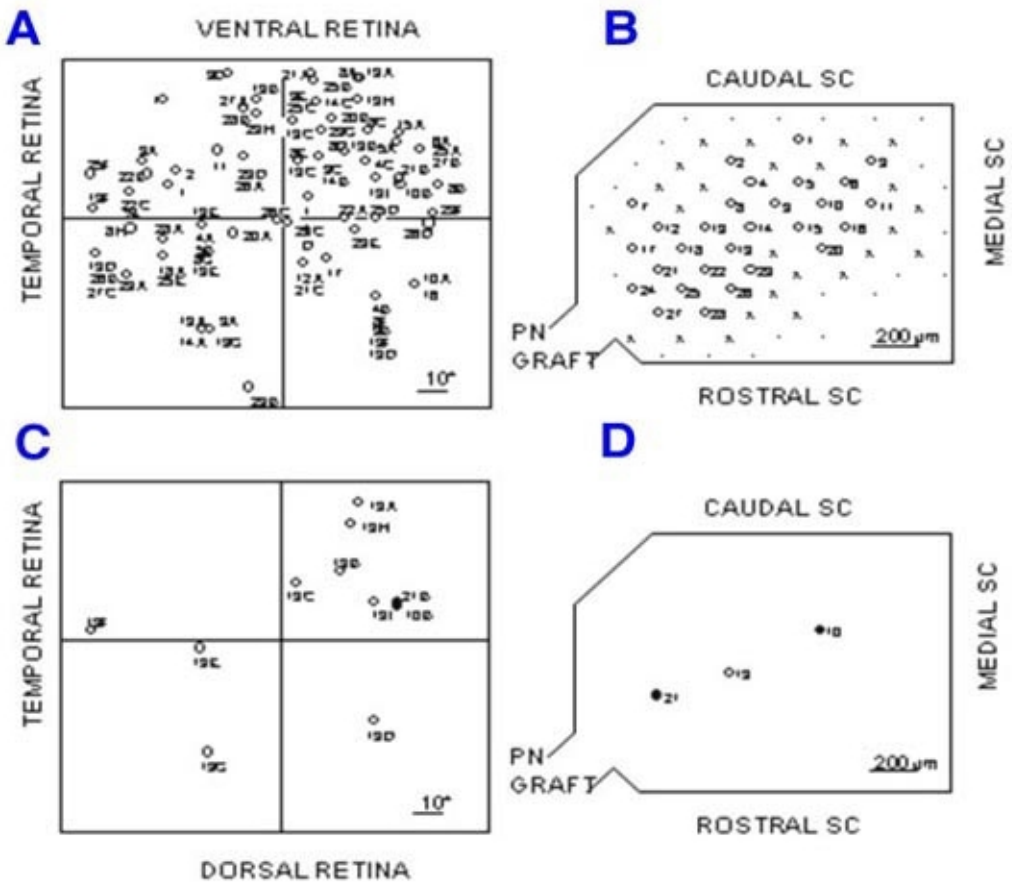

Figure 24. Positions of RGCs in the left retina and the projection sites of their respective axon terminals in the contralateral right SC of a grafted animal. Numbers refer to the recording sites in the SC. Letters indicate multiple receptive fields recorded at a single SC site. A, the positions of RGCs are inferred from the positions of the visual receptive fields as described in Fig. 1. The positions of RGCs are plotted on a linear scale in degrees from the optic disk, located at the intersection of the nasotemporal and ventrodorsal axes. B, in the diagram of the SC, the numbered open circles indicate recording sites at which unitary responses were recorded, crosses indicate sites at which responses to flash were recorded but receptive fields could not be identified, and filled squares are sites at which no visual response could be recorded. C and D, the lower diagrams, extracted from the upper diagrams (A and B), show projection of nine widely separated RGCs to the same recording site (site 19) in the SC (open circles) and projection of two neighboring RGCs to widely separated recording sites (sites 10, 21) in the SC (filled circles). PN, peripheral nerve. From Sauve et al. (24).

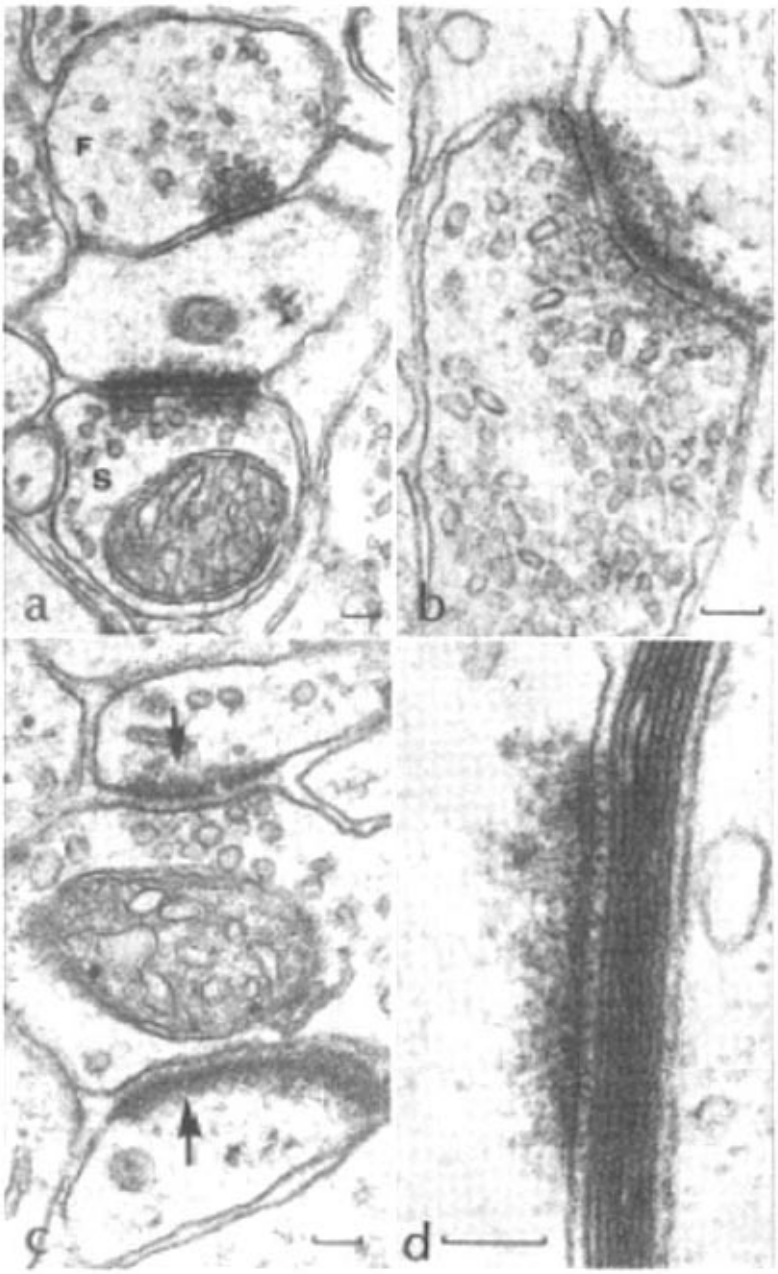

Figure 25. Details of a vesicle and contact morphology in the normal SC of the rat. a, normal S terminal make asymmetric contact (S) and F terminal make symmetric contact (F). b, an F terminal makes symmetric contact. c, an S terminal makes two asymmetric contacts (arrows); only one contact has vesicles aggregated to it. d, myelin lamellae make asymmetric contact. Scale indicates 0.1 μm. From Lund and Lund (152).

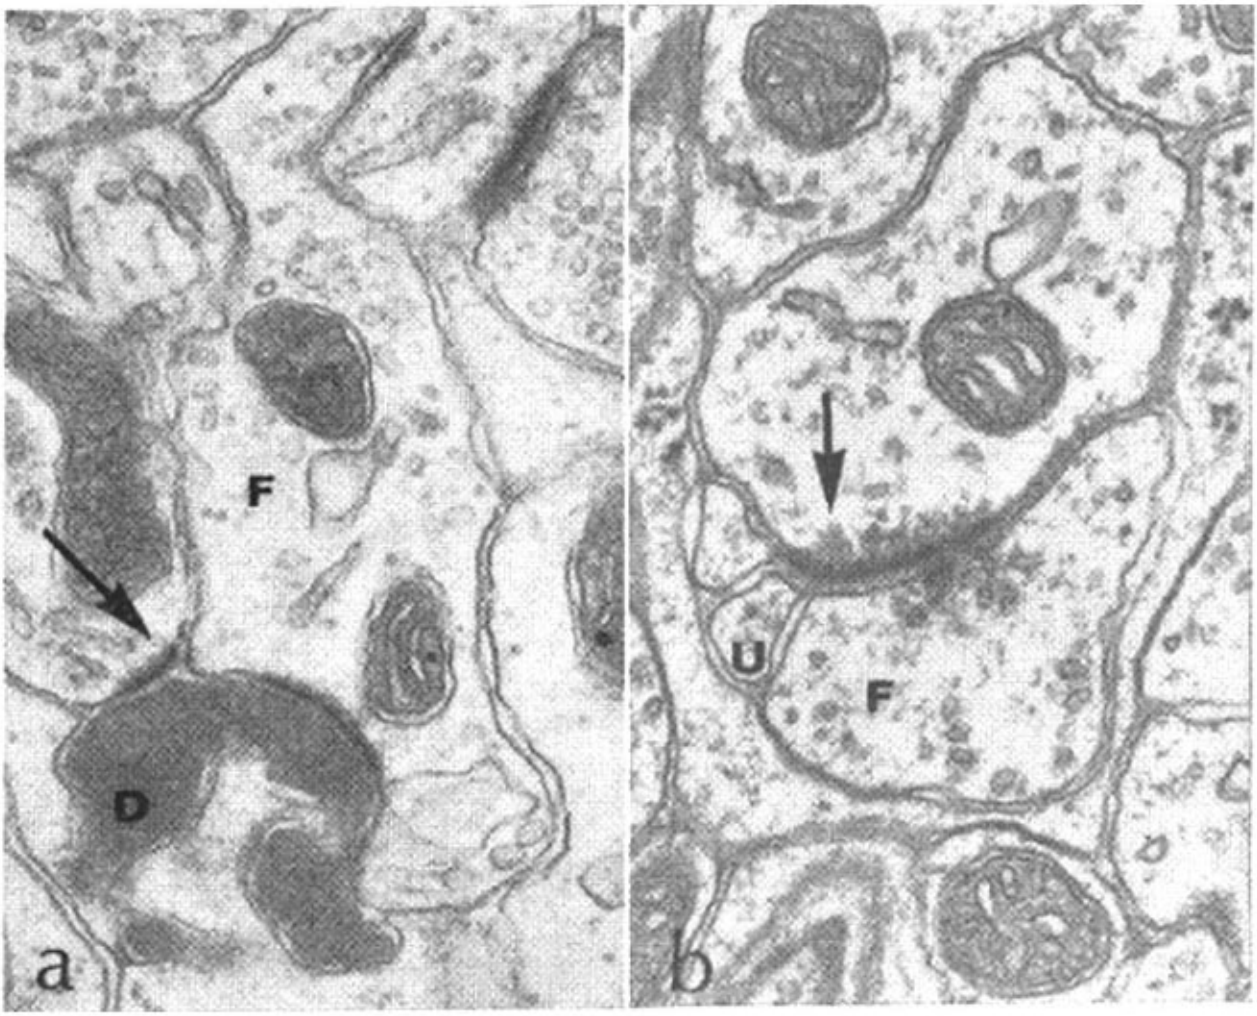

Figure 26. Partial occupation of postsynaptic contacts. a, the contact (arrow) has a degenerate terminal (D) and an F terminal (F) adjacent to it. b, the contact (arrow) is shared by an F terminal (F) and an unidentified profile (U). Magnification ×50,000. From Lund and Lund (152).

About the Authors

Dr. Yves Sauve was born in Montreal, Canada. He attended the University of Montreal where he received his B.Sc. in Biochemistry in 1983 and his M.Sc. in Neuroscience in 1988 with Dr. Thomas Reader, focusing on the neurochemistry of catecholamines and their receptors in the CNS. He then obtained his Ph.D. in Physiology under Dr. Michael Rasminsky at McGill University in 1995, where his research focused on the electrophysiological evaluation of reformed synapses between regenerating RGC axons and neurons in the superior colliculus, using the preparation developed in Dr. Albert Aguayo's group. Dr. Sauve subsequently undertook postdoctoral studies with Dr. Raymond Lund at the Institute of Ophthalmology (University College London), where he developed electrophysiological approaches to evaluate visual responsiveness in rodent models of retinal degeneration. In 2001, he became assistant professor of Ophthalmology and Visual Sciences at the Moran Eye Center (University of Utah), where he is currently evaluating rod and cone function following retinal degeneration, transplant therapies, and regeneration in the adult mammalian visual pathways.

Dr. Frederic Gaillard was born in Tours, France. He attended the University of Poitiers, where he received his B.Sc. (1969) and his M.Sc. (1971) in physiology. He then obtained a Ph.D. (1975) and a Doctorates-Sciences (1984) in neurophysiology. Until recently, most of his studies focused on aspects of binocular information processing in the amphibian visual system, mainly on the functional properties of the crossed isthmo-tectal pathway. He is now examining host-graft relationships in the adult mammalian visual system. Since 1977, Dr. Gaillard has been a senior investigator (Charge de recherches) of the Centre National de la Recherche Scientifique (CNRS) at the Institut de Physiologie et Biologie Cellulaires (UMR 6187), Poitiers, France.

Fetal Tissue Allografts in the Central Visual System of Rodents

Frederic Gaillard and Yves Sauve

Created: May 1, 2005; Updated: June 25, 2007.

Introduction

Injury to the brain areas concerned with vision can cause a variety of disorders ranging from visual field defects to much more complex deficits, such as visual agnosia. It all depends on the location and the extent of the damage. Injury to the occipital striate cortex results in corresponding homonymous visual field defects where typically all visual capacities are lost in the fields. Injury to occipito-temporal structures can affect discrimination, selection, and recognition of visual stimulus dimensions and, at higher stages of processing, of objects, faces, scenes, and letters (for review, see Zihl (1)) (Fig. 1).

Since the 1970s, numerous investigations have focused on trying to restore lost function by replacement of injured brain structures with homologous, allogeneic, embryonic neural tissue. Such approaches have even reached the clinical level as a therapy for the treatment of some neurological disorders such as Parkinson's and Huntington's diseases. With the exception of these specific cases, though, we are not yet ready to go to the clinic. Intracerebral grafting presently remains an experimental model used to address fundamental questions concerning brain development, neuronal plasticity, regeneration, and formation of topographic connections. The latter is a minimal requirement for functional recovery in point-to-point sensory systems such as the visual system (see previous chapter).

Putting fetal brain tissue grafts in the mature central nervous system (CNS) differs from peripheral nerve (PN) grafting in at least the following two ways. First, although a PN graft is used to bridge two brain areas, an intracerebral embryonic tissue graft is meant to restore the function of the damaged area. The fetal grafted tissue must develop its own set of connections with the right structures in the host brain, and these connections must be orderly arranged. Second, although all elements in PN grafting are at the same age, the intracerebral embryonic tissue graft is heterochronic with respect to the host tissue. For a short period after implantation, grafted tissue behaves as an immature piece of brain. Theoretically, this immature status should allow circuitry reconstruction. Donor embryonic cells have a greater potential for axonal outgrowth and regeneration than mature host neurons (2, 3). Thus, they may be better at establishing contacts with host target cells. Furthermore, the fetal graft may produce trophic factors or signaling cues, which are present in the brain only at early developmental stages, and should reactivate neurotropic processes in "dormant" host neuron populations. For instance, embryonic cortical transplants will produce NT-3, which is absent from the cortex past 2 weeks of age (4, 5). In vitro assays (6) have shown that NT-3 has dual effects on layer 2-3 and layer 6 cortical neurons. Fifteen days after implant, cortical grafts will also produce a glial cell line-derived neurotrophic factor (GDNF), a potent survival factor for claustral neurons that project to the occipital cortex (7, 8).

Unfortunately, there is abundant literature suggesting that environmental constraints from the mature host brain alter the restorative capacities of fetal grafts in various ways. First, the mature environment affects both the number of surviving neurons within a graft and the size of the graft itself (9-12). Second, the mature CNS environment is non-permissive for axonal regeneration of host neurons (13-17) (see section 2 from the previous chapter). Third, the mature CNS environment is poorly permissive for receiving outgrowing axons from embryonic allogeneic neurons (18-23).

These above-mentioned results suggest that intracerebral embryonic tissue grafts might only be effective in "diffuse" projection systems, i.e., by exerting a paracrine effect (24-28). In opposition to this, a few investigations have demonstrated that such grafts can restore, at least partially, complex motor behaviors (skilled forelimb reaching for food) that require a precise interaction between neuronal circuits, much more than expected of

paracrine effects (19, 29, 30). However, even in such reports, the donor neurons appear to establish a very limited number of connections with the host.

Pioneer work in the visual system model was done in the mid-1970s by Drs. Raymond Lund and Alan Harvey and colleagues, who transplanted parts of the embryonic CNS to various brain locations in neonatal rats (for a review, see Lund (31)). Most of their studies were focused on CNS development and, therefore, consisted of examining whether such grafts developed near-normal architecture and established extensive connections with appropriate host structures. The outcome of fetal grafts into adult hosts has been studied less extensively, but a limited number of reports suggest that fetal tissues can integrate functionally within the adult host CNS. We will review these investigations that, in contrast to the mainstream opinion, show that tectal and cortical allografts can receive highly ordered inputs and can project to distant visual targets in the adult brain.

The Visual System of Rodents: A Brief Overview

Unless reconstruction of neural circuitries comparable to normal in terms of amount, extension, and topical organization are achieved, we cannot expect complete functional recovery in point-to-point neural systems. The normal structural and functional organization of the visual system of adult rodents has been investigated extensively and now forms a basis for regeneration experiments (for reviews, see Sefton and Dreher (32), Zilles and Wree (33), and Sefton et al (34)). A brief summary of the major findings is given below for comparative purposes.

Retinal Output

In the adult rat, virtually all (>95%) retinal ganglion cells (RGCs) project contralaterally to the superior colliculus (SC) and to the dorsal division of the lateral geniculate nucleus (DLG). In the SC, axons from the retina enter at the level of the stratum opticum (SO) and arborize in the SO and the superficial gray layer (SGL). Dense terminals are also found in lateral posterior nucleus, LP; ventral division of the lateral geniculate nucleus, magnocellular part, VLG; intergeniculate leaflet, IGL; and pretectal nuclei (nucleus of the optic tract, OT; olivary pretectal nucleus, OPT; posterior pretectal nucleus, PPT). Some of these inputs (30-50%) are collateral branches of retinocollicular axons. A small contingent (<5%) of the RGCs contacts the same structures ipsilaterally. Thus, each retinorecipient center receives input from both eyes. Sparse projections are found in the suprachiasmatic nucleus (SCN), the various nuclei of the accessory optic system, the hypothalamus, and the inferior colliculus. A schematic view of these connections is given in Fig. 6 of the previous chapter.

Subcortical Network

The DLG is much more than a relay center for RGC projections to the cortex. In fact, it receives most of its input from structures other than the retina, namely the visual thalamic reticular nucleus (Rt), layer 6 small pyramidal neurons in the occipital cortex (areas 17, 18, 18a; also called, respectively, areas Oc1, Oc2M, Oc2L; or areas V1, V2M, V2L), the SC (SGL layer), some pretectal nuclei (OT, OPT), and the contralateral parabigeminal nucleus (PBg), a homolog of the isthmo-optic nucleus in lower vertebrates. Projections arising from relay cells in the DLG are restricted to Rt (dorsal part) and occipital cortex.

The retinorecipient layers of the SC have reciprocal connections with the VLG, the pretectum, and the ipsilateral PBg nucleus (ventral and dorsal divisions). They receive further afferents from the contralateral PBg and from layer 5 pyramidal neurons in the visual cortex. Major efferents go to the DLG, the LP thalamic nucleus, and to the intermediate (IGL) and deep (DpL) gray layers of the SC, where other sensory systems are represented. The LP nucleus (equivalent of the LP-pulvinar in cats and of the pulvinar in primates) has reciprocal connections with visual (mainly Oc2L, layers 5 and 6) and temporal areas in the ipsilateral cortex. The LP receives additional inputs from the Rt, zona incerta (ZI), and the pretectum (OT). Neurons in the IGL and DpL layers of the SC project to various structures in the pons, brain stem, cervical spinal cord, and hypothalamus.

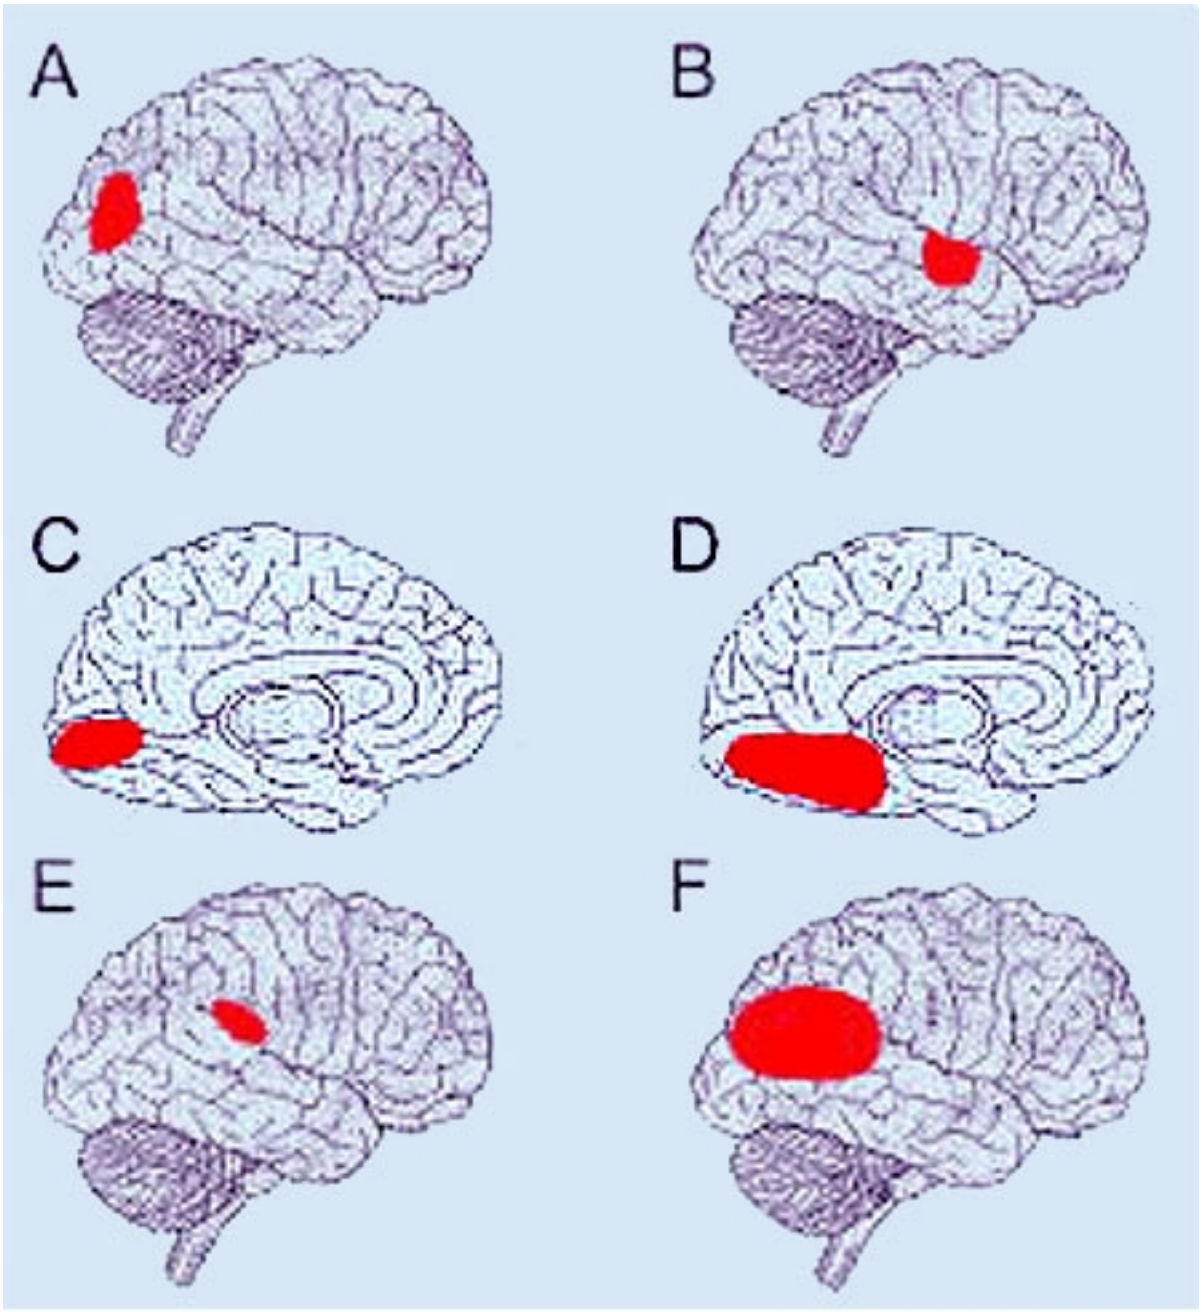

Figure 1. Visual deficits in human and related injured brain regions. A, visual location (lateral occipital gyrus). B, motion blindness (middle temporal gyrus). C, achromatopsia (occipito-temporal gyrus). D, visual agnosia (posterior and medial temporo-occipital cortex). E, visual neglect (inferior parietal lobe). F, Balint-Holmes syndrome (posterior parietal lobe). For more details, see Zihl (1).

The VLG has reciprocal connections with the pretectum (OT, OPT and APT, the anterior pretectal nucleus), SC (SGL and SO layers), and its contralateral homolog. It receives further projection from the occipital cortex (layer 5 neurons) and projects to the ZI, central gray, pons, and the suprachiasmatic nucleus (SCN). Finally, in addition to retinal and collicular inputs, the pretectum receives cortical afferents from the occipital cortex and projects to the LP, to the adjacent lateraldorsal (LD) thalamic nucleus (which has reciprocal connections with the occipital cortex), and to the pons (largely to the reticulotegmental nucleus) (Fig. 2).

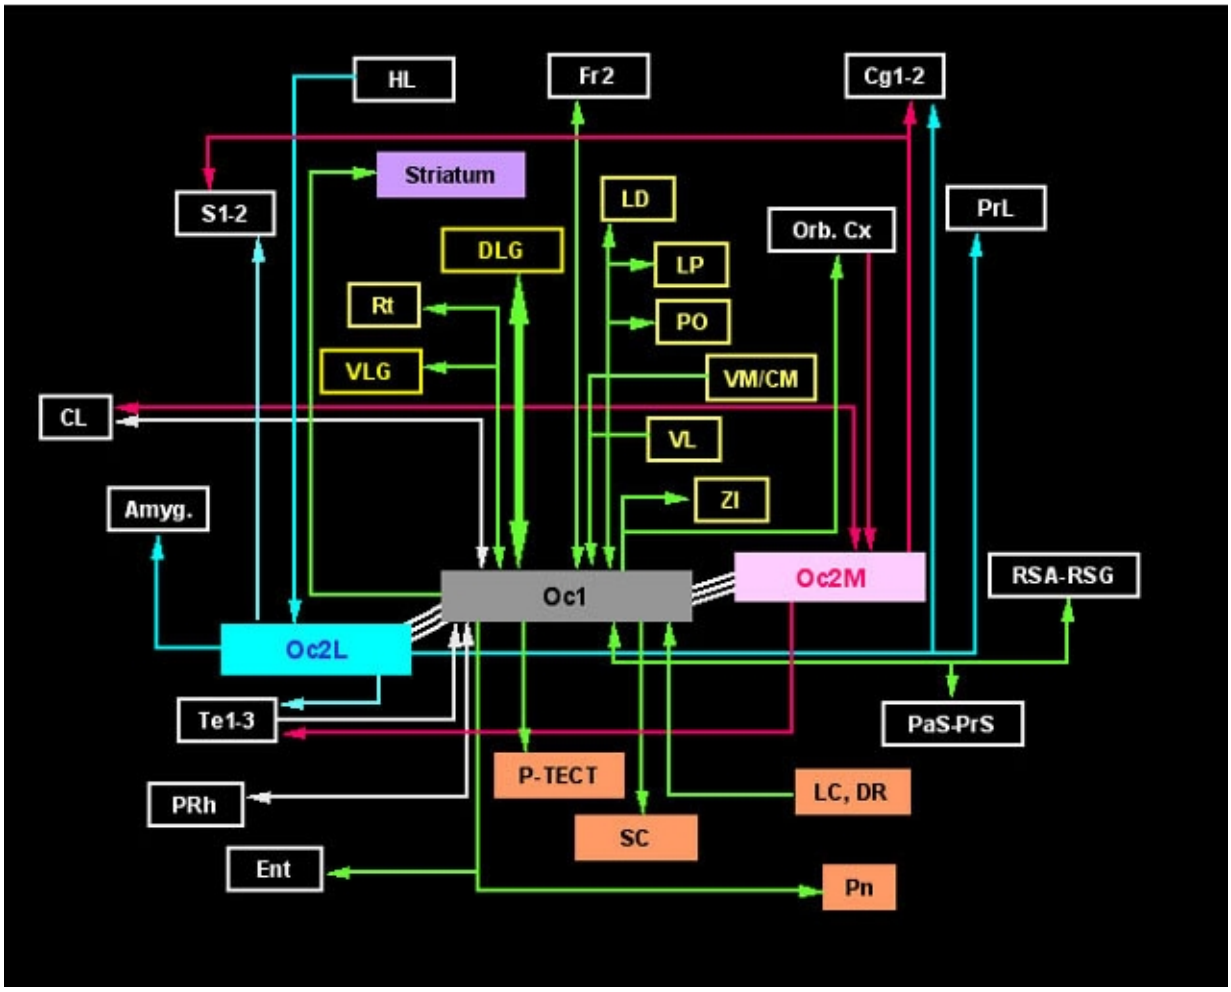

Figure 2. Major ipsilateral connections (designed as arrows) of the visual cortex of rodents. Green-coded connections are valid for all areas. Specific, additional connections for Oc1 (area 17) are white coded; those for Oc2M (area 18) are red coded; and those for Oc2L (area 18a) are blue coded. Reciprocal connections between visual areas are symbolized by large stripes. Abbreviations are given in text.

Cortical Network

Afferents to cortical area Oc1 originate predominantly from the three thalamic relay nuclei: DLG, LP, and LD. Termination sites are localized in layers 4, lower 3, 6, and 1. Other thalamic sources are the posterior complex (Po), ventromedian (VM), centromedian (CM), and the ventrolateral (VL) nuclei. Projections from Po and VM terminate in layer 1; those from CM and VL in layers 1 and 6. Further afferents are provided by frontal (Fr2), temporal (Te1-2), retrosplenial (RSA/RSG), perirhinal (PRh), and adjacent visual areas in the ipsilateral cortex. With respect to this scheme, area Oc2M receives no afferent from Te2 and PRh but an additional input from orbital cortical areas (MO/VO/VLO), whereas area Oc2L receives no afferent from Te1 and PRh but an additional input from the hindlimb region (HL) in the sensorimotor cortex. Afferents from the claustrum (CL) are mostly distributed in the infragranular layers of Oc1 and/or Oc2M areas (35, 36). Oc1-2 areas also receive some callosal inputs from visual areas (layer 2-3 and 5-6 neurons) in the opposite cortex. Callosal terminations extend throughout the cortical depth at the borders of area Oc1 and adjacent extrastriate areas as well as in multiple patches through Oc2M-L areas. Prominent labeling also occurs in the infragranular layers of the temporal cortex. Finally, the visual cortex and subcortical retinorecipient nuclei both receive nonspecific cholinergic, noradrenergic, and serotonergic innervations from various structures in the basal forebrain, from locus coeruleus (LC) and from dorsal raphe nuclei (DR), respectively.

In addition to reciprocal connections, visual cortical areas have widespread ipsilateral projections through the normal adult brain. At the cortical level, efferents from area Oc1 are found into the dorsomedial frontal area Fr2 (layers 1 and 6), the ventrolateral orbital area (VLO), the retrosplenial areas (layers 1 and 6), the perirhinal area (layer 5-6, up to the caudalmost pole of the cortex), and the entorhinal cortex. Additional efferents originating from area Oc2M are observed in the cingulate area Cg1, the parietal areas S1-2 (caudal part; layers 1-3 and 6), the temporal areas Te1-3 (layer 1-3 and 6, mainly), and the claustrum (full extent). Efferents from area Oc2L also target the dorsal half of the prelimbic cortex (PrL area) as well as lateral, basal, and central amygdaloid nuclei (37). Projections from Oc2 areas to Fr2 and Cg1 extend up to the rostralmost pole of the cortex. At the subcortical level, Oc1 and Oc2 areas have dense terminals in hippocampal structures (presubiculum, PrS; and parasubiculum, PaS), striatum (the dorsomedial portion) (38), visual thalamic nuclei (DLG, VLG, LP/LD, Po, Rt), ZI, various pretectal nuclei (P-TECT), SGL and IGL layers of the SC, and pontine nuclei (dorsolateral division) (39). Contralateral projections are confined to Oc1-2 and Te1 areas as well as, but sparsely, to the dorsomedial sector of the striatum and the dorsolateral subdivision of the amygdala.

Visual Field Topography

Retinofugal axons arising in different retinal quadrants maintain their relative positions in the optic nerve, lose this initial order as they progress toward the chiasm, and reform a distinct dorsal-ventral arrangement in the optic tract before reaching primary visual targets, where they terminate in a precise topographic manner (40-43). Retinotopy in visual centers was first seen by Lashley (44, 45) and then abundantly documented by both electrophysiological and anatomical approaches (46-52). Recently, optical imaging techniques have confirmed all previous findings (53, 54). A schematic representation of the visual field topography onto the DLG, SC, and visual cortex is given below (Fig. 3).

At the geniculate level (Fig. 3, A and D), the nasal field (temporal retina) is represented caudally and dorsomedially; the temporal field (nasal retina) occupies most of the rostral part of the nucleus; the lower field (upper retina) is mostly represented in the caudal part of the nucleus, lateroventrally; and the upper field (lower retina) projects mainly to the rostral part of the nucleus, dorsally. The dorsomedial part of the DLG also receives input from the lower temporal quadrant (red sector; Fig. 3B) of the ipsilateral retina. On the contralateral SC (Fig. 3, A and C), the nasal visual field is mapped rostrally; the temporal visual field, caudally; the upper field, medially; and the lower field, laterally. In rats, the representation of the central visual field is not substantially magnified. The ipsilateral retinal contingent projects anteromedially (red sector; Fig. 3B).

At the cortical level (area Oc1/17), the naso-temporal axis of the visual field projects from lateral to medial, the lower field (upper retina) projects rostrally, and the upper field projects caudally. A restricted caudal region of area Oc1 receives input from the ipsilateral retina. The vertical meridian (body axis) is set at the border between area 17 and area 18. Beyond this point, the naso-temporal direction is inverted. Borderline zones in areas 17 and 18 contain binocular neurons. Multiple ordered representations of the visual field are present in the adjacent extrastriate areas (for discussion, see Rosa and Krubitzer (55)).

Standard Strategy for Intracerebral Transplantation: Graft Morphology

Grafts usually consist of blocks or sheets of neural tissue excised from 15-16-day-old (E15-16) embryos, which are put into previously surgically made cavities in the host. Older grafts survive poorly and have reduced size (56, 57). Although not critical for axonal sprouting (see below), delayed implantation has been assumed to enhance cell survival and outgrowth (58-60), probably because endogenous neurotrophic factors can accumulate at the lesion site (61) (Fig. 4).

As in newborns (62, 63), primary connections with the host brain appear 3-4 days after transplantation (64), whereas neovascularization and blood supply require approximately another week to be completed, a delay that

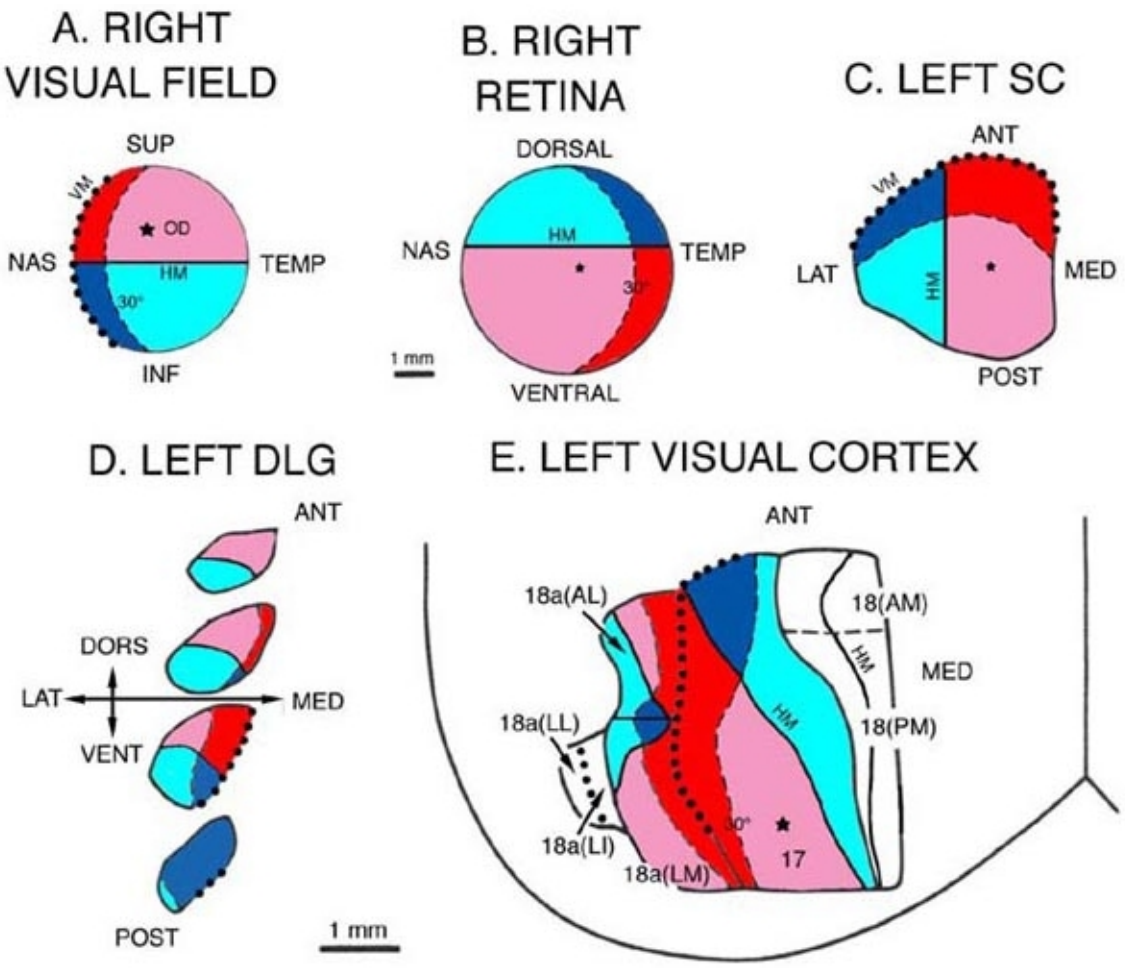

Figure 3. Schematic representation of the right visual field topography onto the DLG, SC, and visual cortex of normal rats. Color code: red, upper nasal field; pink, upper temporal field; deep blue, lower nasal field; sky blue, lower temporal field. Subdivisions of extrastriate areas are from Espinoza and Thomas (47). Visual topography in areas 18 (AM/PM) and 18a (LL/LI) is not shown. may seriously hamper graft cell metabolism (65). Nonetheless, both graft implantation and development in adults can be as successful as in neonate recipients (62, 66, 67). Investigations are usually performed 3-4 months after grafting.

In serial histological sections, all implants look like disorganized cellular masses that are more or less clearly separated from the host tissue by a region of lower cell density or host white matter. Glial scarring at the host-graft interface, although highly variable, is usually minimal (60, 68). At this time point, graft development is achieved. Most neurons in cortical grafts (60-80%) seem mature (expression of Hu/Elav proteins) (66) and look "normal" at the ultrastructural level (69). The remaining neurons have immature characteristics, such as multiple nucleoli or binuclear somas (60, 70) (Fig. 5).

A typical feature of fetal tectal tissue transplants in adult hosts is the presence of dorsally located, myelinated "fiber-free" areas (Fig. 6). In addition, there is a proponderance of cells with small perikarya and short dendrites (67, 71), a relatively high acetylcholinesterase (AChE) activity, a high concentration of alpha-bungarotoxin binding sites, and a low number of neuroglial elements (57, 72-74). Similar characteristics are found in the

retinorecipient layers of the SC in normal rats. In neonate hosts, the "fiber-free" layer over the "fiber-rich" core of the graft (Fig. 6) is penetrated by regenerated retinal afferents (75, 76).

Grafts of blocks of fetal cortex lack the typical layered organization when integrating into the host CNS. Neurons are 60-80% of the normal density and gathered into clusters separated by myelinated bundles (Fig. 7, A-C). They also contain high number of neuroglial and microglial cells (69). Regardless of their origin, cortical grafts typically receive diffuse cholinergic and aminergic input, mostly in their lower part, near the corpus callosum (66, 77-79).

Although roughly similar at a first glance, different cortical grafts show differences in their neuronal phenotypes. On the basis of Golgi-Cox stained material, Aleksandrova and Girman (80) proposed a three-group classification:

- Type I: grafts contain multiple neuron morphologies resembling those in the normal cortex. The small layer 2-3 pyramids have small or medium perikarya (10-16 and 20-26 μm in diameter, respectively) and apical dendrites running for considerable distances along the graft boundary with unpredictable orientations.
- Type II: grafts contain a single class of multipolar neuron with oval or pyriform soma, a short apical dendrite, and several thick processes. Soma sizes are typically large or hypertrophied, ranging between 16 and 50 μm in diameter (Fig. 7D).
- Type III: grafts have intermediate characteristics. In addition to the neuronal phenotypes found in the first group, one-third of the neurons have large somas (30-32 μm in diameter). Interestingly, whereas type I and III graft neurons respond to visual stimuli (see below), type II graft neurons do not, displaying only highly synchronized, burst-like spontaneous discharges (Fig. 10). It remains to be clarified whether unresponsiveness is linked to abnormal neuron morphology or lack of input(s), or both (81).

Neurons within the Transplant Can Be Driven by Host Eye Visual Stimulation

What we learned from the above-mentioned and other histological studies is that fetal tissue blocks grafted in a mature brain will never develop the specific architecture of the normal tissue that they replace. They lack continuity with the host tissue, intrinsic laminar organization, and neuronal arrangement in columns. Structural disorganization, however, does not prevent the formation of synapses able to excite grafted neurons (69, 82-86). Girman and Golovina (87) provided indisputable evidence that both transplanted tectal and cortical neurons can respond to visual stimuli presented to the adult host eye.

Tectal Graft Responsiveness

Girman (71) reported good visual activity in about half of the tectal implants. Spontaneously active at rest, single-units respond to flashing light spots as well as to stationary and manually moved targets (5-16 degrees in diameter) with circular receptive fields (RFs). Best responses are obtained with small (3-5 degrees in diameter) black disks moved on a white background. Some units (29%) are direction selective. Response latencies to flashing spots (Fig. 8) are in the normal range. Tactile and auditory stimuli are ineffectual. No visual response can be recorded in cortical tissue grafts placed at the tectal level.

Cortical Graft Responsiveness

Both field potential (FP) and single-unit recordings have been done in types I and III cortical grafts. FPs in grafts always consist of a negative/positive component. Wave onset and peak have normal latencies (66, 87-89). However, it is interesting to note that none of the FPs undergo polarity reversal with depth, as occus in the

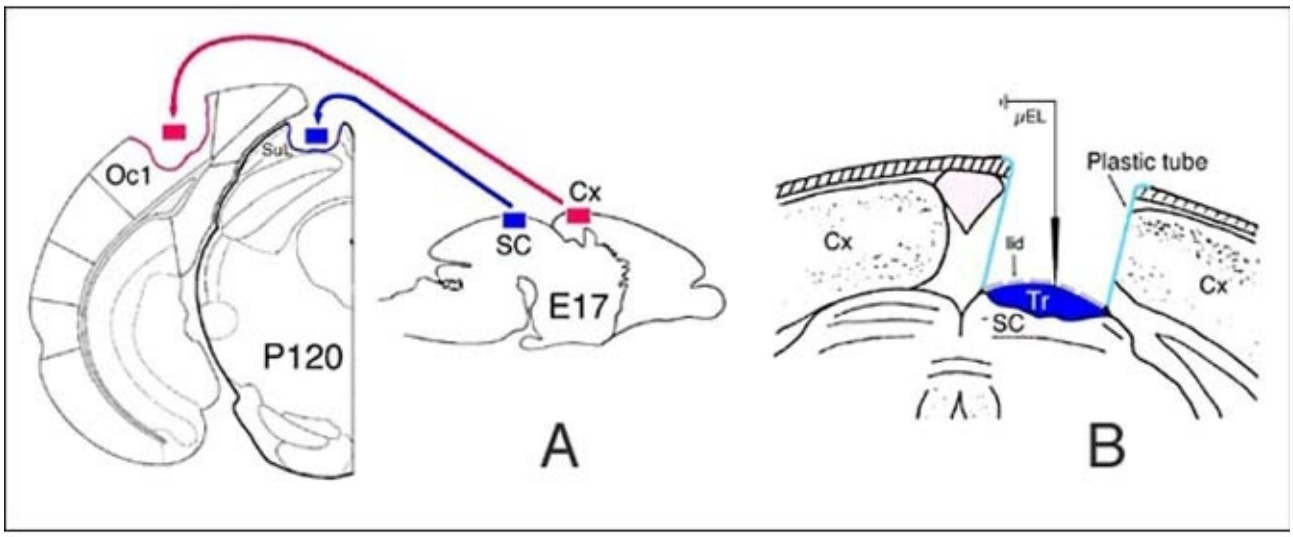

Figure 4. Basic transplantation protocols. A, for current anatomical studies. Blocks of embryonic tissue were implanted in aspirated lesion cavities performed in the host brain 3 days earlier. normal rat primary visual cortex (90), and peak amplitudes correlate with the density of afferents (Fig. 9 and Fig. 10).

Although recording field potentials is useful for delineating the graft outer limits and the most active zones within the graft for tracer injections, field potentials do not mean that these neurons can actually partake in any visual operation. Girman and Golovina (87), however, showed, at the single-unit level, that many graft neurons did respond to visual stimuli. Approximately 84% of the spontaneously active neurons in type I grafts have well-defined RFs (5-20 degrees in diameter; Fig. 11) and exhibit clear responses for either moving or stationary stimuli. Cells preferring the same stimulus seem to be in clusters. Flashing light spots typically evoke a biphasic excitatory/inhibitory response of 36-62 ms latency, followed by a second excitatory discharge. Movement-sensitive neurons fire weakly, or not at all, to light spots. Most of them show clear direction selectivity and orientation specificity. A few active neurons (16.5%) can be driven by stimulation of either eye, the contralateral stimulation being dominant. Visually driven neurons are less frequently encountered in type III grafts. These neurons have larger RFs (20-30 degrees) and react only to light spots after a long delay (100-250 ms).

Finally, graft neurons also fire in response to electrical stimulation (10-50 µA) of either the host ipsilateral DLG nucleus or the contralateral visual cortex. An important finding, suggestive of some form of topographic organization between the DLG and the cortical graft, is that small displacements (200 µm) of the stimulating electrode from the optimal geniculate site lead to a decrease or a complete loss of response.

Are Responses from the Graft Retinotopically Ordered?

To a degree, they are. The same studies by Girman and Golovina (87) indicate that large (3 mm in diameter), highly responsive cortical grafts contain an ordered representation of the contralateral visual field, at least of its central part, which projects normally onto area 17. First, neurons recorded simultaneously at a given electrode position have roughly the same RF location. Second, there is no change in RF position with depth during a single penetration. Third, ordered changes in the recording positions on the graft surface induce concomitant changes in the RF locations. Fourth, the orientation of the visual field projection onto the graft appears normal relative to the skull landmarks (Fig. 12). A rough retinotopic order is also observed in large, type III grafts. The larger the grafts, the better the visual field projection: small grafts contain only a non-ordered representation of a

restricted part (20-30 degrees wide) of the nasal visual field. Visual map order and neuron properties remain unchanged up to at least 10 months after grafting. This is a logical result in view of the fact that long-term survival (2 years *in situ*) does not significantly affect the basic morphological features of cortical grafts (91).

Do Grafts Receive Extensive Afferents?

By this point, it seems evident that under some highly controlled and replicable experimental conditions, allogeneic fetal tissue grafts implanted at homotopic positions in the visual brain can respond to visual stimulation of the host eye. Some cells from the graft perform rather complex operations of visual driven signals, just like the SC and area 17 in the normal rat (92-95). The graft can resume at least a partial, ordered map of the visual field, a prerequisite for recovery of function. However, topographic visual field representation on a graft is likely to involve many more regenerated host afferents than the few, randomly branching fibers reportedly able to generate light flash responses in the PN graft paradigm (96-98). Direction selectivity, orientation specificity, and binocular activation imply sophisticated synaptic input to graft neurons (99). The next question, then, is

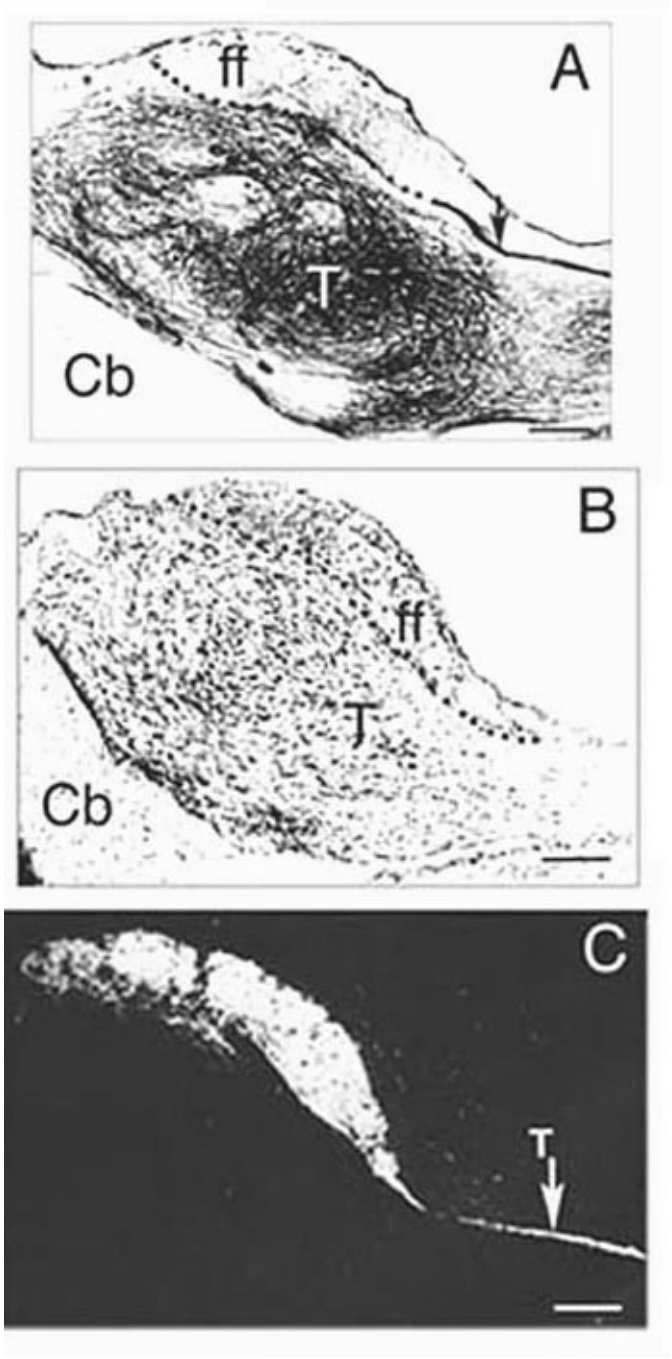

Figure 6. Typical morphological features of embryonic tectal grafts (sheets of tissue) in neonate hosts. A, Holmes neurofibrillar staining. Note the fiber-free (ff) area covering the fiber-rich core of the graft (T). B, Nissl staining. C, widespread retinal input throughout the fiber-free lamina. whether homologous fetal grafts in the adult primary visual cortex receive extensive input from appropriate brain areas.

Tectal Graft Connectivity

The actual substrate of the visual responses recorded in tectal grafts is a puzzling, still unsolved problem. Receptive field properties, latency values, and ordered organization together suggest the presence of direct, widely distributed host retinal input to the grafts. However, the early studies in neonate hosts showed that retinal

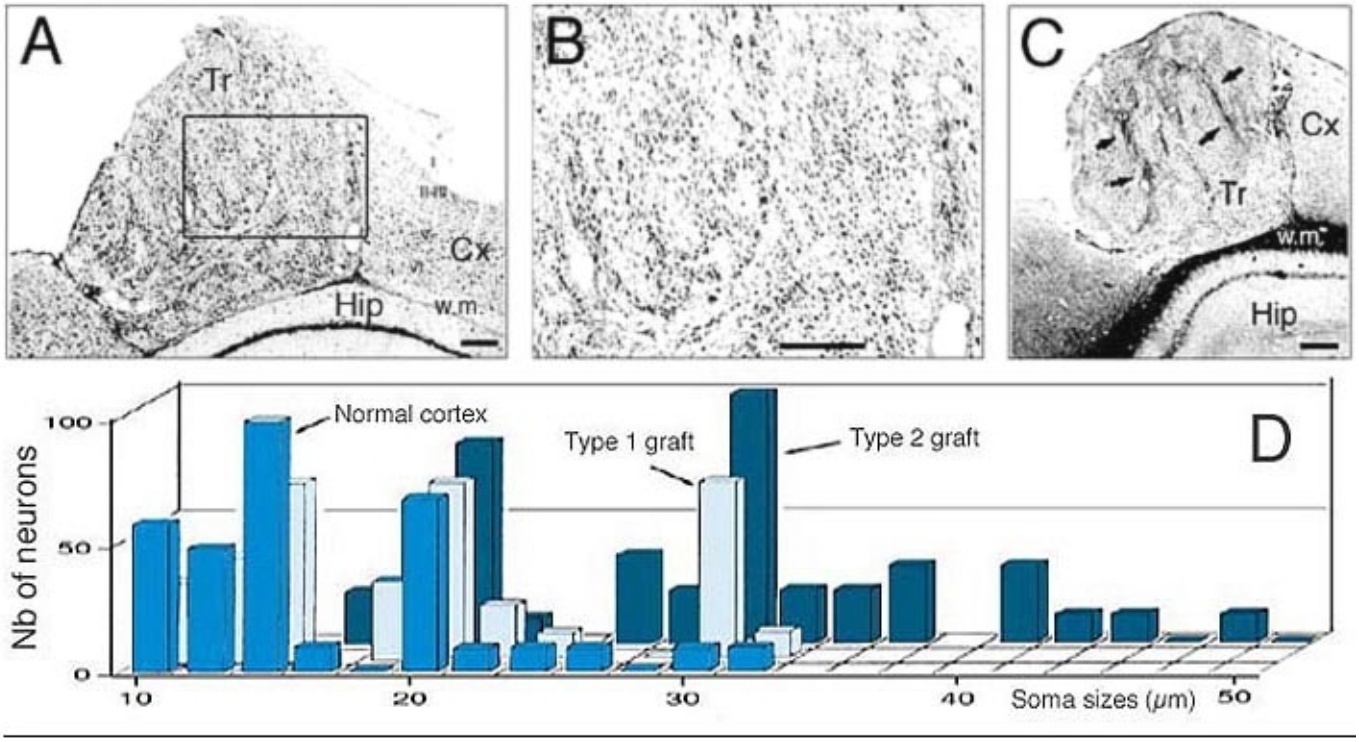

Figure 7. Gross morphology of cortical grafts. A, absence of lamination. Cresyl violet staining. B, typical cell cluster (inset in A). C, intragraft myelin sheets (arrows). Luxol blue staining. afferents never filled the transplants and were restricted to discrete, fiber-free patches. Within these patches, the density of optic terminals was nearly equivalent to that seen in the stratum griseum superficiale of normal rats. By electron microscopy, these terminals made asymmetric (excitatory) contacts onto small, post-synaptic profiles, many of which were dendritic spines (75). However, in striking contrast with Girman's findings, neither visually (light flash and moving disk) nor electrically (optic nerve stimulation) evoked activity were obtained from these grafts (100, 101). Only a minor fraction of the tested units could be excited orthodromically from the ipsilateral visual cortex, the major source of graft input in these preparations (Fig. 8). The failure to record retinal activity in the latter experiments could be attributable to the low number of electrode tracks.

Tectal tissue grafts implanted in juvenile (P15/P18) and adult hosts with the same technical approach also display discrete "fiber-free" patches dispersed dorsally within the fiber-rich core. However, no definitive projections from the host brain have been identified (67), and retinal innervation to the patches remains a matter of debate (67, 73, 102, 103). In short, there is yet very little anatomical evidence for the visual responsiveness recorded in tectal grafts. As suggested earlier by Golden et al. (100), a possible reason for this discrepancy may be the grafting technique. Although grafts done by Golden et al. (100) consist of partly dissociated cells injected onto the surface of the SC, the transplants done by Girman consist of "solid sheets of embryonic tectal tissue laid in the appropriate dorsoventral orientation over the SC surface devoid of superficial laminae". In neonates, a similar paradigm as used by Girman leads to the formation of a single, densely innervated retinorecipient lamina covering a large part of the graft surface (Fig. 6) (75). Up to now, neither the connectivity nor the neurofibrillar structure of such tectal implants in adult hosts have been studied.

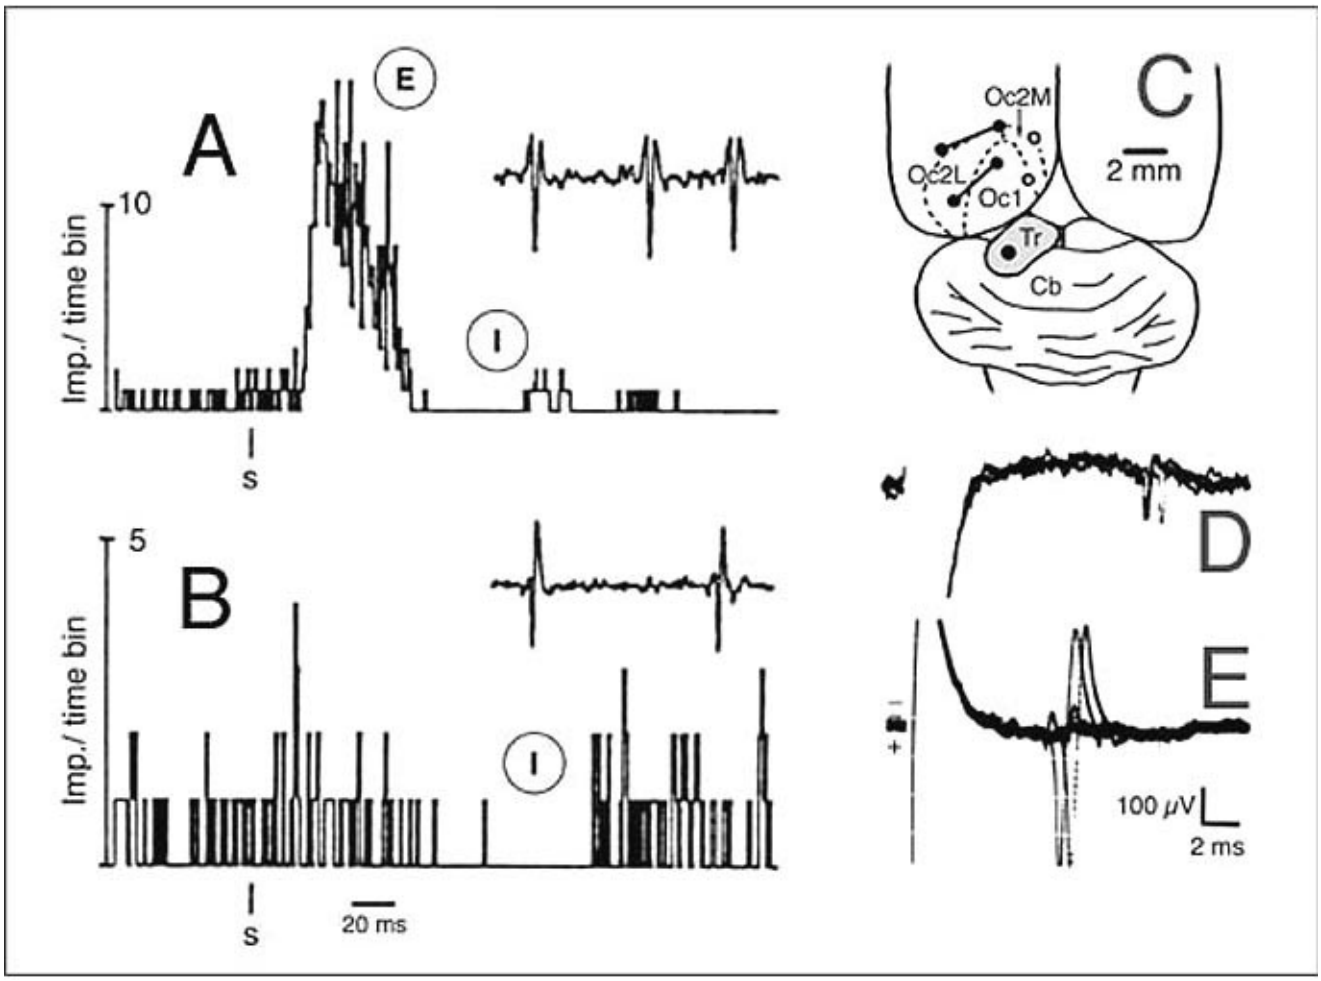

Figure 8. Neuronal discharges in visually responsive (A) and unresponsive (B) tectal grafts in response to light flashes (s). PSTH for 30 presentations. E, excitatory phase; I, inhibitory phase. (101).

Host Afferents to Cortical Grafts

As the electrophysiological data suggest, there should be a strong relationship between graft responsiveness and the presence of regenerating axons (or collateral sprouts) from ipsilateral DLG neurons. Indeed, retrograde tracers injected in type I grafts label high numbers of DLG neurons (one-third of which projected initially to the lesioned cortical site), whereas similar injections in type II grafts produce no labeling at all (81). Whether direct DLG input alone can account for graft visual responsiveness is, however, very unlikely, because some type I grafts receive only extra-geniculate, and no direct geniculate, inputs.

Major Graft Input Originates in Host Layer 5-6

After retrograde tracer (CTB, cholera toxin, b subunit) injection into types I-III grafts, Gaillard and colleagues (66, 88, 89) saw a diversity of afferents. These afferents (always in very low number; Fig. 17) appear in visual-related brain structures ipsilateral to the graft. The densest labeling (55-90%) is observed in the isocortex, mostly in the occipital areas surrounding the graft (see also Galick et al. (104) and Schultz et al. (78)). Together, neurons in claustrum, periallocortical areas, and various non-visual subcortical nuclei account for some 20% of the graft input. As expected, labeling in dorsal thalamus is highly variable. Although practically absent in one-half of the

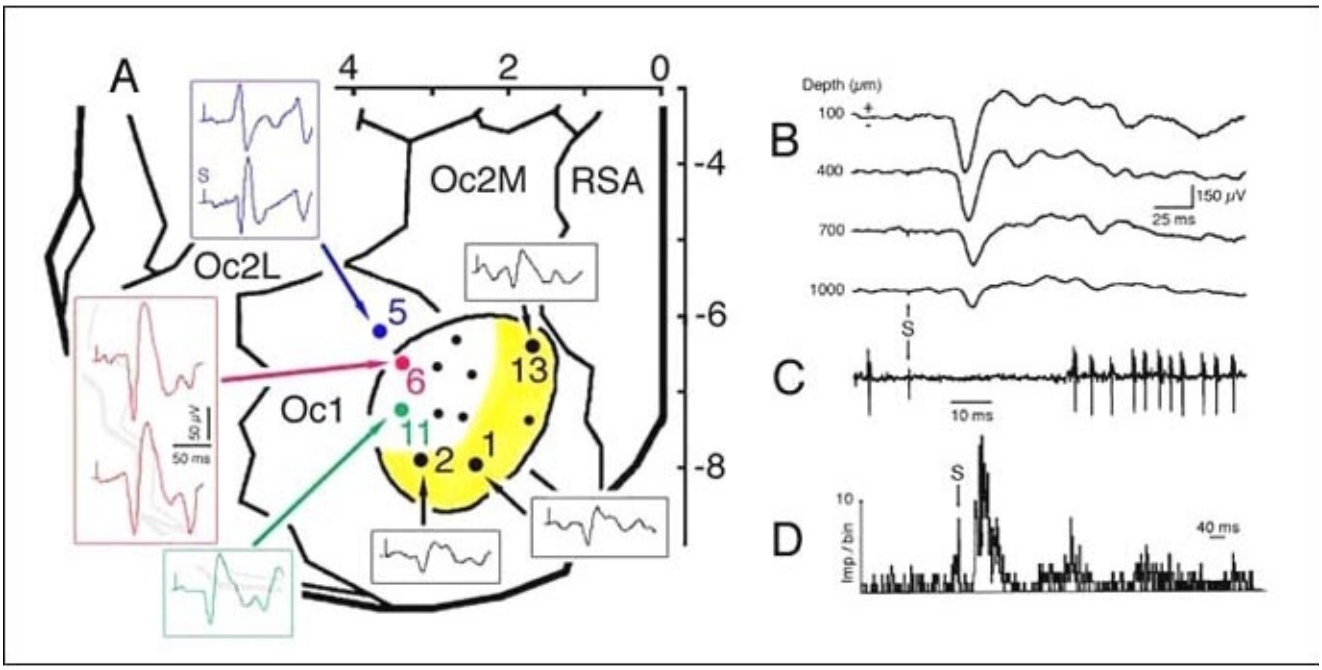

Figure 9. A, field potential mapping in a large occipital tissue graft. Low responses are from the medial yellowish area devoid of thalamic afferents (see Fig. 10). Note the wave reversal with depth (400 *versus* 100 µm) in the adjacent host cortex (point 5), not in graft (point 6). B, depth profile of FPs (average of 20 stimulations; F = 1 Hz) elicited by a flashing light spot placed adequately in the visual field. C, single neuron discharge induced by this flash. D, post-stimulus time histogram (PSTH) for the same neuron (compiled for 20 stimulations; time bin: 2 ms). B-D, redrawn from Girman and Golovina (87).

subjects, it represents 10-30% of all the graft afferents in the other one-half. DLG input never exceeds 10% of the total graft input. Orbital (VO/VLO), motor (Fr2), and brainstem structures (such as the basal nucleus of Meynert, locus coeruleus, and dorsal raphe), all projecting to the normal visual cortex (Fig. 12), are never labeled (33). Labeling in the hemisphere opposite to the graft is always negligible.

Apart from the isocortical area, most labeled neurons (91%) are confined to the infragranular layers (Fig. 13 and Fig. 14), noticeably layer 6 and sublayer 6b, close to the white matter. Layer 6b neurons in normal adult rodents exhibit diverse cell body morphologies (Fig. 14 and Fig. 15) and have widespread terminal arborizations (>3-4 mm) in superficial cortical layers (105). They appear to be remnants of subplate neurons (106-108), which have pivotal functions during early cortical development, for instance in guiding thalamic fibers to their appropriate cortical target area (109-111) and in governing the functional maturation of connections between DLG axons and layer 4 neurons (112). They are also involved in coordinating ocular dominance column formation (113, 114). In the adult cat, subplate (white matter) and pyramidal cells of the normal and inverted types in the infragranular cortical layers support long-range, tangential connections (115).

This Pattern Is Specified by Eye Opening

When performed in neonate hosts, the same experiments always lead to greater density and diversity of graft inputs (89, 116). At the cortical level, for instance, frontal (Fr2; the frontal eye field in primates) and orbital (LO/VLO) areas are moderately but systematically labeled, and the somas of the isocortical afferents distribute about equally between layers 2-3 and 5-6. At the thalamic level, owing to the severe (75%) atrophy of the DLG (117, 118), most inputs originate in the LP/LD complex and the central intralaminar nuclei, an unlabeled cell group in adult hosts (Fig. 16).

We conclude that the age of the recipient appears to affect both the density and the topology of the graft afferents (for similar data with parietal grafts, see Castro et al. (119) and Schultz et al (78).). Additional studies show,

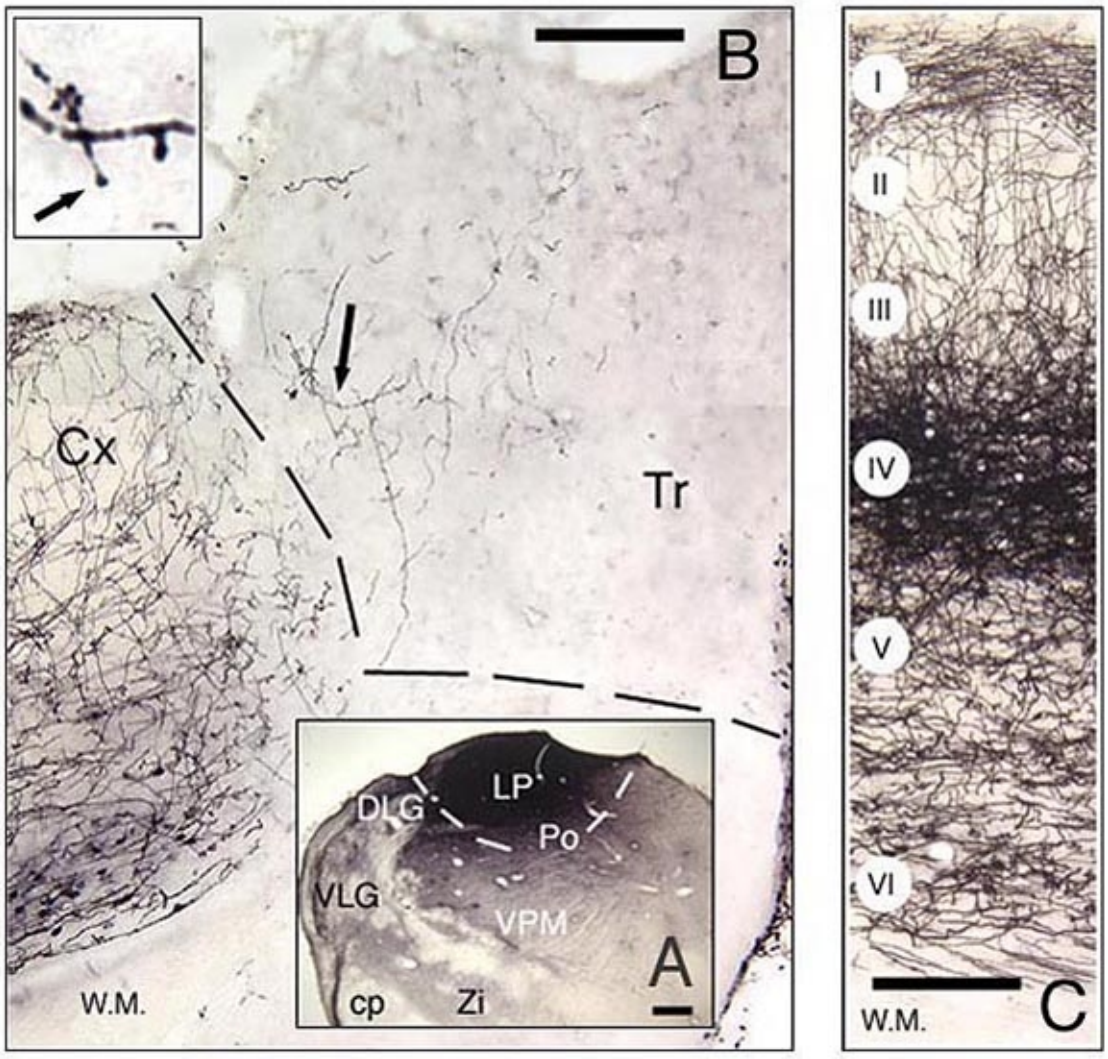

Figure 10. Thalamic input to the preceeding graft (see Fig. 9A) is restricted to the most responsive area. A, biotinylated dextran amine (BDA) injection confined mostly to the LP nucleus (dotted line, lower inset). Strong projections are present in the host cortex either close to the graft (B) or more laterally, in the Oc2L area (C). In contrast, very sparse thalamic fibers innervate the graft (B). The arrow points to a bouton-like terminal structure (see upper inset). cp, cerebral peduncle; Cx, host cortex; DLG, dorsal lateral geniculate nucleus; LP, lateral posterior nucleus; Po, posterior thalamic nucleus; Tr, transplant; VLG, ventral lateral geniculate nucleus; VPM, ventral posteromedian nucleus; w.m., white matter. moreover, that the most dramatic changes in the afferent pattern occur in the second postnatal week, before the onset of the critical period for rat visual cortex (120). Nearly all isocortical inputs to the graft in P15 hosts originate in the infragranular layers, mostly from layer 6, a proportion not significantly different from that found in older recipients (66). This age-related laminar shaping is a two-step process that affects all layers, but the supragranular layers are affected more specifically. It is completed in frontal and temporal areas about 1 week earlier than in the occipital areas surrounding the graft (Fig. 17). The delay is likely related to the cortical ontogenetic program that proceeds radially (121) as well as tangentially through rostrocaudal and lateromedial directions (122, 123).

The Potential of Layer 6 Neurons to Survive Injury and to Drive Grafts

A major outcome of all the above-mentioned studies is that afferent innervation to a cortical graft in adult host originates mostly from a small population of layer 6 neurons located in the immediate graft surround. Cortical layer 6 is a target for thalamic fibers. The layer 6 neurons display all known visual response types (94, 95),

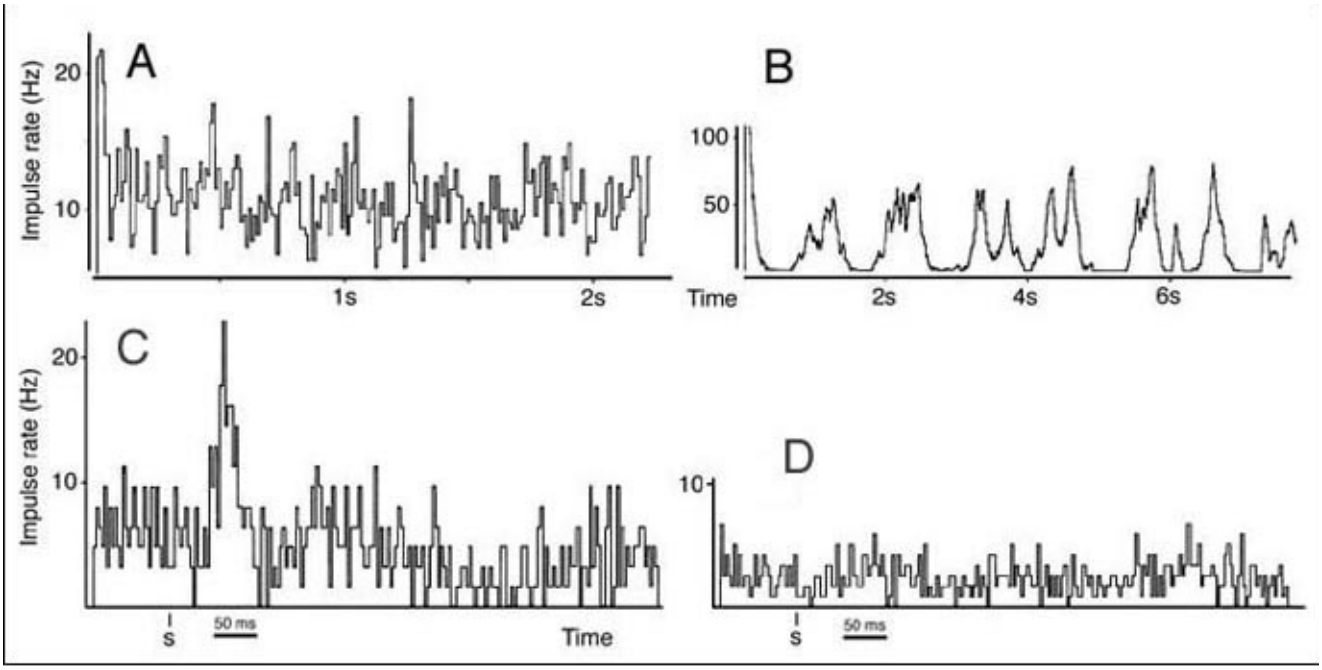

Figure 11. Upper row: autocorrelograms of spontaneous neuronal activity. A, in visually responsive grafts (desynchronized regular pattern). As in the intact visual cortex (94), the spike rate increases with the recording depth. B, in unresponsive grafts (periodic bursting). Time bin: 10 ms. HOR., horizontal plane. V.M., vertical meridian. Redrawn from Girman and Golovina (87).

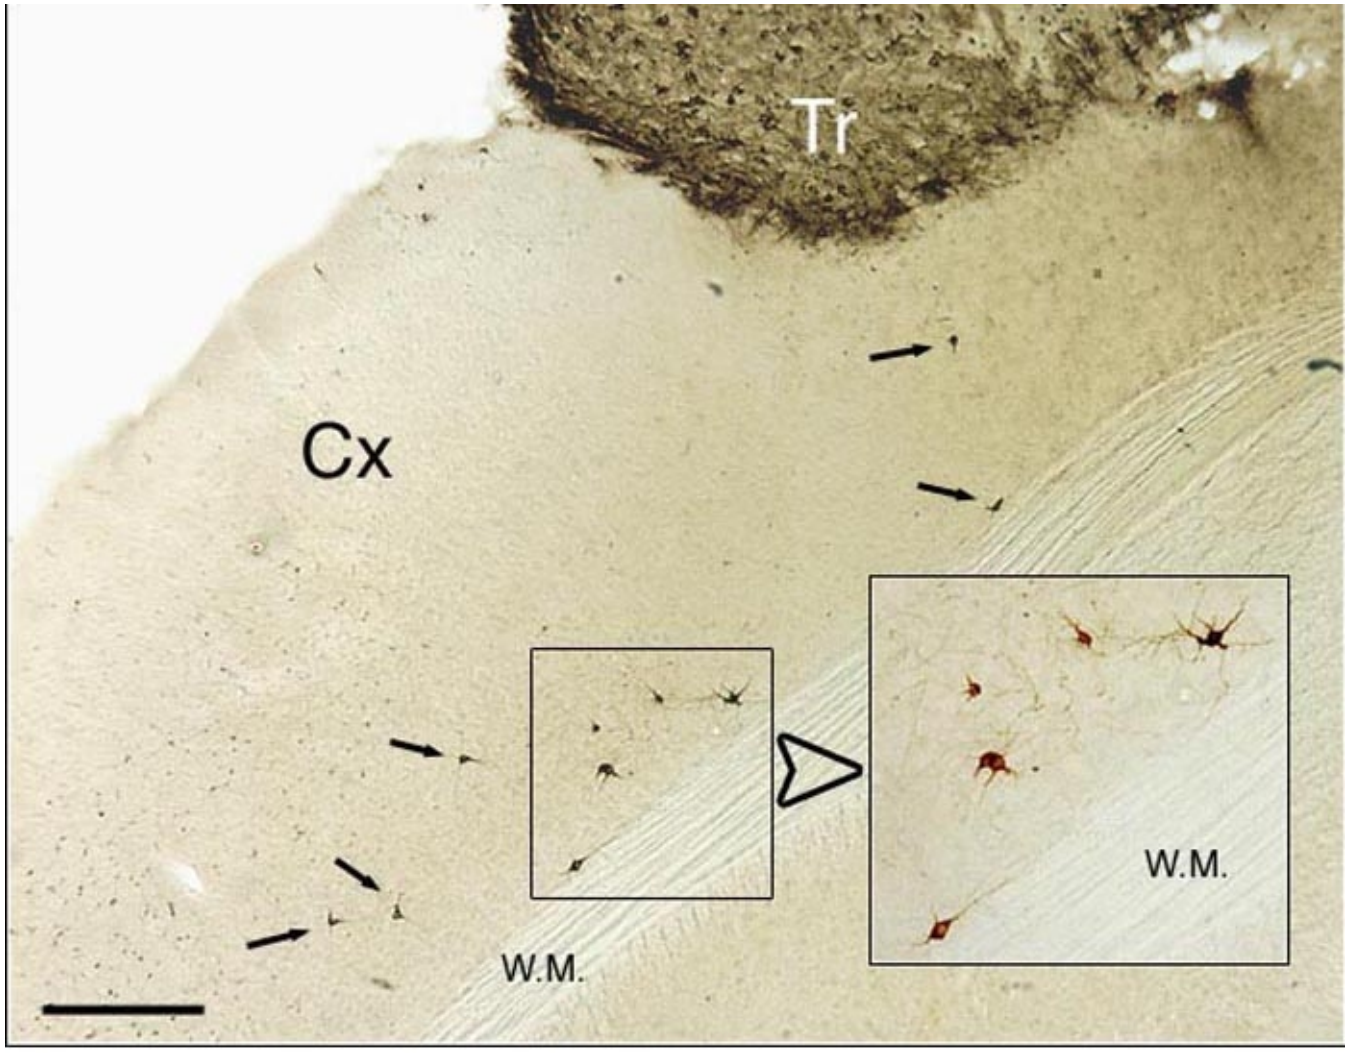

Figure 13. Representative labeling of projection neurons (arrows) in the host cortex (Cx) after injection of a retrograde tracer (CTb; cholera toxin, b-subunit) in a visually responsive graft (Tr). Note their location in layer 6, close to the white matter (w.m.). Non-counterstained, DAB treated material. Scale bar, 200 μm.

regardless of their morphology. Of the four layer 6 cells injected with HRP by Parnavelas et al. (124), one multipolar cell was an "ON-OFF" cell, two pyramidal cells were "complex" cells, and the last fusiform cell type was a "non-oriented" cell. In the absence of direct thalamic input, layer 6 neurons may thus be able to drive visual information to the graft.

Why layer 2-3 neurons do not contact the graft in adults is not understood. Among many possibilities, one would be that these late-generated (E17-E20) corticocortical projection neurons, which have low survival rates during development (125), are very sensitive to lesion-induced retrograde degeneration and/or deleterious changes in their environment (but see Szele et al. (126)). Conversely, these neurons may be able to regenerate axons, but these axons do not penetrate the graft because of negative influences from reactive astroglial elements and/or graft neurons. For instance, *in vitro* assays (6) have shown that endogenous levels of neurotrophin-3 (NT-3) reduce axonal branching and repel layer 2-3 neurons but have opposite effects on layer 6 neurons. For some days after implantation, the graft (which is producing NT-3) may thus be repulsive to layer 2-3 axons but attractive to layer 6/6b neurons, which express NT-3 receptors (127). Regardless of how fascinating these latter observations are, multiple survival and growth-promoting factors produced by the graft and the injured cortex may also allow layer 6 neuron survival and axonal elongation. For instance, neurotrophin-4 (NT-4) is as effective as NT-3 in increasing the length of the dendritic processes of layer 6 pyramidal cells of juvenile ferrets (128).

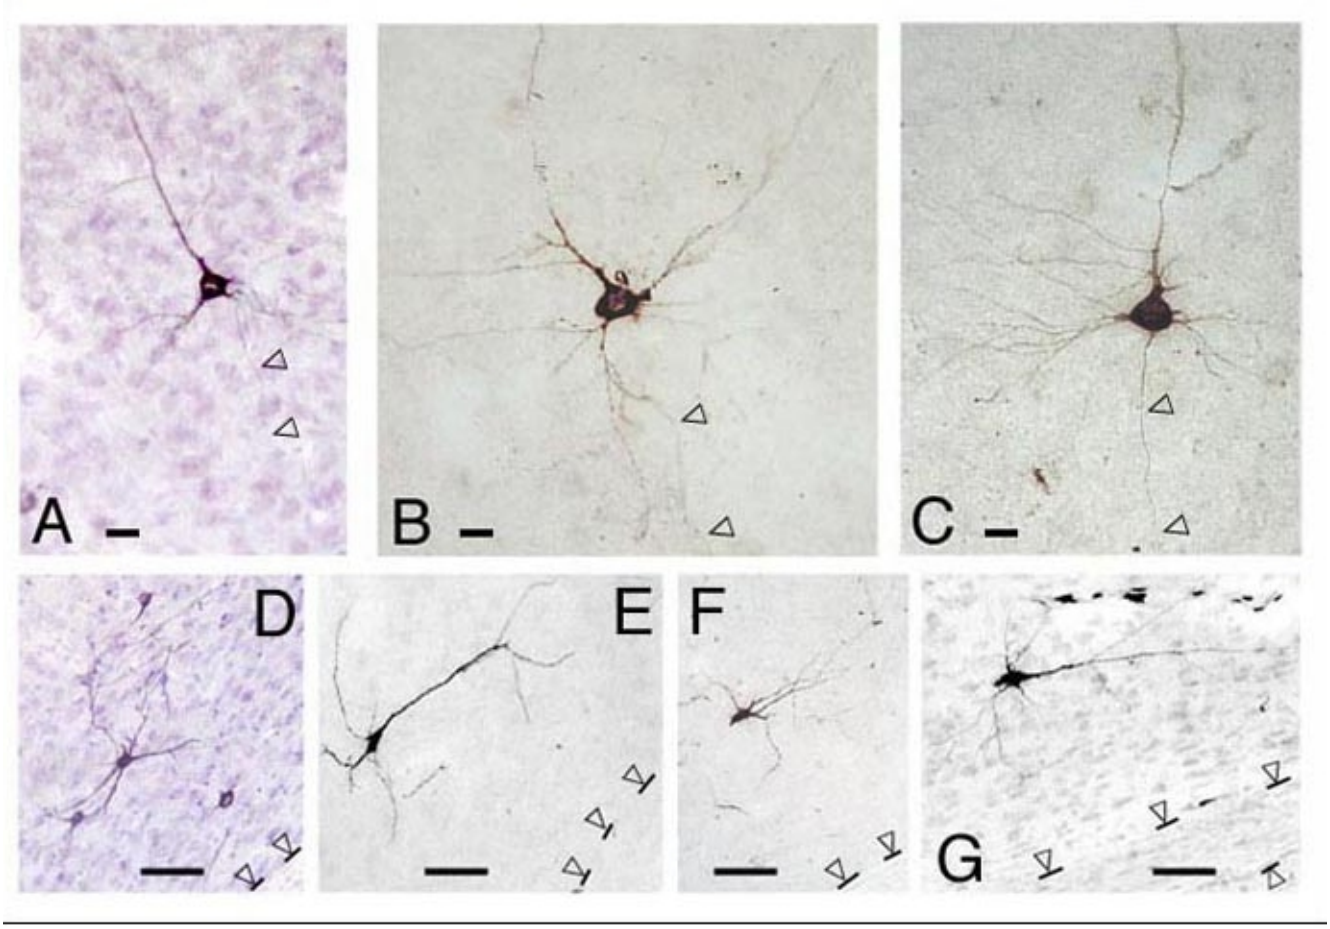

Figure 14. A-C, gallery of retrogradely labeled layer 5 pyramidal cells after CTb injection into three different responsive grafts. Arrowheads indicate axons. All cells are located 400-500 μm from the graft boundary. Scale bars, 13 μm. D-G, gallery of retrogradely labeled cells in layer 6 of visual area Oc2L. These cells are found in the same subject, between 500 and 900 μm from the lateral border of the graft. Arrowheads denote the upper limit of the white matter. Scale bars, 50 mm.

Furthermore, layer 6b neurons have receptors to basic fibroblast growth factor (FGF-2), a critical survival substrate for subplate neurons (129). FGF-2 is suspected to protect adult layer 6b neurons from death after lesions (130) but has no survival effect on 1-week-old, layer 2-3 callosal projection neurons (131). Deciphering why some layer 6 neurons in the adult brain have the potential for elongating their axons and whether these neurons have excitatory phenotypes will be an interesting challenge, especially in the context of these cells consistently labeling regardless of the grafting strategy (78, 132).

Anatomical Support for Topographic Order in Grafts Is Still Lacking

Mapping studies suggest that host afferents are topically organized in large tectal and cortical E15-17 embryonic tissue grafts. These results need anatomical confirmation, however. Beside occasional statements (119), this issue has only been specifically addressed in a single study using neonate recipients. The triple labeling approach by Worthington and Harvey (133) shows that tectal tissue grafts receive non-topographically organized, but nevertheless non-random, rudimentarily ordered cortical inputs. To date, no such investigation has been carried out with adult hosts, likely because one can hardly imagine how the discrete afferent projections reviewed above may form a coherent visual map onto grafts (see section 2.7.3 from the previous chapter). This negative reasoning does not consider: first that map formation may require a specific, highly controlled transplantation procedure (71, 133), including possibly the correct orientation of the graft in the lesion cavity (134, 135); second, that labeled graft afferents may reflect only a negligible proportion of the actual projecting host neurons; and

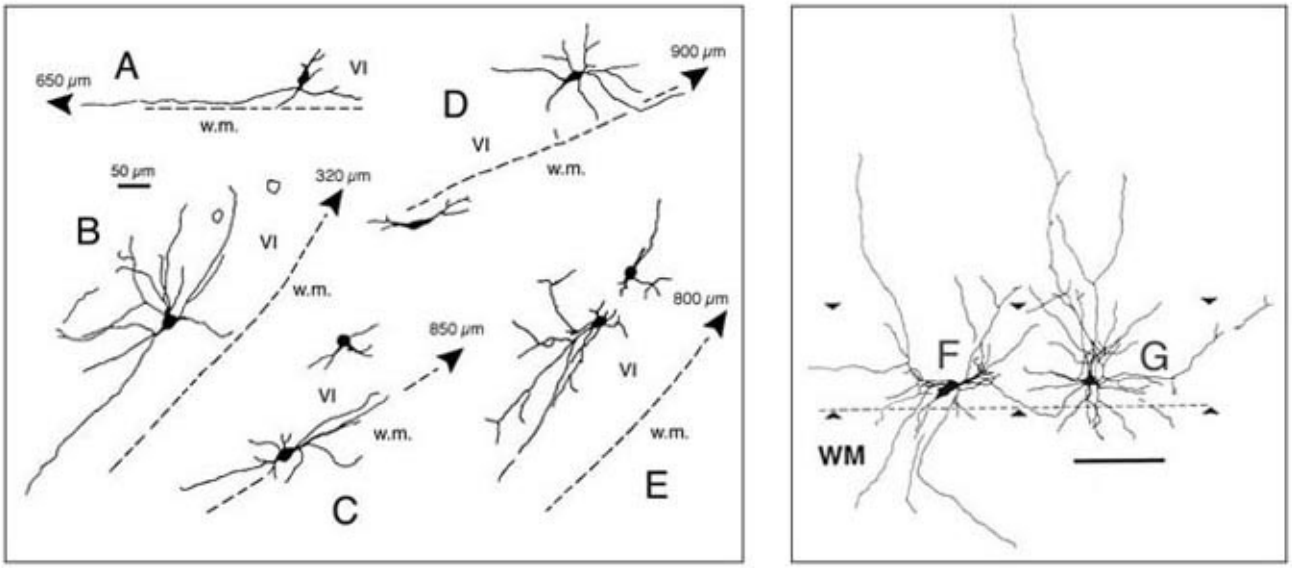

Figure 15. Left panel: camera lucida drawings of retrogradely labeled cells in layer 6b after CTb injection into another responsive graft. Dotted lines denote the upper limit of the white matter (w.m.). Arrowheads indicate the location and the distance of the graft. A, fusiform bipolar cell (Oc1B). B, giant multipolar cell (Oc1B). C, horizontally oriented pyramid-like cell (Oc2L). D, multipolar and flat bipolar cells (Oc2L). E, multipolar cell (Oc2L). Right panel: camera lucida drawings of representative subgriseal neurons filled with intracellular injections of biocytin. Normal adult rodent. F, fusiform neuron. G, triangular neuron. third, that single-unit recordings with carefully engineered microelectrodes (136) may be more powerful than tracer injections to detect small point-to-point shifts in connectivity between restricted brain areas. Meticulous surgical preparation, ingenious recording conditions, and use of self-made, highly specific tungsten in glass electrodes of the Levick's type may together account for Girman's successful recordings (94). In our opinion, unequivocal assessment of topographic host-graft projections requires further studies combining an optimal surgical strategy, a highly sensitive fiber detection process (see below), and a careful electrophysiological approach replicating Girman's approach.

Can Grafts Send Afferents to Host Targets?

In line with numerous results showing low numbers of afferents coming to the transplant, it has been repeatedly assumed that allogeneic embryonic tissue grafts do not send long-range projections to the adult host. Our own attempts using either biotinylated dextran amine (BDA) or the carbocyanine dye DiI (1,1'-didodecyl-3,3,3',3'-tetramethyl-indocarbocyanine perchlorate) as anterograde tracers confirm this assumption. This failure is commonly attributed to growth inhibitory conditions present in the mature brain (14, 137). Possible technical limitations are rarely addressed (138-141). Yet, there are some intriguing morpho-functional observations (84, 85, 142-148), suggesting that blocks of embryonic neurons grafted into the mature brain might not be able to transport exogenously provided tracers beyond the graft-host transition zone. In opposition to this, long axonal trajectories have been clearly detected in some experimental conditions, either after pre-loading dissociated donor cells with dyes (149, 150) or by targeting specific markers expressed by grafted cells (Thy-1.2 allelic system; microtubule-associated protein MAP1x/1B) (151-155). This has been a routine procedure for xenogeneic tissue grafts (for examples, see Lund et al. (156), Li and Raisman (157), Davies et al. (158), Isacson and Deacon (159), and Armstrong et al. (18)). A plausible hypothesis is, then, that all fetal graft neurons, regardless of their origins, are intrinsically capable of elongating processes when placed in a mature brain, but that detection of these processes outside the graft structure requires a non-invasive, anatomical approach. This hypothesis has

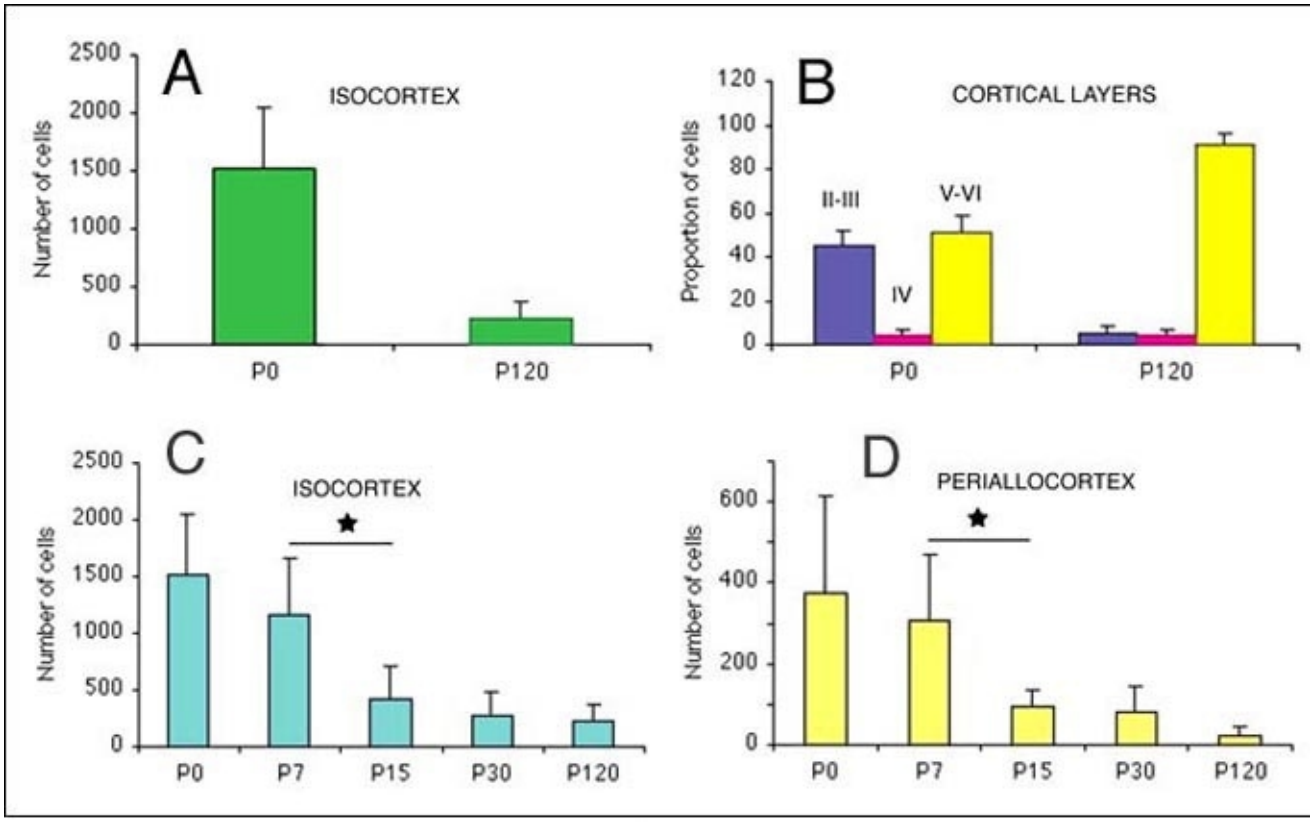

Figure 16. Upper row: quantitative differences (mean ± SD) in graft input between neonates (P0) and adult (P120) recipients. A, raw number of isocortical cells. B, proportions of cells per isocortical layer. Counts performed on half the brain of each subject. Redrawn from Domballe et al. (66). Lower row: decrease in graft afferents (mean ± SD) with the age of the host. A, in the isocortex. B, in the periallocortex (cingulate, perirhinal, and retrosplenial areas). Stars indicate significant differences ($p < 0.05$). Counts performed on half the brain of each subject. Redrawn from Domballe et al. (66).

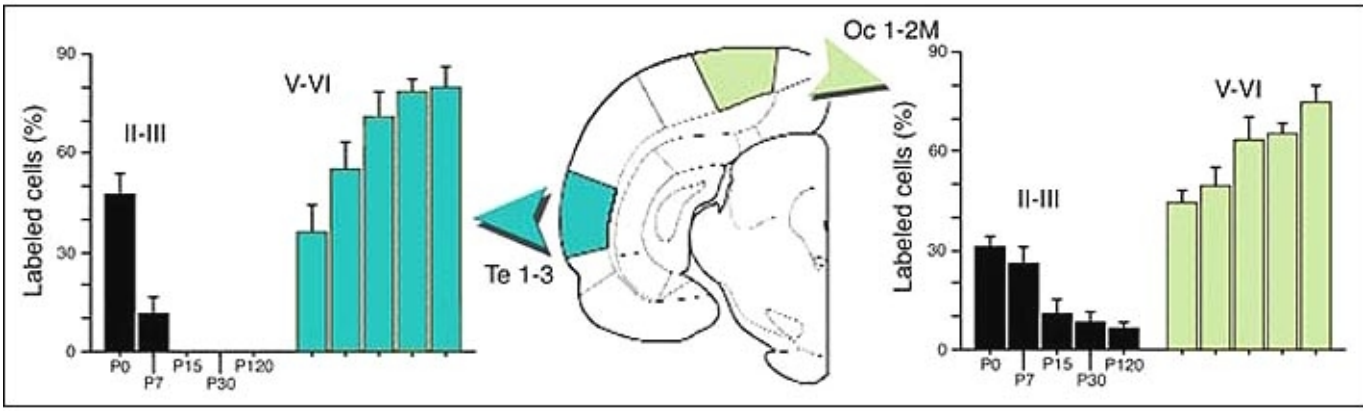

Figure 17. Proportions of labeled cells (mean ± SD) in the temporal (Te1-3) and occipital (Oc1-2M) areas as a function of the age of the host. Note the absence of supragranular input from temporal areas in 2-week-old recipients. Redrawn from Domballe et al. (66).

been verified recently in occipital cortex tissue grafts (160) using transgenic E15 mouse fetuses expressing a GFP protein variant under the control of a chicken beta-actin promoter (161) as donors (Fig. 18 and Fig. 19).

Figure 18. Dr. Okabe's eGFP-expressing neonate mice look "green" all over their body when illuminated with an UV source. See: http://kumikae01.gen-info.osaka-u.ac.jp/tg/tg-ad.cfm.

Embryonic Cortical Tissue Allografts Have Massive Efferents

A major finding of the above study is that despite immediate implantation, nearly all grafts into mature (P60/P90), wild-type mice appear physically well integrated in the host cortex (Fig. 19). Moreover, they show massive outgrowth all along their interface with the cortical parenchyma and send extensive efferents throughout the host ipsilateral pallium, mainly to its cortical mantle (Fig. 20).

Rostrally, graft fibers innervate a large medial sector of the brain including frontal association (FrA), secondary motor (M2), prelimbic (PrL), anterior cingulate (Cg1-2), medial orbital (MO), and infralimbic (IL) areas. Discrete fibers terminate within the orbital areas VO/LO and the claustrum (CL). At the bregma level, efferents distribute from area Cg1 medially to the somatosensory cortex laterally. Labeling extends throughout layers 2-3 and 5-6 in motor (Fr2) and sensorimotor (HL) areas but remains in lamina 6b at the barrel field (BF) level (Fig. 21 and Fig. 22).

At the transplant level and beyond, labeling from the GFP donor tissue fills the host ipsilateral cortex from the retrosplenial granular area to the lateral entorhinal region. Efferents in V2L and Te1-2 areas are especially dense in layers 1-3, 5a, and 6. Further caudally, labeled fibers occupy predominantly the cortical layers 5-6 as well as the PrS/PaS hippocampic regions.

Finally, afferents with terminal-like profiles are systematically present in the dorsomedial sector (as well as along the lateral rim) of the striatum and into the basolateral and central amygdaloid nuclei (Fig. 23). All these structures, including the cortical areas listed above, are normal targets of the rodent visual cortex (see Fig. 2).

Although always disrupted by surgery (Fig. 19 and Fig. 27), the white matter (external capsule and corpus callosum) never appears to provide an attractive substrate for graft efferents. Even at the exit point from the

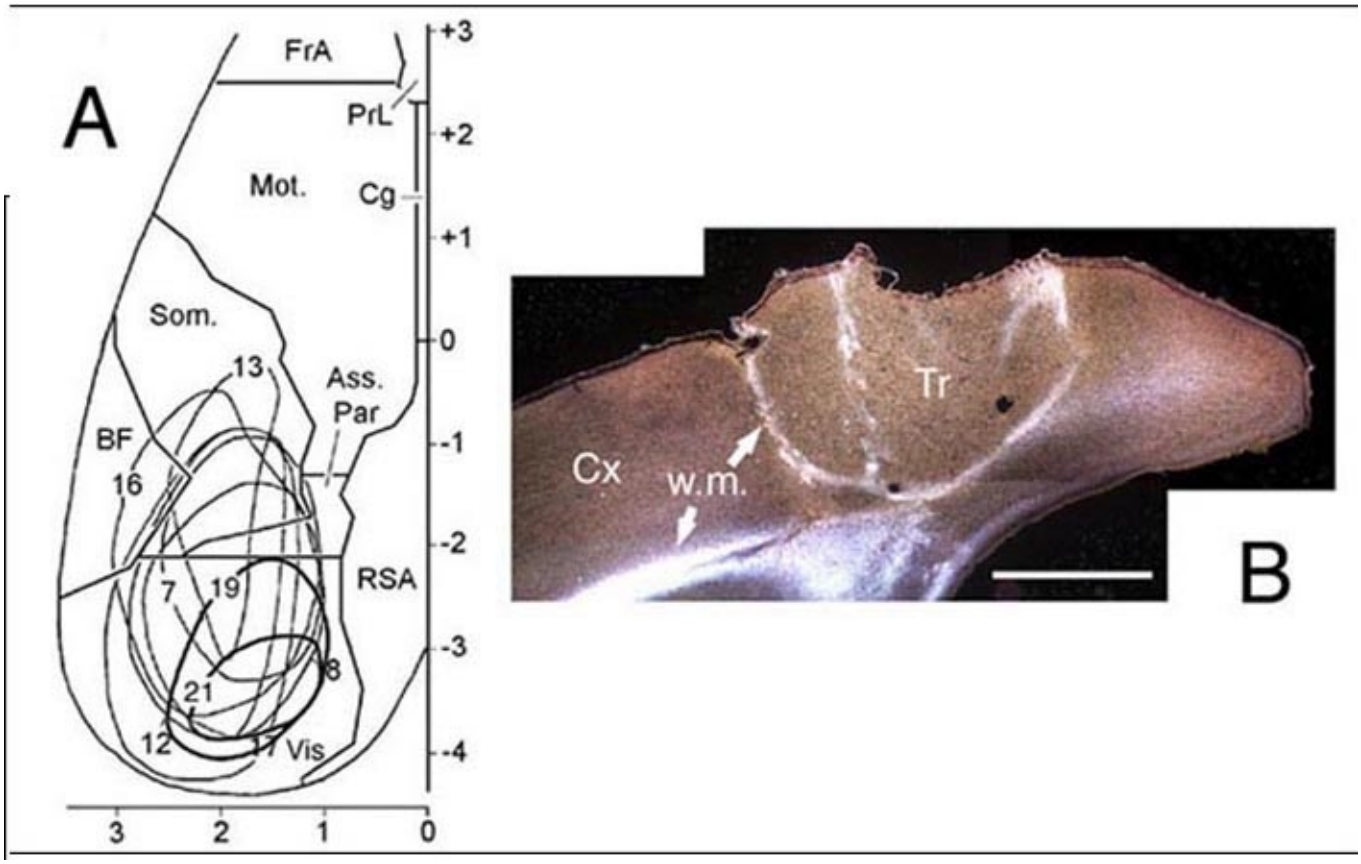

Figure 19. A, location of the eGFP-positive grafts at the cortical surface with respect to bregma (B = 0) after reconstruction from serial brain sections. B, representative implantation (B-3.5). Darkfield microscopy. Note white matter bundles around and within the grafted tissue. Abbreviations are given in text. Scale bar, 500 μm. From Gaillard et al. (163).

graft, outgrowing fibers always appear to prefer elongating through the deep gray matter (layer 6) of the cortex, the major pathway for long distance, intrahemispheric corticocortical axons in rodents (162) (Fig. 24).

Very few fibers can, therefore, extend to subcortical visual targets and the opposite hemisphere. Terminal-like arrangements can nevertheless be detected in the dorsal visual thalamus (Rt, LP/LD, DLG, Po), the pretectum (APT), SC, and even in the lateral division of the pontine nuclei (Pn; Fig. 22), the ultimate target of the rodent visual cortex (39) (Fig. 25 and Fig. 26).

Implications for Future Research

Besides the unequivocal demonstration that developing and regenerating fetal allograft neurons possess a strong capacity for extending axons over considerable distances in the mature host brain parenchyma, the results deserve further comments. First, allowing a delay between tissue sampling and implantation is clearly not necessary for outgrowth. Using a similar surgical protocol, extensive outgrowth can be achieved with cortical frontal and substantia nigra tissue grafts (64, 163). For instance, 11 days after grafting, frontal graft growth cone-like figures end up in the cerebral peduncle. Second, the massive fiber outgrowth taking place along the graft-host parenchyma interface argues against the current suggestion that lesion-induced glial scar formation and local overexpression of repulsive molecules (137) impede neurite growth *in vivo*. Third, most outgrowing axons follow a normal route in the brain parenchyma and terminate in normal target fields, indicating that cues for correct axonal guidance are readily present in the mature brain (159, 164). However, some outgrowing axons spread into inappropriate targets. Fibers and terminal fields have been detected at considerable distances from the graft locus in the acumbens area, olfactory peduncle, tenia tecta, and PBg nucleus, raising again the question

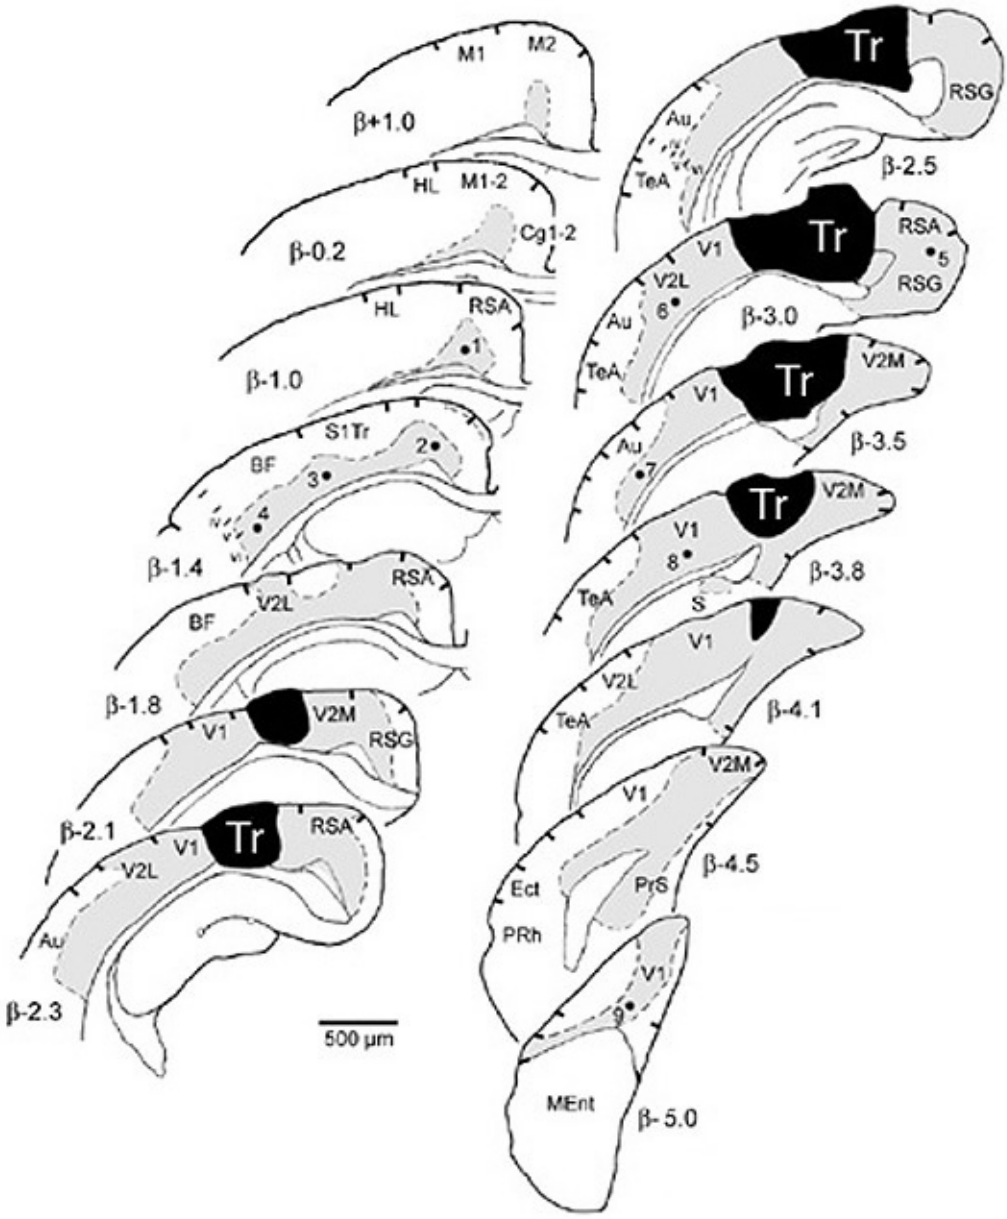

Figure 20. Camera lucida drawings of graft projections into the ipsilateral cortex of the former case as seen at a low magnification power (×4). Brain sections are arranged according to their bregma level. The grayish zone in each section corresponds to the extent of the labeling readily detectable in this condition. Outside this zone, fiber detection requires a higher magnification. Except for local variations in fiber density, present topography is valid for all grafts. From Paxinos and Franklin (175).

of the specificity of innervation (see section 2.4 from the previous chapter). Non-target-directed elongation in the mature brain has already been reported for olfactory bulb neurons transplanted ectopically into the frontal cortex (152). Fourth and finally, adult white matter appears to be an insurmountable obstacle for most developing axons in view that graft fibers grow clearly less through white matter tracts than through infragranular cortical gray layers. In addition, accidental removal of the white matter during surgery allows graft efferents to invade the underlying hippocampic structures (neuropil layers, dentate gyrus, and subiculum).

Neurite growth inhibition by myelin is currently (but not exclusively (165)) explained by interactions between myelin-related inhibitory factors (Nogo-A protein; myelin-associated glycoprotein, MAG; and oligodendrocytes-myelin glycoprotein, OMgp) and a common neuronal Nogo receptor (166-168). Whether such inhibitory

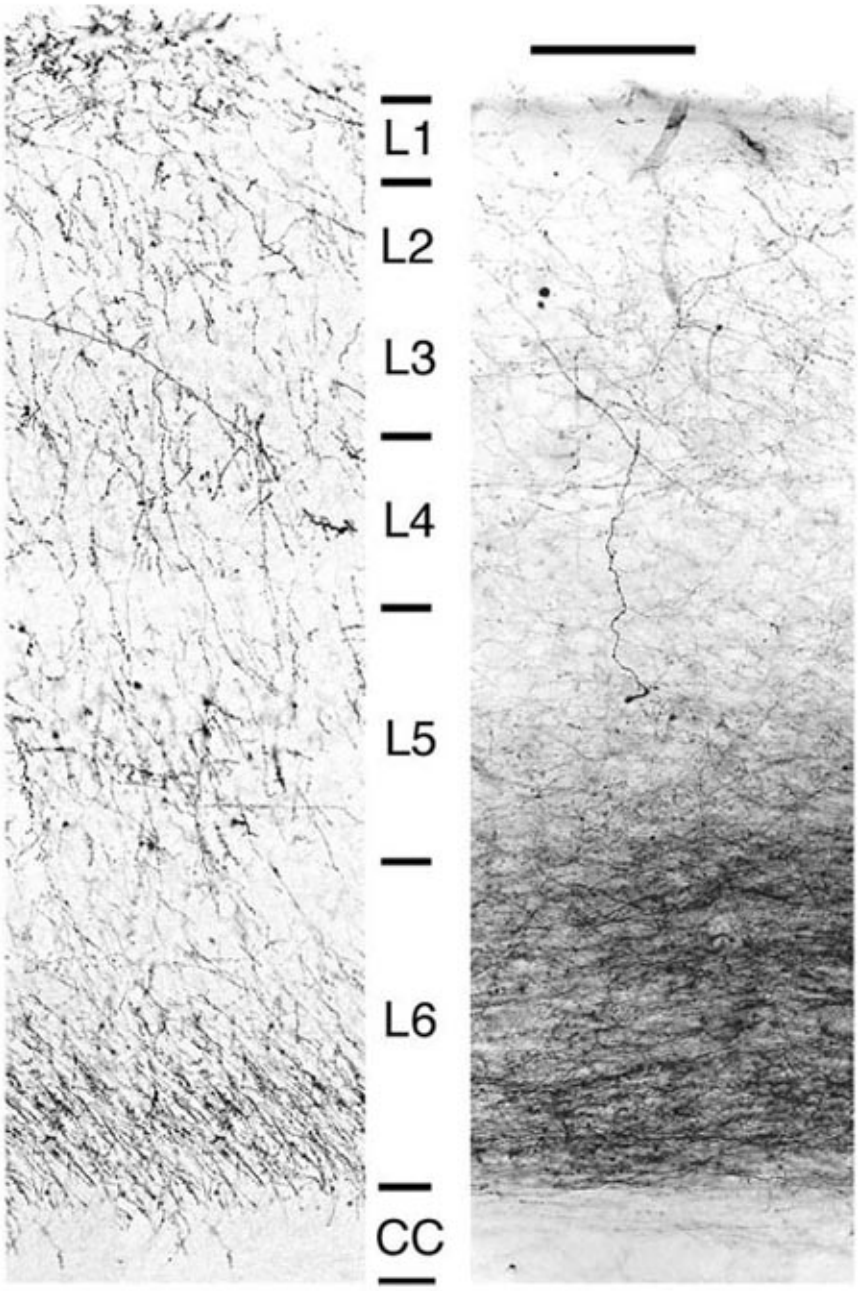

Figure 21. Composite images showing the cortical distribution of graft efferents in HL (left) and V2L (right) areas of two different animals. Note the high density of fibers in layer 6. Inverted contrast from fluorescent material. Corpus callosum (CC) is downward. Scale bar, 100 μm.

interactions make for graft axon repulsion in graft situations is debatable, in part because the neuronal Nogo receptor seems barely detectable in the normal brain, at least until the end of the first postnatal week (169). The implication is that graft axons would be able to navigate for some 2 weeks in white matter tracts before being stopped by inhibitory ligands. This is clearly not what we saw.

Restoration of Visual Behavior

Only a few behavioral studies have investigated whether fetal tectal or occipital grafts can mediate recovery of impaired visual function in adult rats. Results are inconsistent. Stein et al. (170) transplanted frontal and occipital E18-19 tissue blocks into bilateral aspirated occipital cortices and then trained subjects (albino rats) on

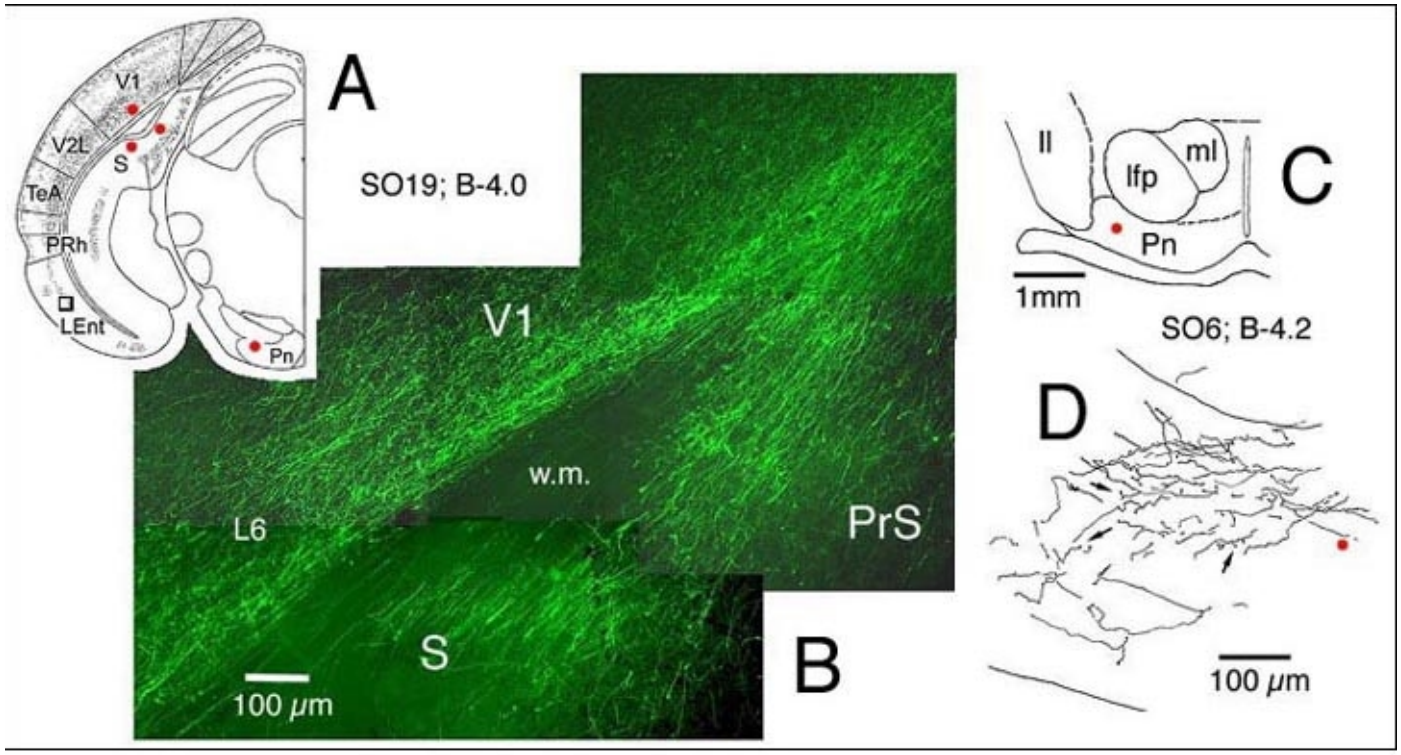

Figure 22. Graft efferents in the caudal brain (4 mm beyond bregma). A, schematic drawing (adapted from Paxinos and Franklin (175)) showing the location of the accompanying pictures (red dots). Gray levels are representative of the fiber density. B, efferents in occipital (V1, layer 6) and hippocampic (S and PrS) regions. Fluorescence microscopy. Note the fiber-free white matter (w.m.). C and D, terminal field in the lateral pontine nucleus (Pn). Camera lucida drawing. Arrows point to bouton-like profiles. Abbreviations are given in text.

both a brightness (neutral-grey levels) and a pattern (oblique stripes) discrimination task. Rats with frontal tissue grafts can learn the brightness task more rapidly and more accurately than animals with lesions alone. Occipital tissue grafts are inefficient. None of the grafted subjects can solve the pattern discrimination problem. In no case can graft efferents be clearly identified following HRP tracing methods. In a later work, Stein and Mufson (171) obtained equally good results in both types of transplants in solving both tasks after pretreatment of the recipients (pigmented rats) with cyclosporin A. How these experimental modifications might affect the performance of rats having occipital tissue grafts is not discussed in this study. The puzzling effect of the frontal grafts is attributed to the release of specific (but unknown) recovery-promoting factors able to spare some residual visual circuits in the host brain. Some studies emphasize, however, that sparing of function is possible only with homotopic grafts (172), and that heterotopic transplants cannot form viable synapses with the host tissue (173). Clearly, the behavioral performance of adult subjects with occipital grafts needs closer examination.

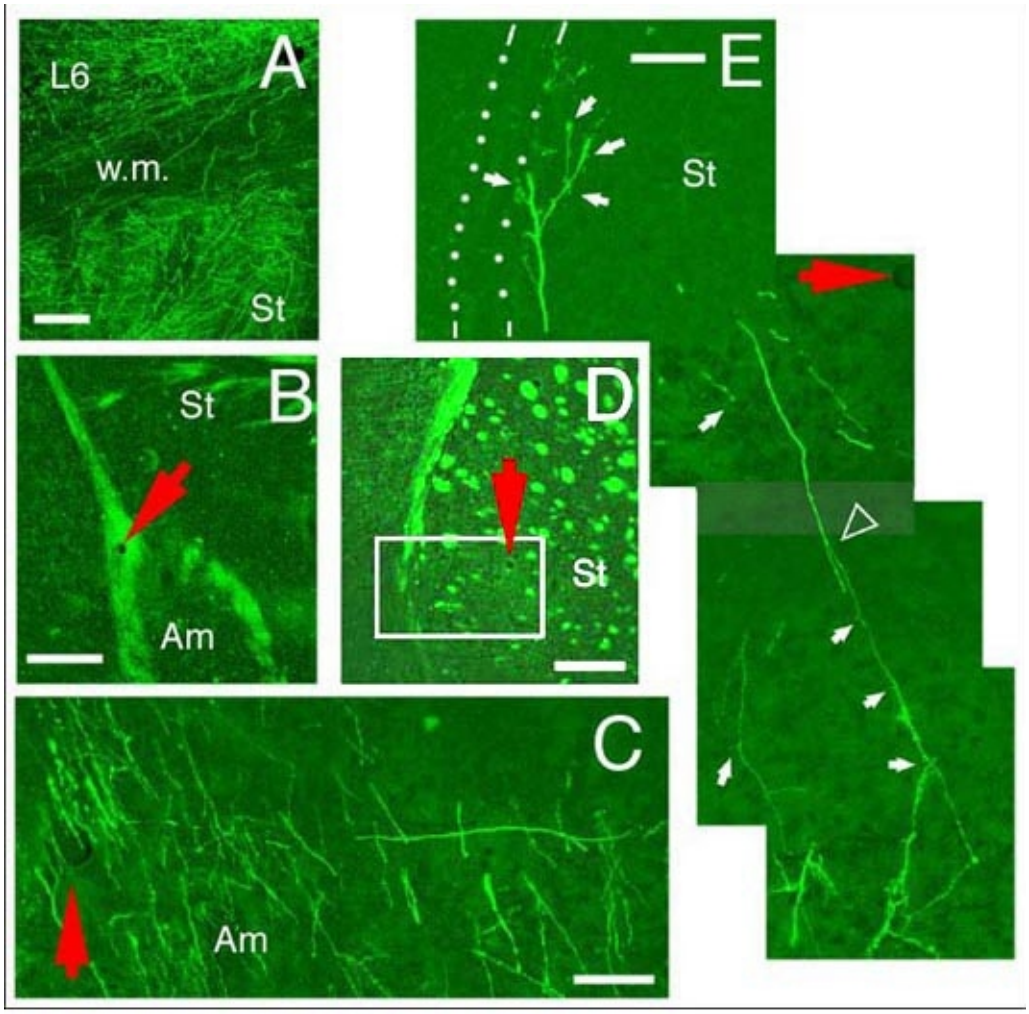

Figure 23. Graft efferents in the striatum and the amygdala. Fluorescence microscopy. A, labeling in the dorsomedial striatum, below area Fr1 (B+1.2). Scale bar, 100 μm. B and C, labeling in the amygdala, laterodorsal nucleus (B+1.0). Scale bars, 150 and 50 μm, respectively. D and E, labeling in the striatum, lateroventral rim (B = 0). Scale bars, 150 and 50 μm, respectively. Red arrows point to blood vessels as landmarks. White arrows indicate terminal-like profiles. Open triangle shows collateral branching. Am, amygdala; St, striatum; w.m., white matter.

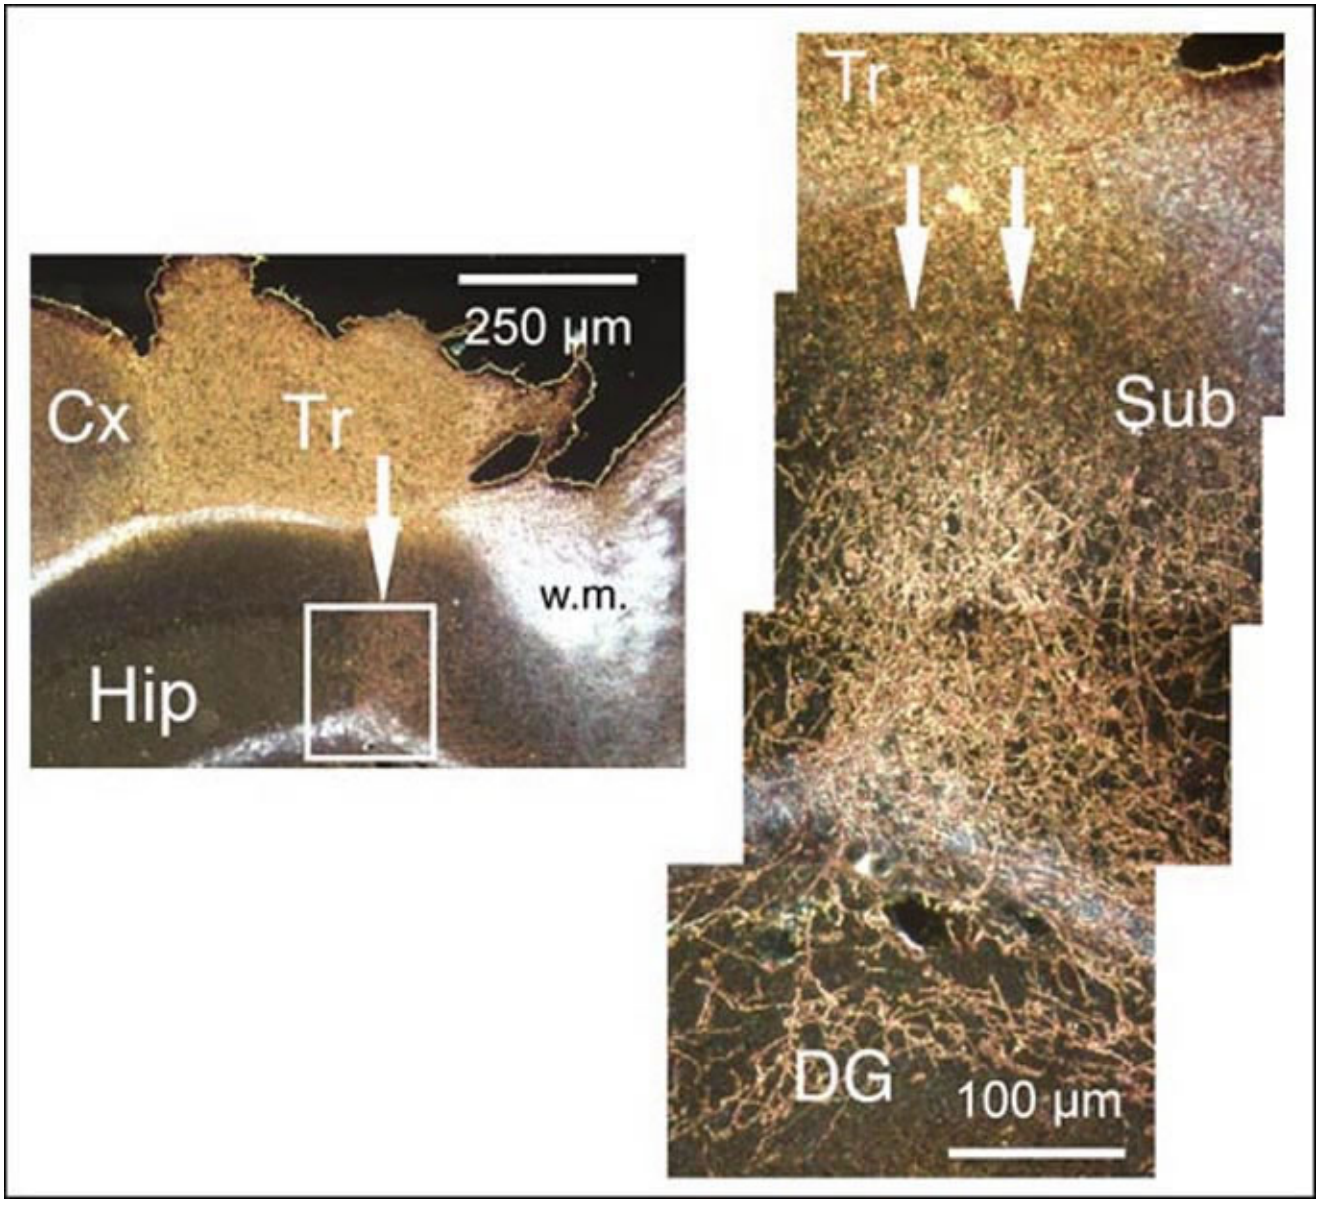

Figure 27. Destruction of the underlying white matter (arrows) allows graft efferents to invade the hippocampus (B-3.6). Darkfield microscopy. Cx, host cortex; DG, dentate gyrus; Hip, hippocampus; Tr, transplant; Sub, subiculum; w.m., white matter.

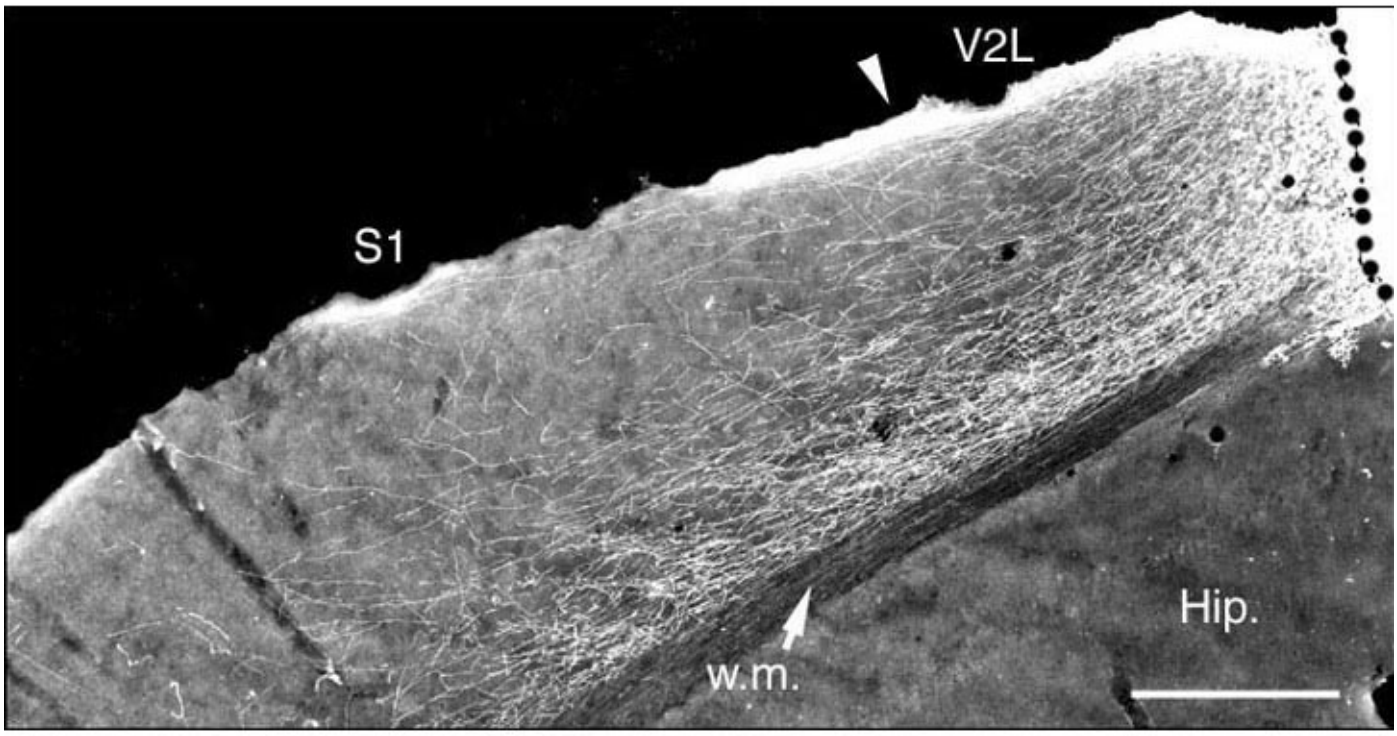

Figure 24. Fiber outgrowth from a small (0.5 mm^2) transplant centered 2 mm caudal to bregma within the lateral parietal association (LptA) area. Outgrowth occurs throughout the graft-cortex junction (V2L area). More laterally (S1 area), fibers display obvious preference for the deep gray *versus* white matter (w.m.). Photographic montage from unstained, DAB-treated material. Hip., hippocampus. Scale bar, 250 μm.

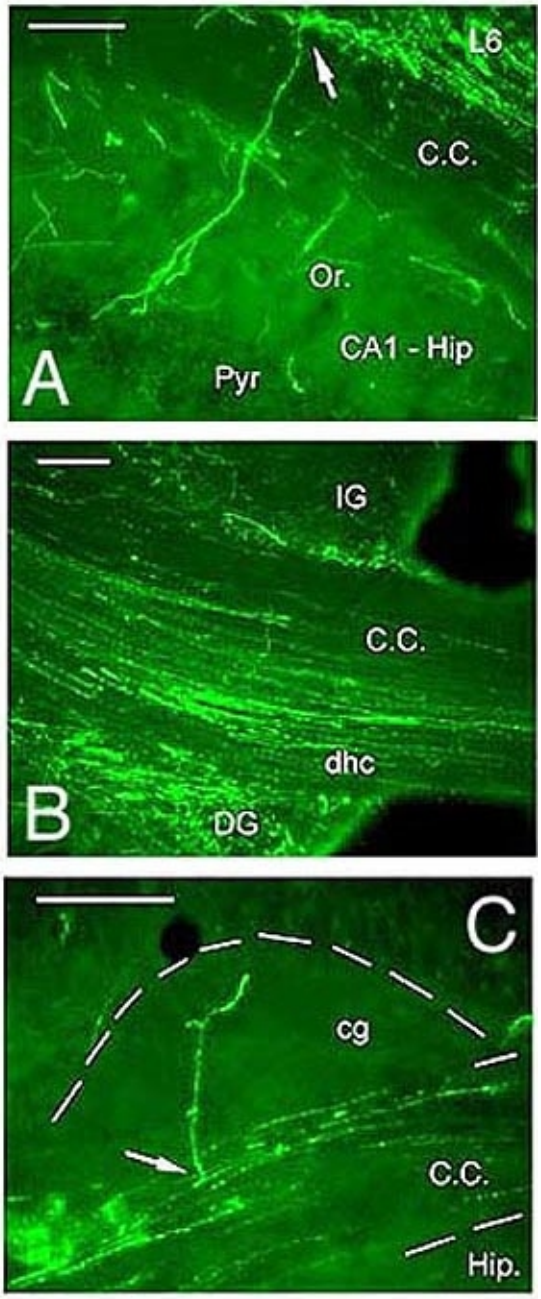

Figure 25. Graft efferents into the corpus callosum (CC). All pictures are taken between the cingulate bundle (cg) and the brain midline. Fluorescence microscopy from Alexa-fluor-treated material. A, callosal fibers are rare at this brain level (B-1.7). Note the fiber coursing vertically from cortical layer 6 to the pyramidal layer (Pyr) of the hippocampic (Hip) CA1 field, a non-visual target. B, just at the rostral pole of the graft (B-2.1), callosal fibers appear much denser. A significant contingent travels into the dorsal hippocampic commissure (dhc). C, contralaterally, very few fibers extend beyong the cingulate bundle (cg). Note the branching pattern to this structure. Or, oriens layer; IG, indusium griseum; DG, dentate gyrus. Scale bars, 100 μm.

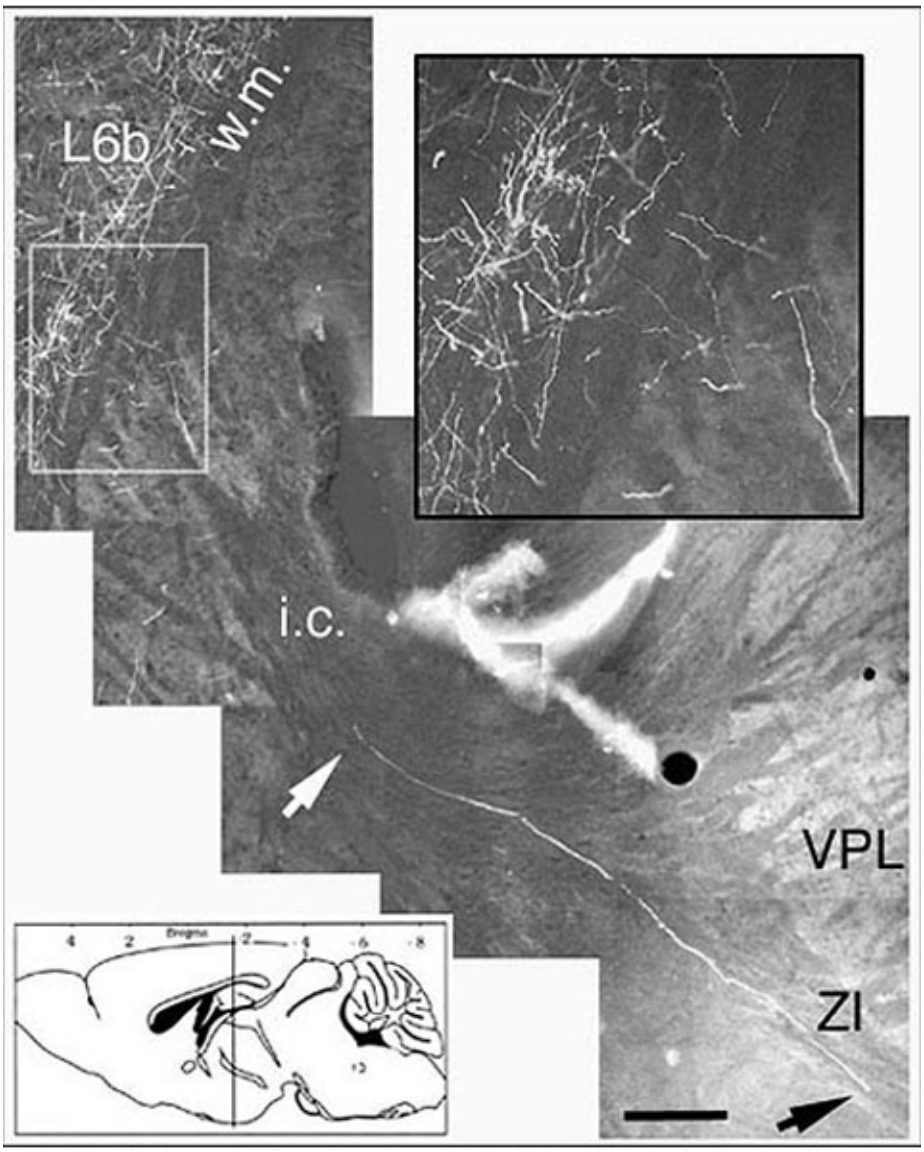

Figure 26. Single graft fiber elongating in the internal capsule to zona incerta, a normal subthalamic target of the occipital cortex. Terminal fields are never seen in this region. Fluorescence microscopy. Scale bar, 150 μm. Upper inset, enlargement of the selected area. Lower inset, location of the section (B-1.6 mm). i.c., internal capsule; VPL, ventral posterolateral nucleus; w.m., white matter; ZI, zona incerta. From Gaillard et al. (163).

About the Authors

University of Poitiers, where he received his B.Sc. (1969) and his M.Sc. (1971) in physiology. He then obtained a Ph.D. (1975) and a Doctorates-Sciences (1984) in neurophysiology. Until recently, most of his studies focused on aspects of binocular information processing in the amphibian visual system, mainly on the functional properties of the crossed isthmo-tectal pathway. He is now examining host-graft relationships in the adult mammalian visual system. Since 1977, Dr. Gaillard has been a senior investigator (Charge de recherches) of the Centre National de la Recherche Scientifique (CNRS) at the Institut de Physiologie et Biologie Cellulaires (UMR 6187), Poitiers, France.

Dr. Yves Sauve was born in Montreal, Canada. He attended the University of Montreal where he received his B.Sc. in Biochemistry in 1983 and his M.Sc. in Neuroscience in 1988 with Dr. Thomas Reader, focusing on the neurochemistry of catecholamines and their receptors in the CNS. He then obtained his Ph.D. in Physiology

under Dr. Michael Rasminsky at McGill University in 1995, where his research focused on the electrophysiological evaluation of reformed synapses between regenerating RGC axons and neurons in the superior colliculus, using the preparation developed in Dr. Albert Aguayo's group. Dr. Sauve subsequently undertook postdoctoral studies with Dr. Raymond Lund at the Institute of Ophthalmology (University College London), where he developed electrophysiological approaches to evaluate visual responsiveness in rodent models of retinal degeneration. In 2001, he became assistant professor of Ophthalmology and Visual Sciences at the Moran Eye Center (University of Utah), where he is currently evaluating rod and cone function following retinal degeneration, transplant therapies, and regeneration in the adult mammalian visual pathways.

Electrophysiology

The Study of Light-Evoked Field Potentials

Visually Evoked Potentials

Donnell Creel, PhD[1]

Created: March 1, 2012.

Introduction

The terms visually evoked potential (VEP), visually evoked response (VER) and visually evoked cortical potential (VECP) are equivalent. They refer to electrical potentials, initiated by brief visual stimuli, which are recorded from the scalp overlying visual cortex. VEP waveforms are extracted from the electro-encephalogram (EEG) by signal averaging. VEPs are used primarily to measure the functional integrity of the visual pathways from retina via the optic nerves to the visual cortex of the brain. VEPs better quantify functional integrity of the optic pathways than scanning techniques such as magnetic resonance imaging (MRI).

Any abnormality that affects the visual pathways or visual cortex in the brain can affect the VEP. Examples are cortical blindness due to meningitis or anoxia, optic neuritis as a consequence of demyelination, optic atrophy, stroke, and compression of the optic pathways by tumors, amblyopia, and neurofibromatosis. In general, myelin plaques common in multiple sclerosis slow the speed of VEP wave peaks. Compression of the optic pathways such as from hydrocephalus or a tumor also reduces amplitude of wave peaks.

This review covers a brief history of visual evoked potentials, the most commonly used stimuli to initiate visual evoked potentials, the methods of recording, the sources of visual potentials, the effects of maturation and acuity, and sample patients.

History

VEPs initiated by strobe flash were noticed in the early years of clinical encephalography (EEG) in the 1930s. A VEP can often be seen in the background EEG recorded from the occipital scalp following a flash of light (Fig. 1). Evoked potentials, whether auditory, visual or somatosensory, are extracted from the EEG by a simple program. This technique of extracting a signal from random noise is one of the oldest applications of computer technology. This process is similar to programs used to extract radar signals from jamming nearly 70 years ago. Adding the electrical activity for set time periods is called "signal averaging". Dawson first demonstrated a signal-averaging device in 1951 and signal-averaging computers have been available since the early 1960s. The computer programs save a defined time period of EEG activity following a visual stimulus, which is repeated over and over adding the signals together. The random EEG activity averages away, leaving the visually evoked potential. Depending on the signal to noise ratio, an evoked potential can be seen forming following only a few stimuli such as flashes of light.

Electrode locations on the scalp

Visually evoked potentials elicited by flash stimuli can be recorded from many scalp locations in humans. Visual stimuli stimulate both primary visual cortices and secondary areas. Clinical VEPs are usually recorded from occipital scalp overlying the calcarine fissure. This is the closest location to primary visual cortex (Brodmann's area 17). A common system for placing electrodes is the "10-20 International System" which is based on measurements of head size (1). The mid-occipital electrode location (0Z) is on the midline. The distance above the inion calculated as 10% of the distance between the inion and nasion, which is 3-4 cm in most adults (Fig. 2). (The inion is the most prominent projection of the occipital bone at the posterioinferior (lower rear) part of the skull. The nasion is the intersection of the frontal bone and two nasal bones of the human skull.) Lateral occipital

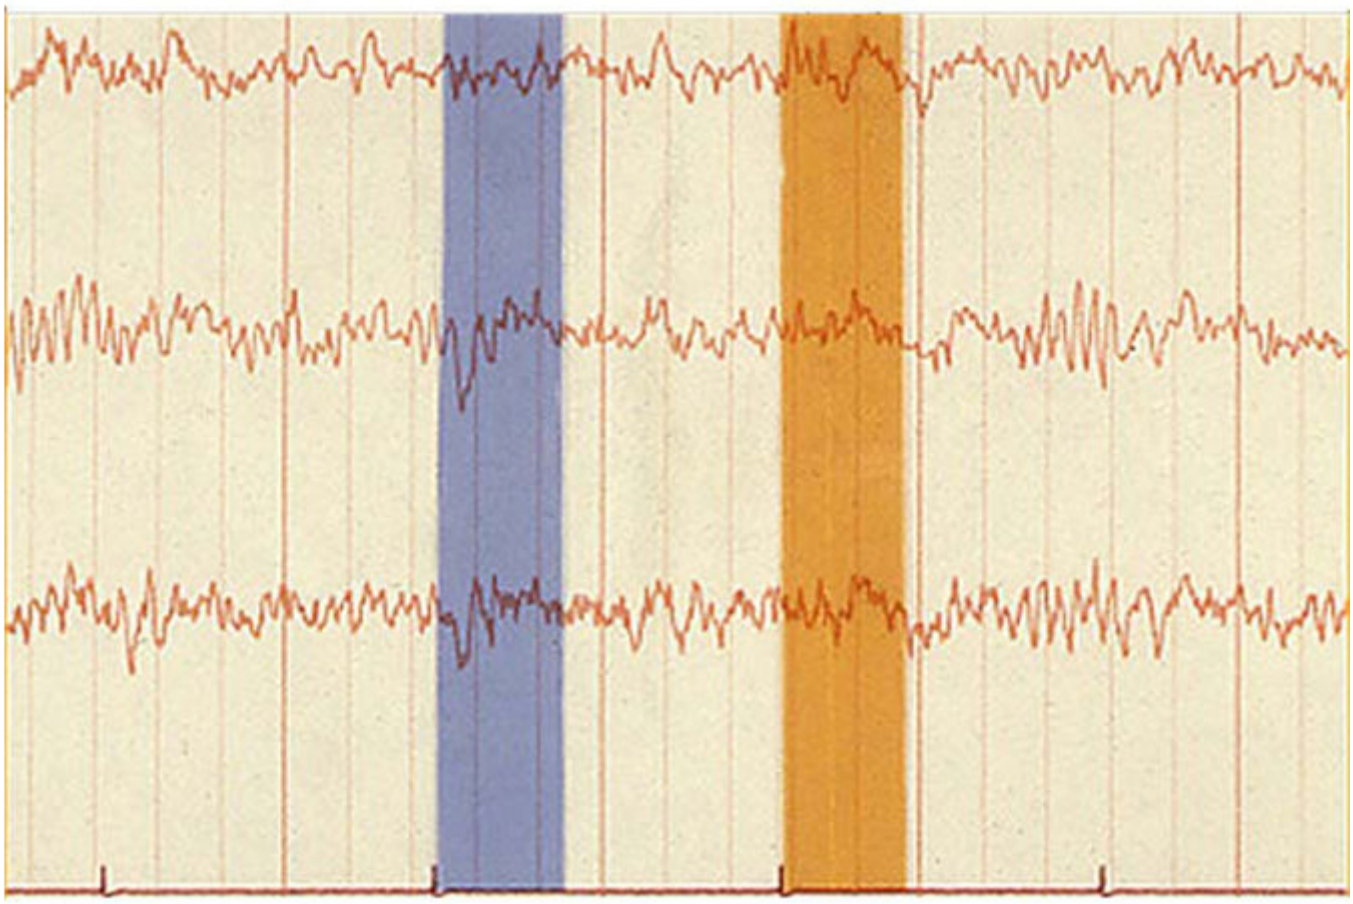

Figure 1. EEG tracings showing the time periods following flash presentations (blue and yellow areas) that are typically the waveforms of the VEP.

electrodes (01, 02) are a similar distance off the midline. Another set of locations is the "Queen Square system" in which the mid-occipital electrode is placed 5 cm above the inion) on the midline and 5 cm lateral from that location for lateral occipital electrodes (2). The Queen Square locations, further off the midline, are better able to lateralize anomalies such as when using hemi-field stimulation. Some laboratories, and unique applications, have other preferred scalp locations.

Many laboratories record from an array of locations placed horizontally across occipital scalp in an attempt to lateralize pathology. Other laboratories use only a single positive midline recording electrode at OZ with one earlobe as negative location and the other earlobe as ground location. A second montage is necessary for recording multifocal visually evoked potentials (mfVEPs). A common mfVEP montage is to place two electrodes on the midline one just below the inion and another 3 centimeters above the inion; and laterally place electrodes 3-4 centimeters off the midline several centimeters above the inion.

Sources of visual evoked potentials

Most of primary visual cortex in humans is located in fissures, not on the cortical surface of the occipital pole. At most, only about the central 10 degrees of visual field are located on the surface of the occipital pole. Furthermore, the area located on the surface of the occipital pole is quite variable, even between hemispheres of the same individual. Because most electrical potentials are generated in sulci (deep cortical fissures) simultaneously at multiple locations, and because of the vertical cancellation that occurs between upper and lower fields, lateralization of pathology is difficult. Potentials occurring at different cortical locations in vertical

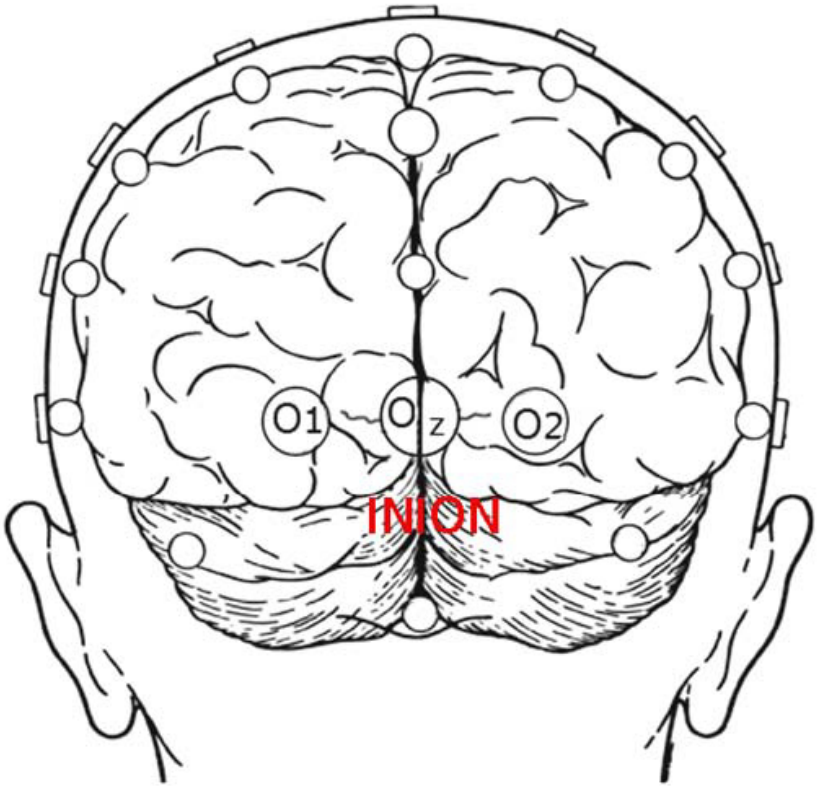

Figure 2: Occipital scalp electrode locations using the 10-20 International System. The INION is the scull location at the position shown. The nasion is on the face between the eyes.

and horizontal planes that vary between hemispheres produce paradoxical lateralization and obscures source localization.

The series of MRIs in Figure 3 demonstrate locations of significantly higher blood flow in occipital visual areas while the subject views a video monitor. The monitor subtends a 30-degree field displaying a 100% contrast, checkerboard pattern, flashing at 4 Hz. Note the lack of high levels of activity on the surface of the occipital pole and the interhemispheric variation (Fig. 3).

The neural generators of the waves of the visual evoked potential (VEP) (see Fig. 5) are not clearly defined. Research with multichannel scalp recordings, visual MRI activity and dipole modeling, supports the interpretation that the visual cortex is the source of the early components of the VEP (N1, N70) prior to P1 ("P100") (3). The early phase of the P1 component with a peak around 95-110 msec, is likely generated in dorsal extrastriate cortex of the middle occipital gyrus. The later negative component N2 (N150) is generated from several areas including a deep source in the parietal lobe (4).

As depicted in the functional visual MRIs in Figure 3, brain activity varies considerably in the occipital area. A number of dipole fields are generated resulting in a complicated interaction (5). These multiple sites of generators interact at different levels in the visual areas making source localization difficult when making individual clinical decisions. Because of individual idiosyncrasies in occipital anatomy and visual projections, one cannot make the assumptions about sources that one can using electroretinograms (ERGs), (see basic and clinical chapters on ERGs in webvision) or auditory brainstem responses.

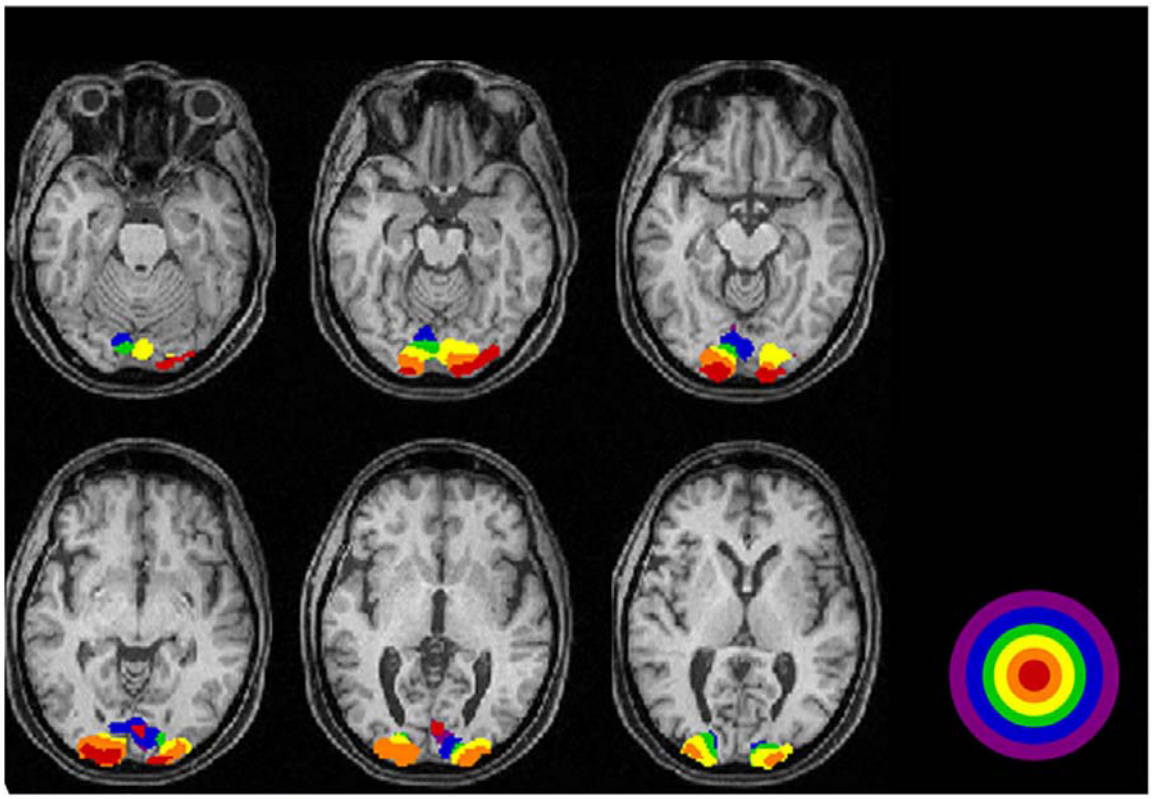

Figure 3: Functional MRI sections of the occipital visual areas showing maximal blood flow (activity) during visual pattern stimulation. Maximum is red, minimum is blue to purple. These functional MRIs were provided by Jeffrey Anderson, University of Utah.

VEP Recording methods

When applying electrodes, and cleaning scalp locations for electrodes one must remember the computer adage "garbage in, garbage out". Scalp locations need to be cleaned to produce low electrode impedance. One must be precise about recording with low impedance and choosing electrode locations.

A reference electrode is usually placed on the earlobe, on the midline on top of the head or on the forehead. A ground electrode can be placed at any location, mastoid, scalp or earlobe. The time period analyzed is usually between 200 and 500 milliseconds following onset of each visual stimulus. When testing young infants, analysis time should be 300 msec or longer because components of the VEPs may have long peak latencies during early maturation. Most children and adults may be tested using an analysis time of 250 msec or less. The most common amplifier bandpass frequency limits are 1 Hz and 100 Hz. Amplifier sensitivity settings vary with +/- 10 μV common for older children through adults and +/- 20 to 50 μV for infants and younger children. Sometimes the sensitivity setting must be changed to accommodate larger EEG voltage in all age groups. See the ISCEV (International Society for Clinical Electrophysiology of Vision) standard for clinical VEPs for variety of recommended test protocols (6). Commonly used visual stimuli are strobe flash, flashing light-emitting diodes (LEDs), transient and steady state pattern reversal and pattern onset/offset.

The most common stimulus used is a checkerboard pattern, which reverses every half-second (Fig. 4). Pattern reversal is a preferred stimulus because there is more inter-subject VEP reliability than with flash or pattern onset stimuli. Several laboratories developed pattern reversal visual stimuli in the 1970s including A. M. Halliday at Queen Square in London and Lorrin A. Riggs at Brown University. Originally Halliday back-projected a checkerboard pattern onto a translucent screen with two projectors that each projected reversed checkerboard

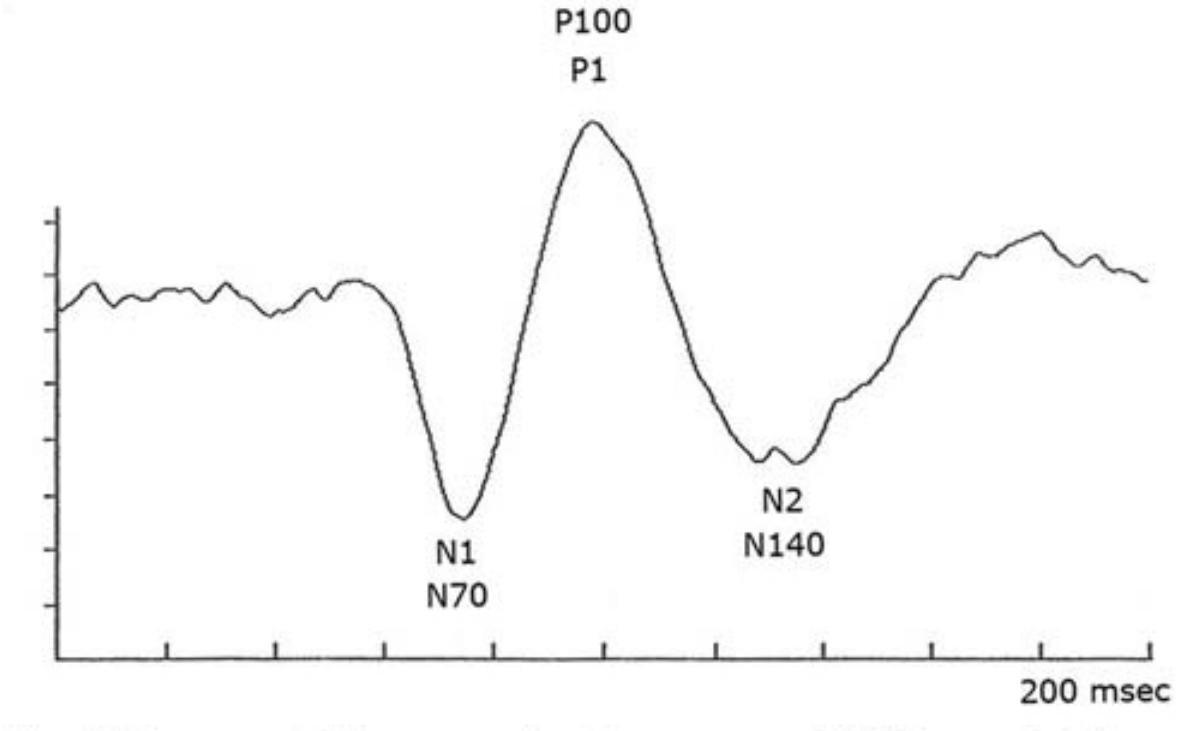

Figure 5: Representative normal pattern reversal VEP recorded from mid-occipital scalp using 50' checkerboard pattern.

images. Camera shutters on each projector controlled the display of each checkerboard reversing at a rate 2 per second. Riggs originally projected alternating vertical stripes using a reversing mirror system. Commercially produced visual evoked potential systems simulating these pattern reversals now use video monitors.

Using cathode ray tube monitors (CRT) nearly everyone with close to normal visual function produces a similar evoked potential using pattern reversal stimuli. There is a prominent negative component at peak latency of about 70 msec (N1, Fig. 5), a larger amplitude positive component at about 100 msec (P1, Fig. 5) and a more variable negative component at about 140 msec (N2, Fig. 5). The major component of the VEP is the large positive wave peaking at about 100 milliseconds (Fig. 5). This "P100" or P1 in the jargon of evoked potentials, is very reliable between individuals and stable from about age 5 years to 60 years. The mean peak latency of the "PI00" only slows about one millisecond per decade from 5 years old until 60 years old.

Video monitors that produce brighter, faster changing patterns such as liquid crystal displays (LCD) evoke faster VEPs than cathode ray tube video monitors. The "P100" or P1 component is much faster using liquid crystal displays (LCD) evoking P1 peak latency times of less than 90 milliseconds. Variation in stimulus parameters is a good reason for each laboratory to have their own normative data even if the manufacturer provides such data.

The size of each check in the pattern and size of the visual field affects the VEP. Most laboratories initially screen patients using a video display with field subtending 10-40 degrees of arc and fairly large individual check size of about 1 degree of arc. A large check size is used because most clinical laboratories are recording from patients who lack good visual acuity. The largest amplitude, fastest peak latency VEP is recorded using the smallest check size the subject can see sharply. A person with 20/20 (6/6) or better vision will produce the largest amplitude, fastest VEP components using a small check size (a visual field comprised of checks only 5-6 mm viewed at 1 meter). Each check would measure about 15-20' of arc. A person with poor visual acuity would produce the largest amplitude, fastest components with a larger check size subtending a degree or more (such as a 20 mm

check or larger viewed at 1 meter distance). This is the basis for one being able to estimate acuity by testing a subject with several check sizes. The "P100" (P1) component is sensitive to defocusing and can, therefore, be measured following stimulation with different check sizes to estimate refractive error. For most clinical screening, a single check size of about 1 degree of arc, or a little smaller, such as about 50' of arc, is sufficient. One need not use larger checks for children. Once a child is mature enough to attend and maintain fixation their visual systems are mature enough to use the same size stimuli as adults.

The VEP waveform, amplitudes and peak latencies depend upon the parameters of the stimulus. Steady state VEPs are those recorded using stimulation rates of 3 or more per second. Transient VEPs are recorded using rates of less than 3 per second. Transient pattern VEPs have components that can be followed during maturation, pathological conditions and changes of acuity. Flash-evoked and pattern onset VEPs are reliable in form within the individual but vary considerably between patients. The checkerboard pattern can also be made to appear (onset) and disappear (offset). In many individuals the pattern onset VEP is opposite in polarity compared to flash and pattern reversal VEPs. The pattern onset VEP usually includes a positive component at about 80 msec and a large negative component at about 110 msec. Another advantage of the pattern reversal VEP is that it has a smaller standard deviation for the P1 component (about 6 msec). The P110 component of the flash VEP and the N110 component of the pattern onset VER have standard deviations of about 10 msec.

Maturation of VEPs with age

By age three years, children can usually co-operate fully allowing use of the same recording parameters as adults. The problem is not that a child's visual system is developed insufficiently. It is. The problem for children less than 3 years of age is one of maintaining fixation. Below approximately age three, in examinations under anesthesia, trauma cases, and other causes of very poor vision, flash stimuli generated by strobe or LED flash may be required. Retinal development, cortical cell density, myelination and visual acuity are close enough to that of an adult by age 5 years, that children by this age produce adult VEP waveforms. There are changes that take place into adolescence, but these have subtle effects on the VEP.

Thus, the most dramatic changes are in the first several years after birth (7). What will mature into the "P1" component of the flash VEP can be recorded in the full term infant within 5 weeks of age with a peak latency of less than 200 msec. VEPs change rapidly in form and complexity in the first six months. As the infant matures this late "P1" appears earlier and earlier so that by about age 4-5 years, peak latency shortens to about 100 msec using pattern reversal stimuli, and about 110 msec using flash stimuli. Peak latency times remain at this point for most of one's adult life with no statistically significant change until after age 55 years.

Components of the VEP change gradually after age 55 displaying attenuation in amplitude and slowing of the P1 component (Fig. 6). Thus, the two periods in life that vary most in VEP physiology are the first few years during early maturation and during aging after age 60 years. Aging adults late in life vary even more than developing children. Figure 6 shows a sample scattergram of P1 peak latencies across age.

The amplitude of the mature P1 component of flash and pattern VEPs is greatest at about age 7-8 years. The brain reaches 90% of adult size as early as age 6 years. Preadolescence is the period when the brain is largest relative to skull, scalp and muscle thickness. As children enter adolescence and mature these tissues thicken attenuating the brain's signal as recorded from the overlying scalp. The amplitude and speed of VEPs remains stable until about age 28 years at which time amplitudes begin to attenuate (8).

The VEP recorded from mid-occipital scalp is about 90% weighted in that it reflects the function of the central 10 degrees of the visual field. Ten degrees is about the maximum visual field that is on the occipital cortical surface. Whatever method is used, it is important for a laboratory to replicate testing of each subject and to gather normative data. Each subject should be placed the same distance from the visual stimuli, and room lighting should be the same.

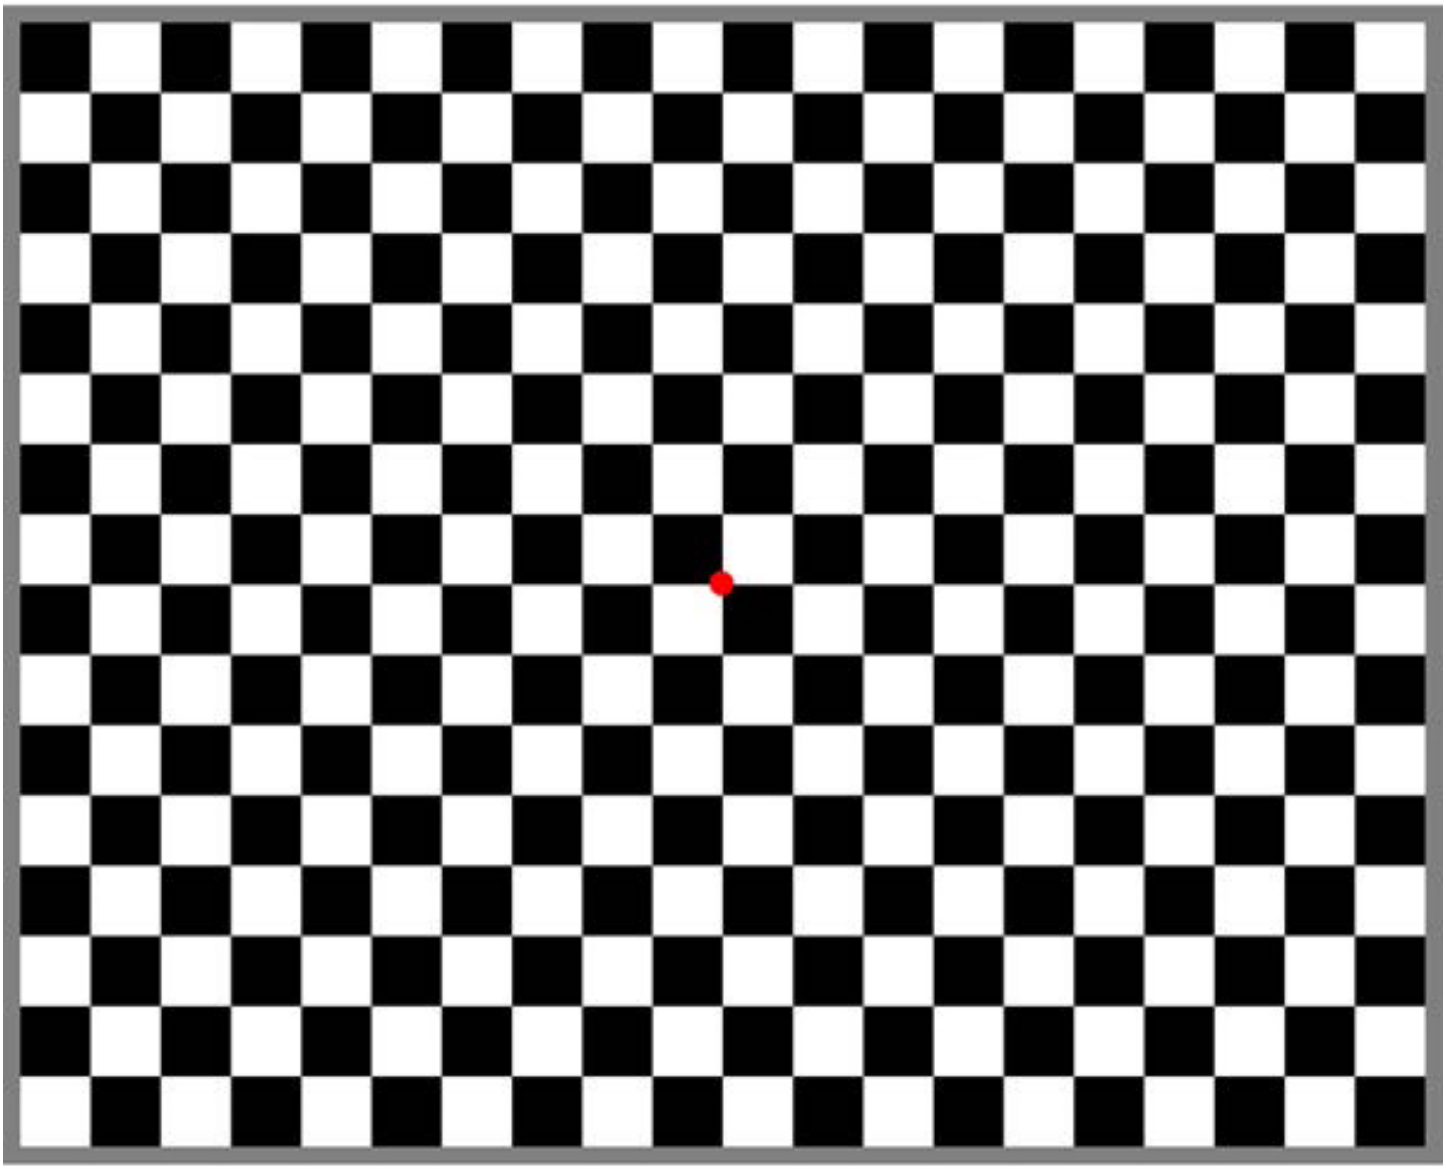

Figure 4: Checkerboard pattern with red fixation point.

VEPs quantify visual system function. Abnormal VEPs can be symptomatic of dysfunction, but are not diagnostic of it until carefully considered within the context of the patient's clinical picture. When recording VEPs the diagnostic yield is dependent upon appropriate selection of visual stimuli.

If the history and ophthalmic examination of a patient raises the possibility of dysfunctional retina, optic nerves, tracts or cortices, the VEP may yield diagnostically useful information. A common clinical referral is patients where the question is whether their visual problems are due to retinal or central visual dysfunction. Recording both an electroretinogram (ERG) and VEP will usually answer this question.

VEP testing under anesthesia (E.U.A.)

Examinations under anesthesia (E.U.A.) can be conducted recording both VEPs and ERGs. Anesthesia is used for various reasons ranging from 'the patient is unexamineable while alert' to, more often, that some of the examination procedures are uncomfortable or painful (such as biopsies). Unfortunately, anesthesia affects the

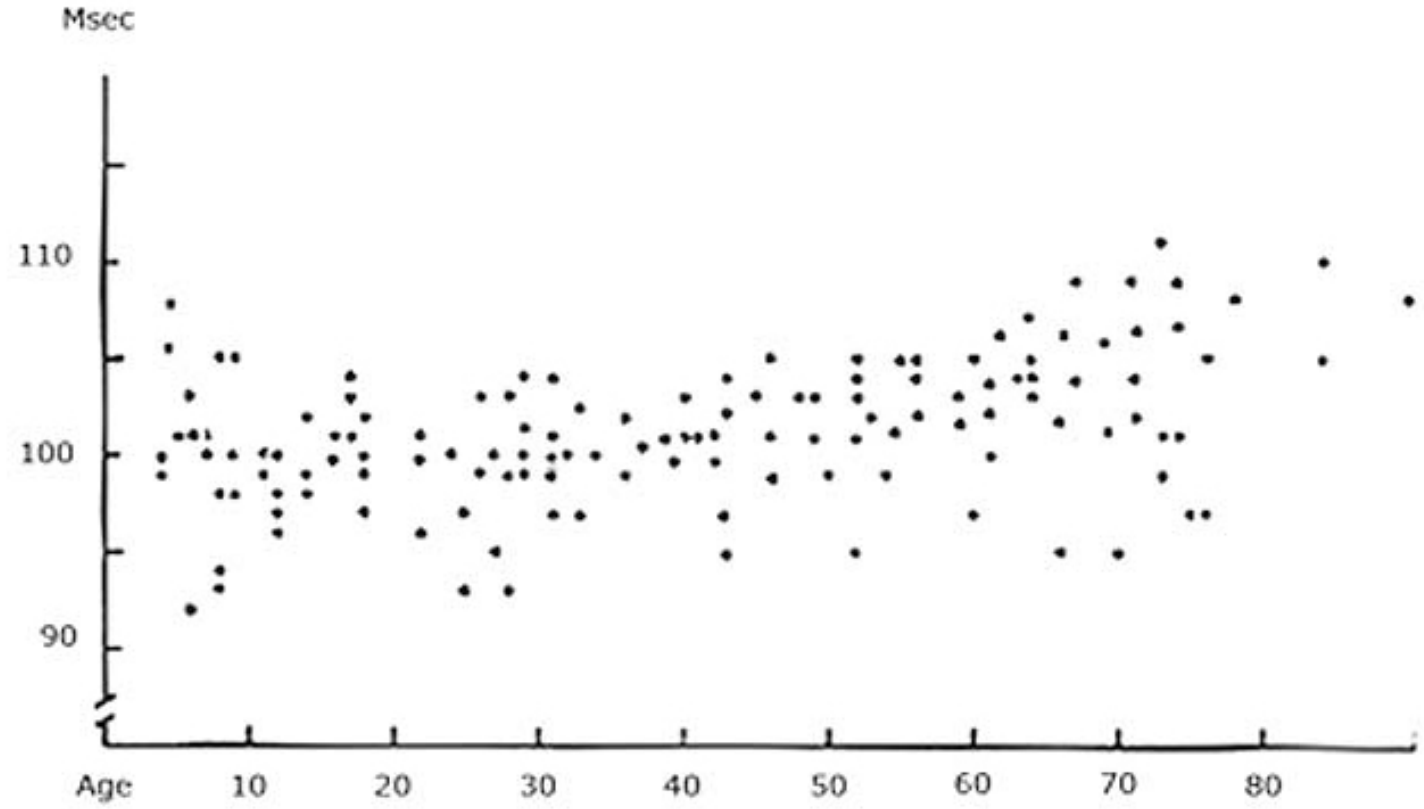

Figure 6: Scattergram of pattern reversal VEP "P100" component peak latencies recorded from normal individuals ages 5-90 years of age.

VEP, varying with type and depth of anesthesia. Most surgical deep anesthetics obliterate the cortical activity necessary to produce the VEP. Yet auditory brainstem responses (ABRs) and somatosensory evoked potentials (SEPs) can still be recorded. Most VEP computers display the EEG. If the EEG is flat you will not record VEPs.

Anesthesiologists start with fairly deep anesthesia while putting in lines. I usually ask the anesthesiologist: "When the patient is stable will you please lighten the anesthesia as much as you are comfortable with." Ask permission before touching the patient. This is especially important if you wish to raise the head to place the occipital electrode. Raising the head may crimp the tracheal tube.

If recording both ERGs and VEPs under anesthesia, record the ERG first because it is more resistant to anesthesia. In the minutes it takes for the ERG recording, the patient's anesthetic depth lightens further. Rarely must one wait more minutes for the patient to lighten.

The influence of refractive error

If pattern stimuli are to be used, it is important that a patient be tested with refractive error corrected. Refractive errors will affect the interpretation of the VEP results. For example, adults with LASIK correction so that one eye is for distance vision, the other for near, will affect VEP amplitudes and peak latencies. Select the most powerful stimulus that the visual acuity and cooperation of the patient will allow. If the corrected visual acuity of the patient is approximately 20/200 (6/60) or better, and the patient does not have nystagmus, the stimulus of first choice would be pattern reversal starting with about a 50' check. If the resulting VEP appears well formed, and if measuring acuity is an issue, next use a smaller check size in the range of about 15-20' of arc. When testing for

refractive errors such as estimating acuity, smaller check sizes (e.g., 15') and lower contrast (<50%) are recommended. In the normal infant 20/20 (6/6) vision is present by about 9 months of age. Check sizes subtending 10-20' of arc are the best stimuli for testing foveal vision. Checks of 40-50' are superior in evaluating parafoveal function, therefore using more than one check size increases diagnostic yield. If the resulting VEP using the 50' check is poorly formed, retest using a larger check size or use a pattern onset stimulus. Pattern reversal stimuli are the best choice in cooperative patients with good visual acuity, particularly when testing for possible effects of optic neuritis, hydrocephalus, ventriculitis, cortical hematomas, optic atrophy, neurofibromatosis or compression of the optic pathways.

If the corrected acuity of the patient is approximately 20/200 to 20/400 (6/60-6/120) and/or the patient has nystagmus, the preferred stimulus would be pattern onset. Pattern onset or "pattern flash" stimuli produce a more robust VEP than does pattern reversal. Pattern reversal stimuli usually exacerbate nystagmus interfering with the ability of the eye to maintain foveal fixation. Pattern onset stimuli can also be the most productive stimulus in conditions such as monitoring amblyopia, in patients with poor acuity, possible hemispheric asymmetry or a defect in geniculo-striate projections. Pattern onset usually produces a more robust VEP initiated from the central 30 degrees of retina (9).

If the patient's acuity is approximately 20/400 (6/120) or worse, or the patient is uncooperative, unconscious, sedated or anesthetized, the stimulus of choice is strobe or LED flash. Flash stimuli are useful in infants who will not maintain fixation on a pattern. The resulting VEP will usually detect significant optic atrophy and other abnormalities of the central visual pathways. In many cases of cortical blindness the flash VEP will be abnormal, although sometimes it is normal. The VEP is often prognostic in delayed maturation of the visual system (usually the infant with delayed maturation has a normal flash VEP). Permanently cortically blind infants usually have abnormal VEPs. Flash stimuli produced by LEDs can be useful in some patients. LED arrays are available inside goggles and on discs about 50 mm in diameter. These are more effective than a strobe lamp for monocular stimulation, and useful in the operating room when monitoring VEPs during surgery or E.U.A.

For initial screening of most patients the electrode montage of choice is a single recording electrode placed on the midline overlying the central pole of the occipital cortex, which lies approximately 3-4 cm above the inion. The VEP recorded from this location exaggerates the contribution of the macular portion of the retina due to the fact that only the macula is projected onto the occipital pole. This recording site is referred to an electrode placed on the earlobe or on the midline of the upper forehead or head. There is no significant difference in the VEPs obtained using most reference points although technically the earlobe is the more electronically neutral site than scalp locations. As mentioned earlier, correct lateralization of pathology by using recording electrodes off the midline overlying occipital cortex, is difficult using the VEP. Information obtained from computed tomography (CT) and MRI scans better localize such pathology.

Examples of VEP recordings in different retina-brain pathologies

There are hundreds of syndromes and visual anomalies that can affect VEPs. A limited sampling is presented but in the same format as in Figure 7 for all the following case figures. The N1 wave is called N75, The P1 wave is called P100 and the N2 wave is called N145, in all our data (VEP normal averages under our testing conditions).

Multiple Sclerosis

The visually evoked potentials in Figure 7 were recorded from a patient with early signs of multiple sclerosis including optic neuritis. As is usual in these cases, initially one nerve (right eye measurements, top traces, Fig. 7) yields normal evoked potentials (98 msec close to the P100 norm. Scale is 25 msecs between vertical ticks). The left nerve, affected with retrobulbar optic neuritis shows a delayed P100 component (Fig. 7, left eye measurements P100 is 110 msecs, lower traces). Since the standard deviation for the peak latency of P1 is usually about 6 milliseconds, a P1 peak of 110 milliseconds is considered abnormal. Patients with MS usually develop

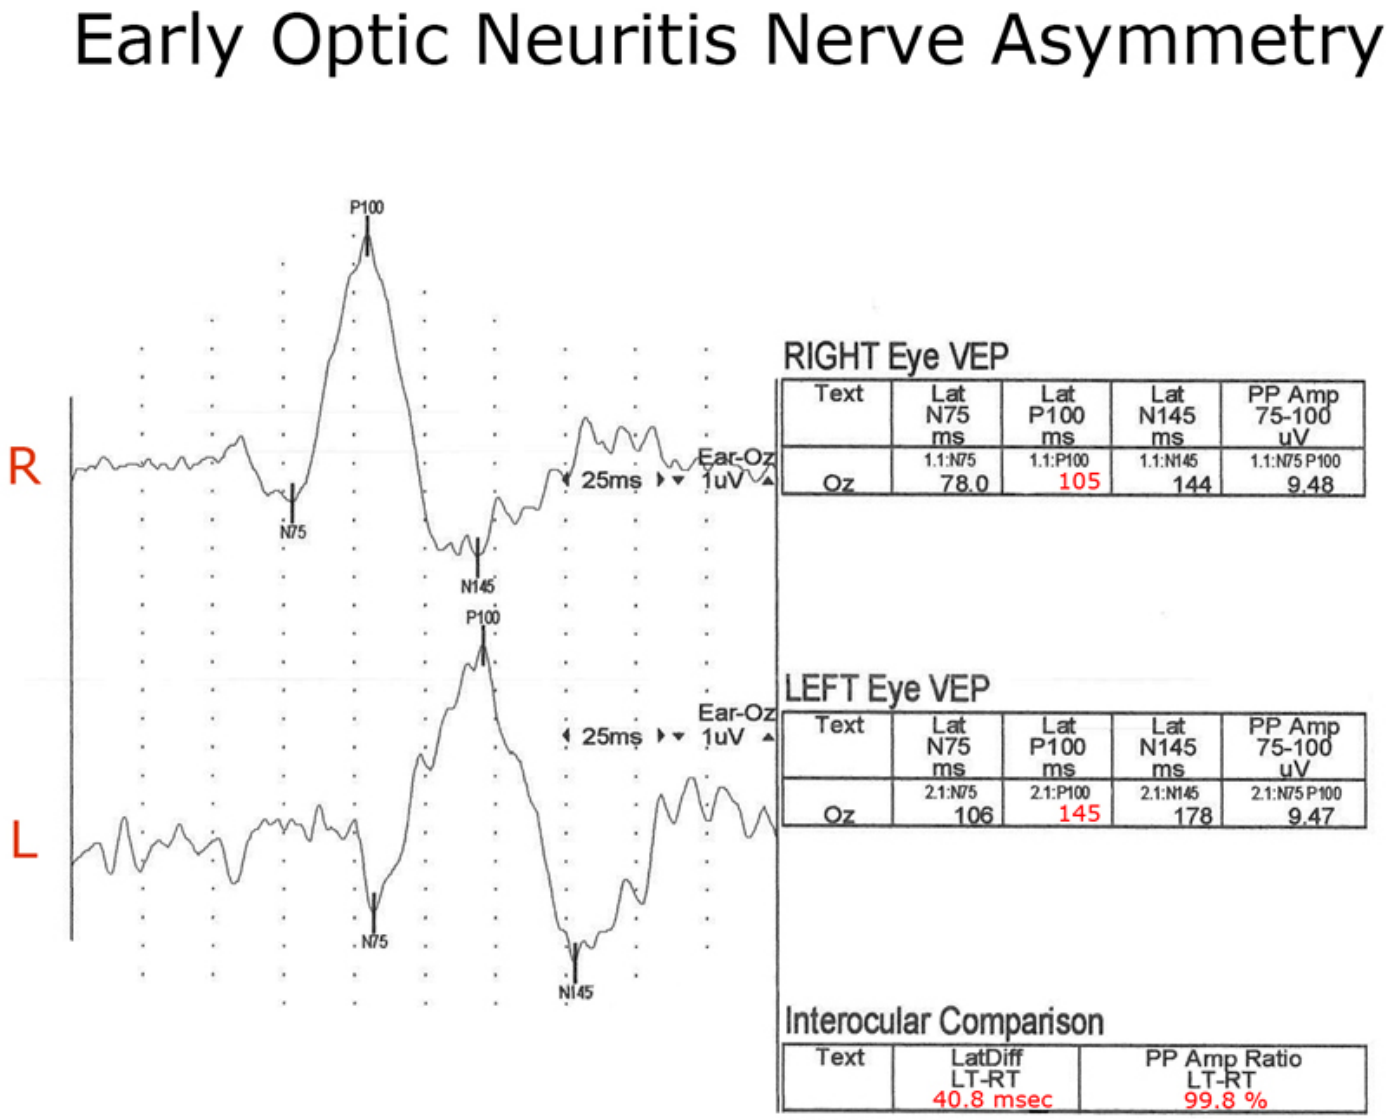

Figure 7: Pattern reversal VEPs recorded from adult female with early unilateral optic neuritis. N75, P100 and N145 waves are labeled. VEP traces of Right and Left eye stimulation are displayed. The vertical tick marks are in 1uV intervals. The RIGHT eye peak latencies are normal range. The LEFT eye peak latencies are significantly slow. The Interocular differences are shown in the lowest box.

optic neuritis later in the other nerve (Fig. 8). Over the years the VEPs in patients with MS become progressively slower eventually attenuating in amplitude as demyelination increases (Fig. 9).

Trauma

Another application of VEPs is to quantify visual system function following trauma. It is not unusual that compression of optic pathways immediately after severe trauma results in no recordable VEPs. However, VEPs may be recordable days later when inflammation subsides. Figures 10, 11 and 12 show the sequence of recovery in an infant with head trauma producing compression of the optic nerves and the occipital brain area.

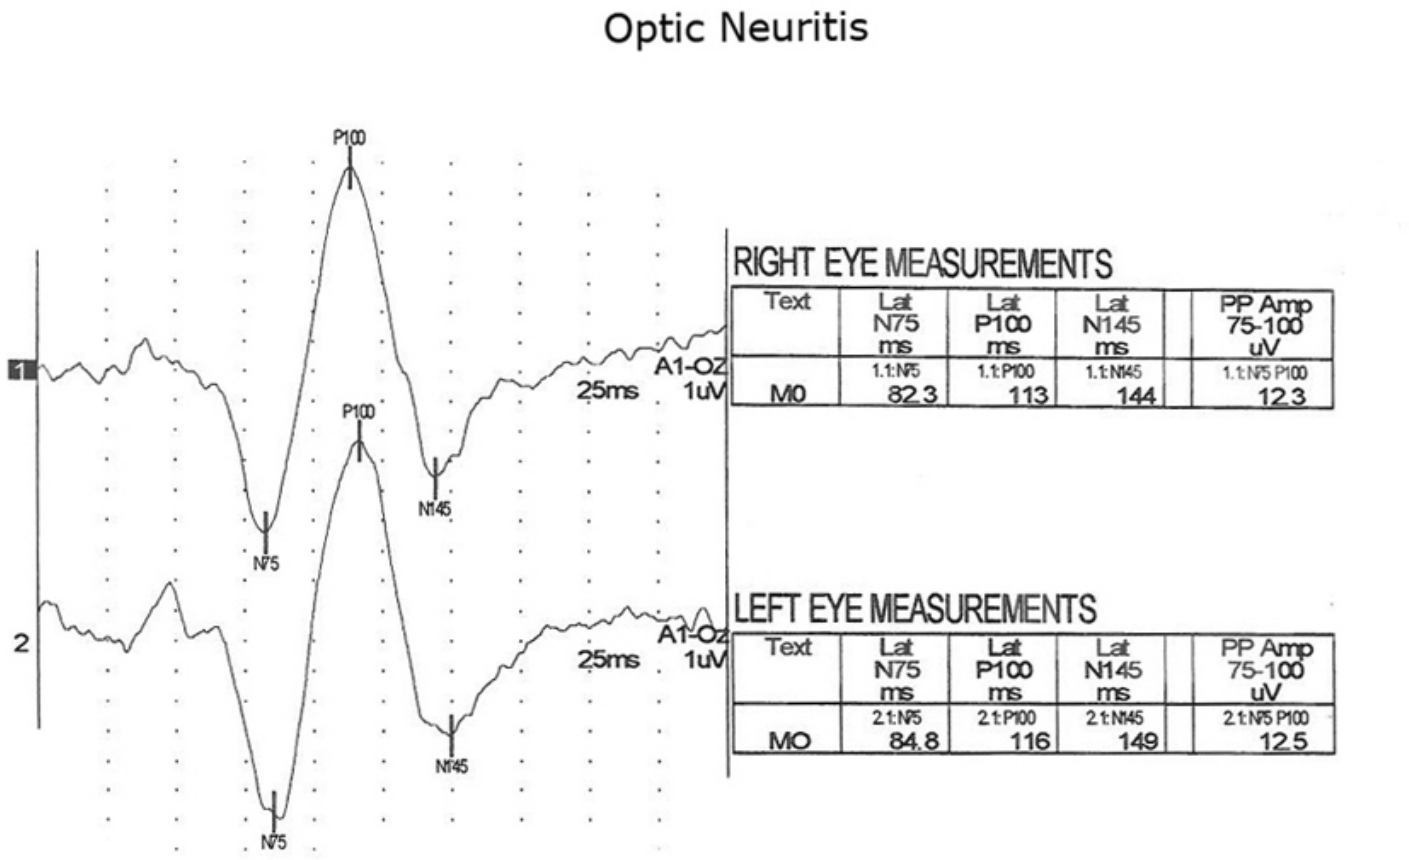

Figure 8: Pattern reversal VEPs recorded from a 37 year old with bilateral optic neuritis showing slowing of components.

Tumors

Children with neurofibromatosis type 1 (NF1) are vulnerable to development of optic nerve gliomas. The VEP can be a more sensitive and cost effective test to follow the progress of nerve pathology than MRI tests alone. Essentially all children with NF1 show slowing of VEPs by school age (Fig. 13).

As is true for any space-occupying tumor or other compression such as hydrocephalus affecting visual pathways, the VEP is useful to quantify compression of pathways. The next three figures (14, 15 and 16) show progression of development of bilateral optic nerve gliomas in a child with NF1.

Recovery of function

VEPs are also useful in following recovery of most optic pathway dysfunction. The next two figures (17 and 18) show flash VEPs recorded prior to and 2 weeks following removal of a large orbital mass from a 3 year old.

Figure 19 shows the VEPs of another type of tumor in a child - a unilateral neuroblastoma.

VEPs can be useful in quantifying and following the progression of optic nerve hypoplasia, optic atrophy or pale nerve. Figure 20 is an ocular fundus photo of a child with a pale optic nerve. Figure 21 displays flash VEPs recorded from the 9-year old child with pale optic nerves (Fig. 20). The VEPS are both attenuated in amplitude and have prolonged component peak latencies.

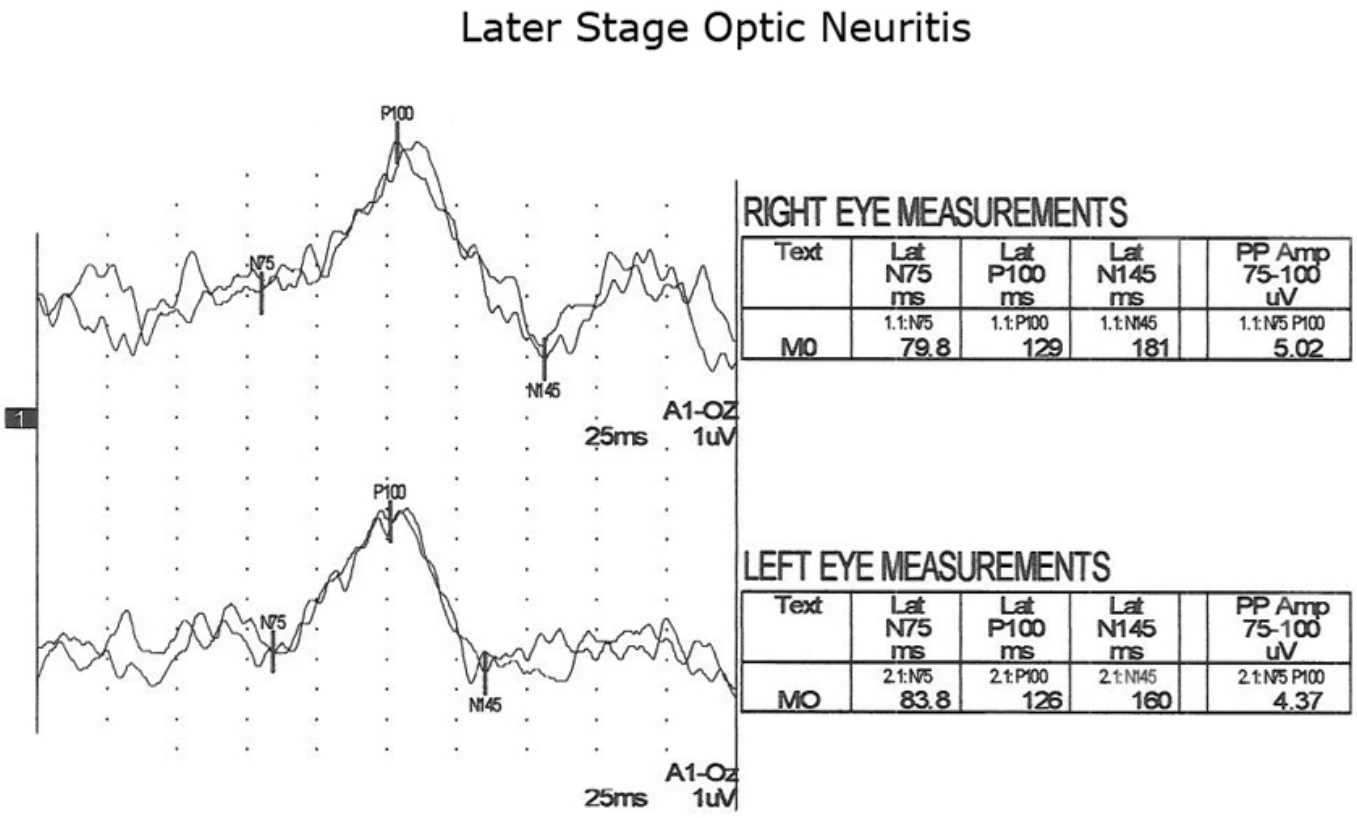

Figure 9: Pattern reversal VEPs of the MS patient years after initial onset of optic neuritis showing progressively slower P100s.

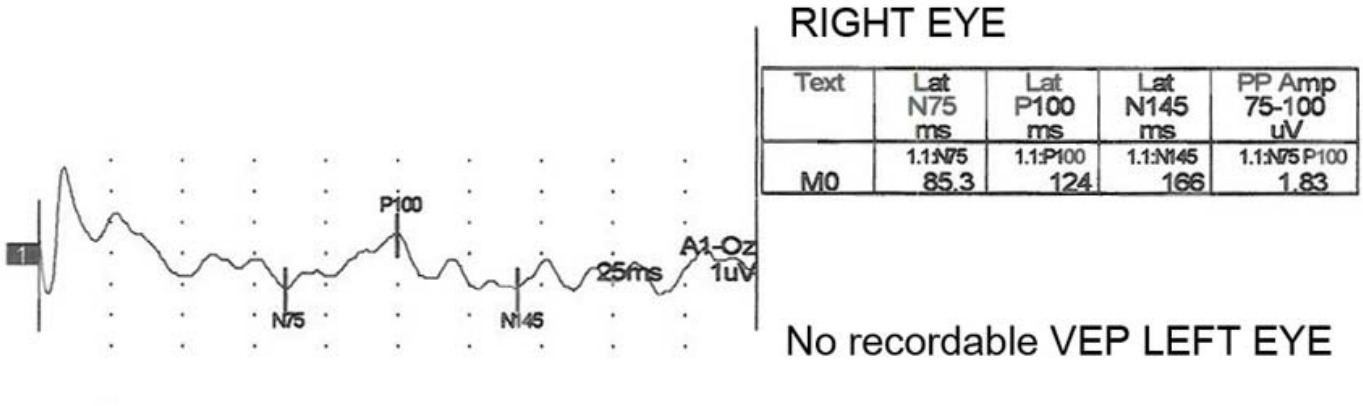

Figure 10: Flash VEPs recorded soon after occipital trauma in a 2 year old showing a small VEP amplitude in the right eye and no VEP in the left eye.

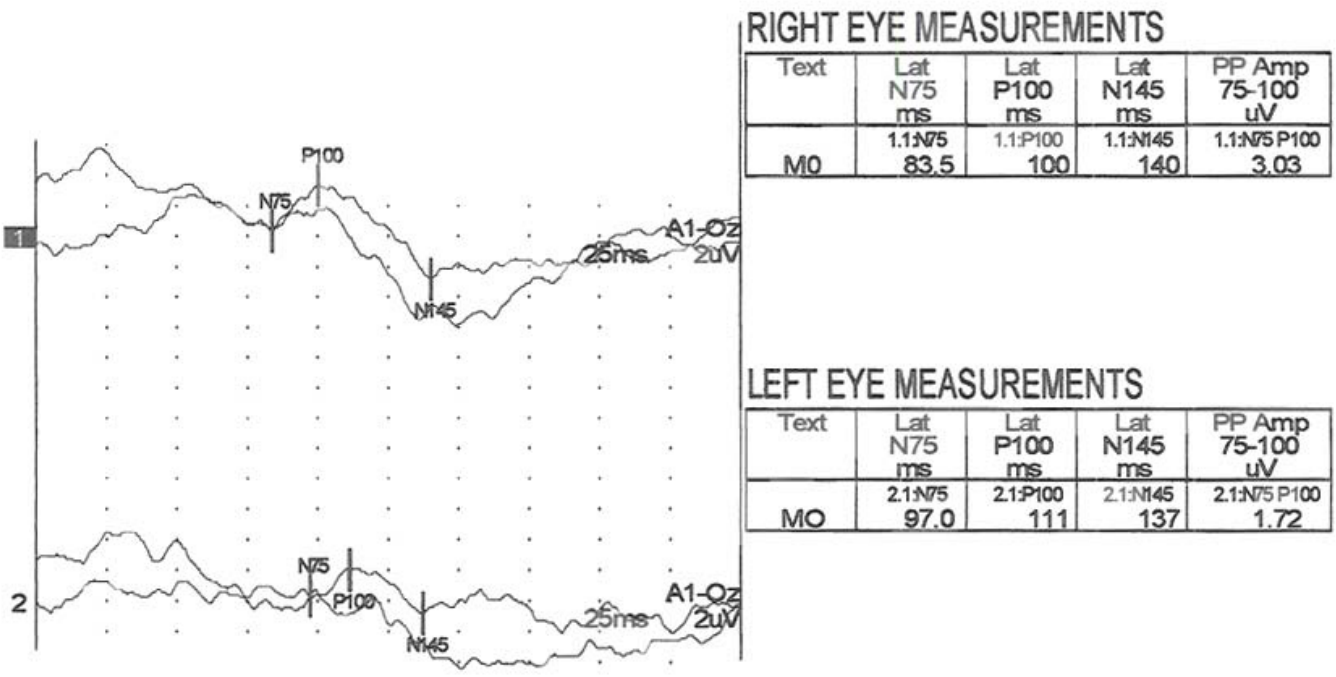

Figure 11: Flash VEPs recorded from the 2 year old, one month after occipital trauma showing some recovery of the optic nerve pathways.

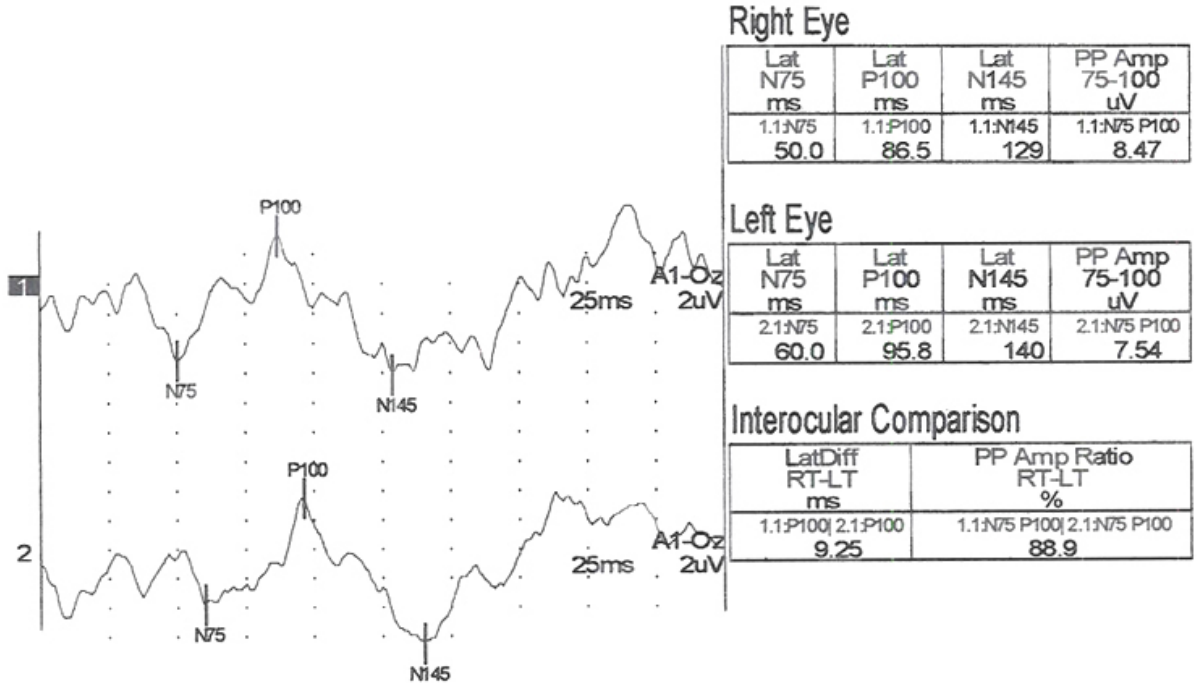

Figure 12: Flash VEPs recorded from the 2 year old, two months after occipital trauma showing further recovery.

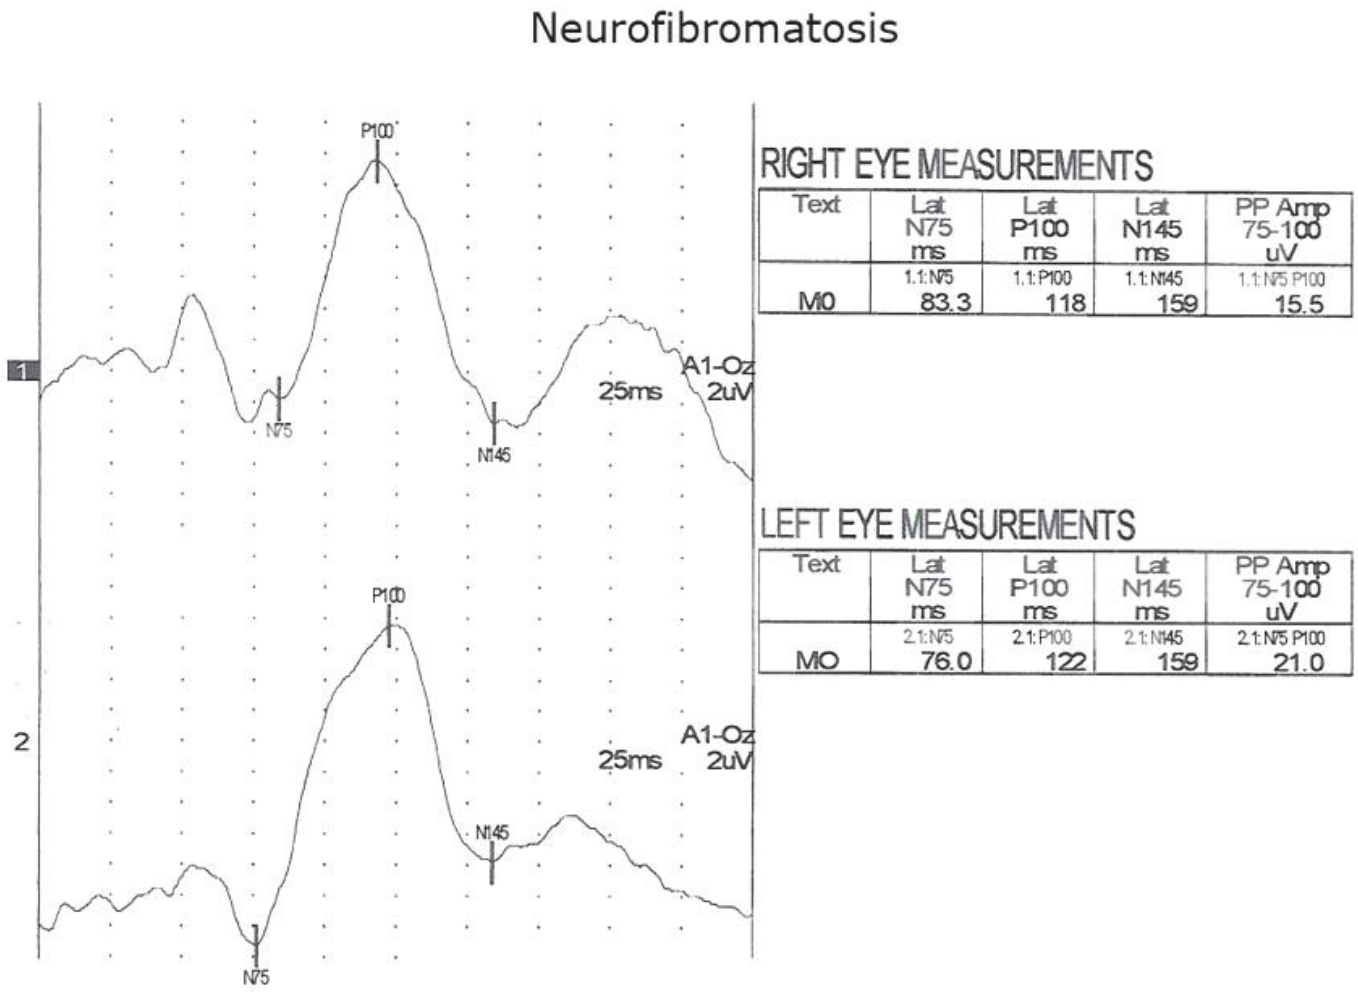

Figure 13: Pattern reversal VEPs recorded from a 5 year old with neurofibromatosis type 1 (NF1) showing slowing of VEP components in both optic nerves.

Optic Nerve Toxicity

Some medications can be toxic to optic nerve function. Figure 22 displays pattern reversal VEPs in an adult with Ethambutol optic nerve toxicity. Again there are delayed peak latencies.

There are several medications that can be toxic to the optic nerves including Amiodarone an antiarrhythmic medication used to treat ventricular tachycardia or ventricular fibrillation. In some patients Amiodarone is associated with ischemic optic neuropathy. The VEPs of these patients show prolonged peak latencies.

A partial list of toxins and medications associated with optic neuropathy includes carbon monoxide, ethylene glycol, and methanol. The antimicrobials Ethambutol, Isoniazid and Linezolid, are drugs that have indirect effect on the optic nerve. Sildenafil (Viagra) and Infliximab can also affect optic nerve function. VEPs also provide information about visual cortical function. VEPs, recorded from patients suffering from birth anoxia or near-death drowning, will quantify the degree of occipital cortex dysfunction. In general recordable VEPs are a positive prognostic sign.

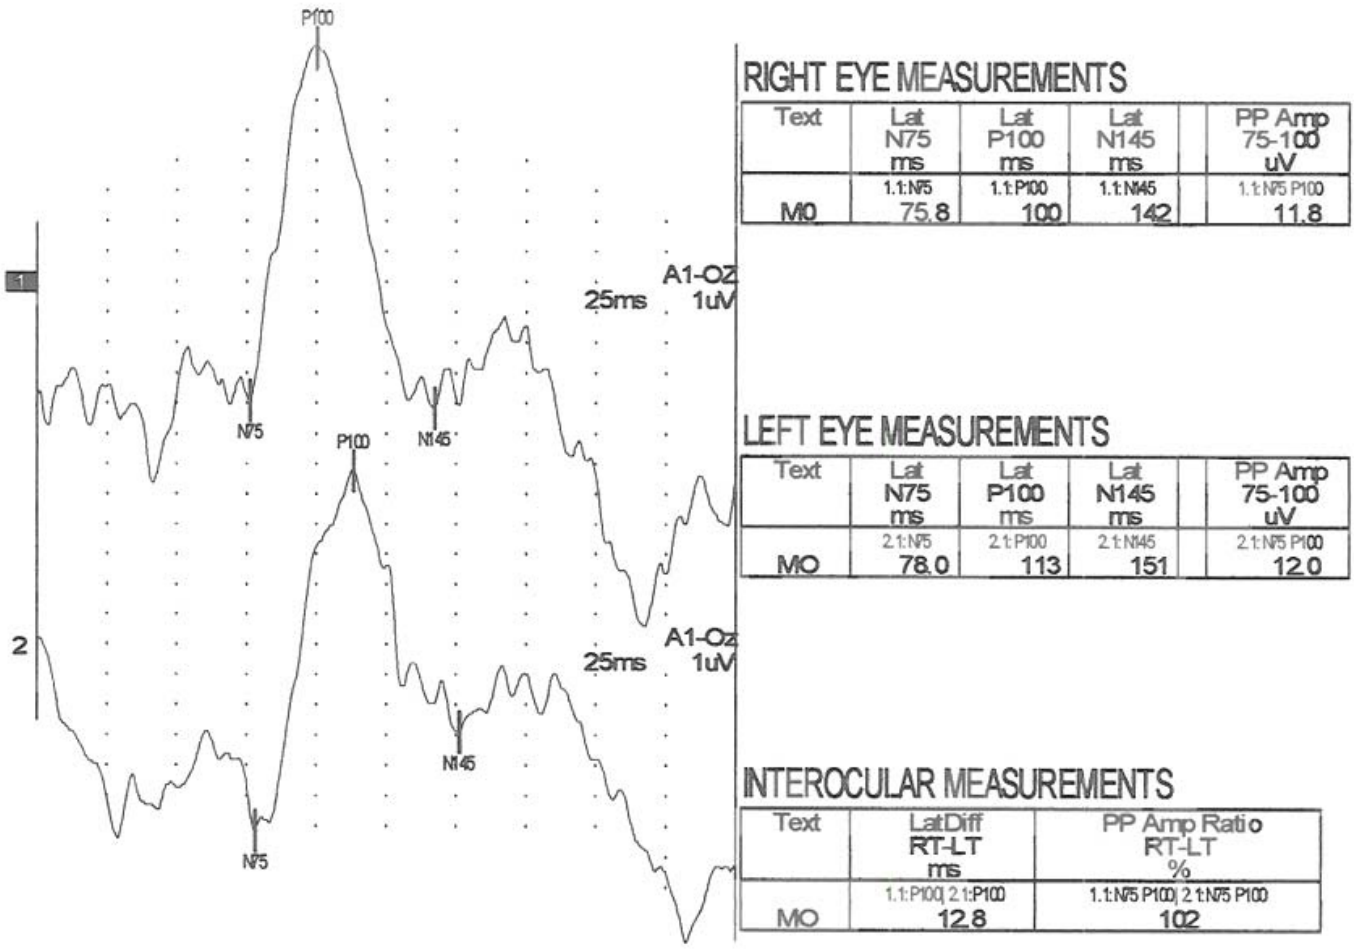

Figure 14: Initial pattern reversal VEPs recorded from an 8 year old with NF1 showing slowing of the left nerve but good amplitude.

Infections

Similar to dysfunction in the visual pathways, any pathology affecting visual cortices can be quantified using VEPs. Figure 23 shows pattern reversal VEPs in an adult with meningeal tuberculosis. Here slow VEP peak latencies are also seen (Fig. 23).

Multifocal VEPs

An important development in VEPs is the multifocal VEP (mfVEP). Erich Sutter adapted the mathematical sequences called binary m-sequences creating a program that can extract hundreds of VEPs from occipital scalp. This program allows assessment of VEP activity in over 100 "channels" of each optic pathway (10).

Traditional VEPs evaluate the optic nerves and central pathways as a whole. Often small or localized optic pathway dysfunction is not detected. Using multifocal VEP analysis one may isolate smaller dysfunctional areas using hundreds of stimulations presented in the same amount of time it would take to record a single whole nerve VEP with conventional methods (11). Multifocal VEPs best evaluate asymmetry of visual function caused by optic nerve dysfunction. Pathology can sometimes be detected that may be missed with a traditional single VEP.

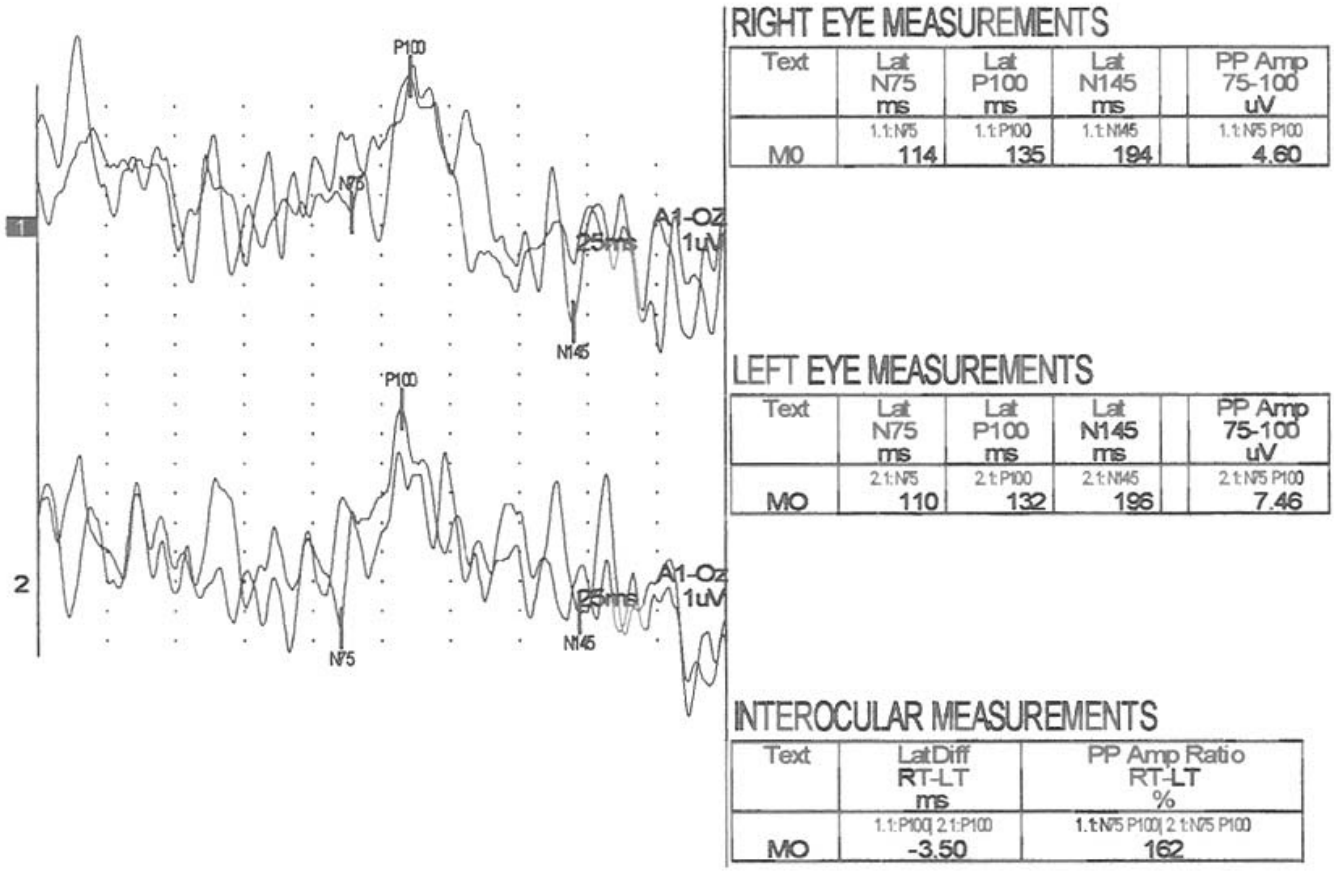

Figure 15: Pattern reversal VEPs of the same patient as Fig. 14 at age 11 showing prolongation of VEPs and amplitude attenuation.

Whereas stimulus patterns for multifocal electroretinograms (mfERGs) are an array of flickering patterns, multifocal visually evoked potentials (mfVEPs) are better elicited with reversing checkerboard patterns (10).

Four occipital scalp electrodes are required to record mfVEPs. A common mfVEP montage is to first place two electrodes on the midline. One just below the inion and another 3-4 centimeters above the inion; and laterally place electrodes 4 centimeters off the midline several centimeters above inion. The ground lead can be anywhere on the body. See Hood et al. (12) for suggested International Standard for recording mfERGs.

The stimulus for multifocal electroretinograms is a focal pattern stimulation m-sequence modulated flicker (See chapter on The Electroretinogram: Clinical Applications by Donnell Creel). The common stimulus for multifocal visually evoked potentials (mfVEPs) is a dartboard pattern with each sector a contrast reversing check pattern (Fig. 24).

Multifocal visually evoked potentials from a normal subject are shown in Figure 25. Red traces are from right eye stimulation. Blue traces are from left eye stimulation.

Sample patients tested with mfVEPs

A common application of mfVEPs is recording these potentials from patients with optic neuritis. Usually optic neuritis appears first in one optic nerve. Figure 26 displays the VEPs of a patient with unilateral optic neuritis

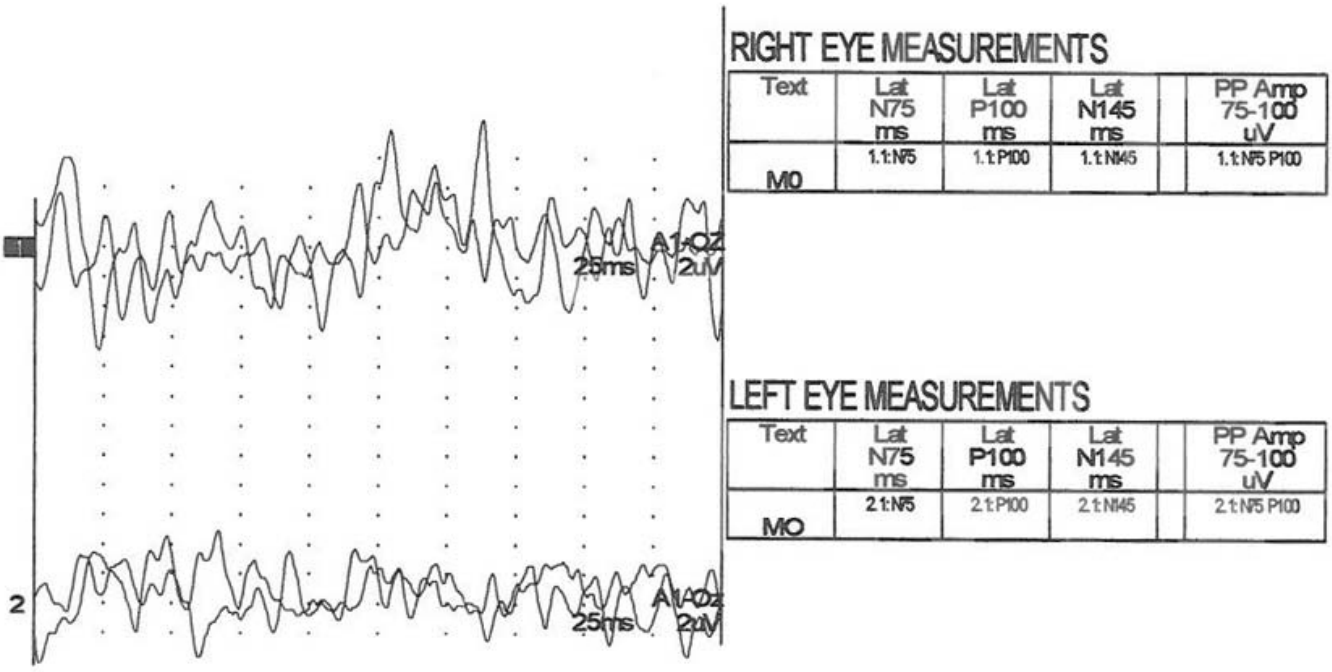

Figure 16: Pattern reversal VEPs of the same patient as Figs. 14 and 15 at age 12 showing obliteration of VEPs due to the growth of the gliomas.

during the acute phase affecting the right optic nerve. During the acute phase most of the responses in the central 30 degrees were abnormal. Many responses in the central 5 degrees were nearly extinguished.

This same patient tested 2 months later shows significant recovery in the amplitudes of the responses, but slower peak latencies persist due to demyelination (Fig. 27).

An example of another optic nerve disorder is a patient with optic nerve damage due to glaucoma. The mfVEPs of a patient with unilateral glaucoma are shown in Figure 28.

Summary

Visually evoked potentials are useful to quantify nerve dysfunction from retina to visual cortex. VEP recordings are done by a number of methods to evaluate visual pathway function (13, 14). Choices of which VEP stimuli and protocol to apply need to be made based on the patient's symptoms, history and other information available. Abnormalities seen in VEPs are symptomatic, but not diagnostic. VEP abnormalities do not specify etiology. For example, retinal disease alone will drastically alter VEPs. Interpretation of VEPs must be considered within the context of the patient's clinical appearance and information available from other tests and examinations.

About the Author

The Electroretinogram: ERG

Ido Perlman

Created: May 1, 2001; Updated: June 27, 2007.

Historical View

As early as 1865, Holmgren found that a light stimulus could cause a change in the electrical potential of the amphibian eye. Shortly afterwards, similar findings were reported by Dewar from Scotland. He showed that light illumination through the pupil, which had previously been covered, caused a slight movement of a galvanometer, suggestive of a positive electrical change in the cornea relative to the back of the eye (1). This light-induced electrical activity of the eye was called the electroretinogram. Now, the electroretinogram response is commonly abbreviated to the ERG.

Gotch (2) was the first to report that the response of the eye to a light flash consisted of two waves; first the cornea became negative and then a positive wave of larger amplitude appeared. Later, Einthoven and Jolly (3) separated the ERG response into three waves. The first wave to appear immediately after turning on a light stimulus was negative on the cornea. It was followed by a positive wave and a final slower wave that was also positive. Einthoven and Jolly (3) suggested that the light stimulus triggered a chain of reactions leading to the formation of products A, B, and C, and that every electrical wave indicated a change in a "relevant" product. These authors' work was the foundation for the form of analysis of the ERG used to the present day. The waves are called a-, b- and c-waves. An additional corneal-positive wave, that is more rarely recorded at the termination of the light flash, is called the d-wave.

Fig. 1 shows ERG responses from different species. These responses are to bright light stimuli applied in the dark-adapted state. The ERG of the turtle eye (Fig. 1A) as elicited by a long (900-ms) step of light, shows an a-wave and b-wave complex separated from the d-wave, which is generated at stimulus offset. A bright light stimulus of 40 sec duration is used to record the ERG of the bullfrog in Fig. 1B (4). The a-wave and b-wave are followed by the slow, corneal-positive c-wave. After termination of the stimulus, a d-wave develops. The ERG responses of the rabbit (Fig. 1C) and the human (Fig. 1D) are elicited by fast bright flashes (50 or 100 ms in duration), and therefore, only the a-wave and b-wave are seen. In the human response (Fig. 1D), fast oscillations can also be seen on the ascending limb of the b-wave. These ERGs in the different species clearly differ in amplitude and pattern. Some of this variability is due to species differences, particularly the relative densities of rods and cones, whereas technical factors, such as duration and intensity of photostimulation and method of recording, also affect the waveform. Nevertheless, ERG responses of turtle, bullfrog, rabbit, and human (Fig. 1), in addition to those recorded from other vertebrate species, are characterized by the basic features of a negative a-wave followed by a positive b-wave.

In 1911, Piper published his analysis of the ERG. He divided the ERG into three components: I, II, and III (1). Unlike Einthoven and Jolly, who suggested that the waves reflected transient chemical processes, Piper suggested that all the ERG components lasted for the duration of the light stimulus. According to Piper, the first two waves, I and II, were characterized by different latencies and temporal properties so that the interaction between them resulted in the formation of the a- and b-waves. Wave III was equivalent to the c-wave. Although Piper's analysis was very speculative and based only on a few facts, this interpretation together with that of Einthoven and Jolly's has set the basis for the idea that the ERG is the result of a few components. In 1933, Ragnar Granit published a more detailed study of the components of the cat ERG as illustrated in Fig. 2a and Fig. 2b (5). He recorded the ERG from the anesthetized cat using corneal electrodes and observed the gradual removal of the different components as the level of anesthesia was deepened. Granit termed the different components in sequence of their disappearance: P-I, P-II, and P-III. The P-I component is a slow, cornea-positive wave. P-II is also a corneal-positive wave that rises relatively fast to a peak amplitude and then recovers to an intermediate potential while the light stimulus is still on. The last component, P-III, which was the most resistant to the level of anesthesia, is

a cornea-negative wave that develops faster than the other two and remains as a negative potential for as long as the light stimulus is on. The component analysis of Granit has been modified slightly over the years but remains the basis for our understanding of the ERG. For his work on the ERG, Ragnar Granit won the Nobel Prize for Physiology and Medicine in 1967.

The Electrical Basis of ERG Recordings

ERG responses are recorded with an active extracellular electrode positioned either on the cornea, in the vitreous, or at different levels inside the retina. An extracellular recording of electrical activity of living tissue is rendered possible when electrical currents spread along an extracellular matrix with electrical resistance. An example of extracellular electrical current in the vertebrate retina is the "dark" current spreading from the inner segments to the outer segments of the photoreceptors (see the chapter on photoreceptors).

In the vertebrate retina, the photoreceptors are arranged in parallel, and therefore, their "dark" currents are in parallel and sum up, giving rise to a strong radial extracellular current flowing away from the inner nuclear layer toward the pigment epithelium. Similarly, extracellular currents from all retinal cell types will sum up only if they are directed radially. In contrast, lateral currents will cancel each other because the retinal lateral arrangement is completely symmetrical. Therefore, when a homogeneous light stimulation is directed at the whole retina, only radial extracellular currents are formed. We assume that a light stimulus elicits extracellular electrical currents that flow from sources to sinks. These currents will flow through different pathways, including local and remote ones. We can divide these currents into two principal pathways, the local one (A) and the remote one (B), as shown schematically in Fig. 3a. The current in pathway A flows through a local route remaining entirely within the retina, whereas the current flowing through pathway B leaves the retina through the vitreous and anterior ocular tissue and returns to the retina through the sclera, the choroid, and the pigment epithelium layer. The light-induced current flowing through pathway B can be recorded in a noninvasive manner, with extraocular electrodes, as illustrated in Fig. 3a.

According to Ohm's law in electricity, when an electrical current flows through a resistor, a gradient of electrical potential is formed that equals the product of multiplying the magnitude of the current by that of the resistance. By applying this law, we can derive the relationships between the currents, IA and IB (Fig. 3a), the resistances of the ocular tissues, and the measurements of potential differences. Fig. 3b shows an equivalent electrical circuit of the eye (6). A light stimulus elicits an extracellular current (source I) that divides into two pathways; one flowing through the retina (local pathway, IA in Fig. 3a) and the other through extra-retinal and extra-ocular tissues (remote pathway, IB in Fig. 3a). Each tissue (e.g., retina, vitreous, sclera, choroid, and pigment epithelium) is represented in Fig. 3b by an electrical resistor. According to Ohms' law, the potential difference between two points is independent of the pathway through which the current is flowing. Therefore, the voltage difference between points A and B can be calculated for the local or remote pathways.

$$I_A R_1 = I_B (R_2 + R_3 + R_4 + R_5 + R_6) \text{ (Equation 1)}$$

Since the sum of the resistances on the right side of the equation ($R_2 + R_3 + R_4 + R_5 + R_6$) is larger than R_1, the current I_A in the local pathway must be greater than current I_B.

When using two electrodes to record light-induced electrical activity of the retina, the largest light-induced potential change will be monitored if the measurement is done between points A and B, which are on the two sides of the cells producing the electrical response. However, when the electroretinogram is recorded from humans or from laboratory animals during chronic experiment, the electrodes cannot be inserted into the retina. The alternative is to record from extraocular sites by placing both active and reference electrodes outside the eye. If these electrodes are placed at the loci designated in Fig. 3b as C and D, the voltage gradient between them is given by

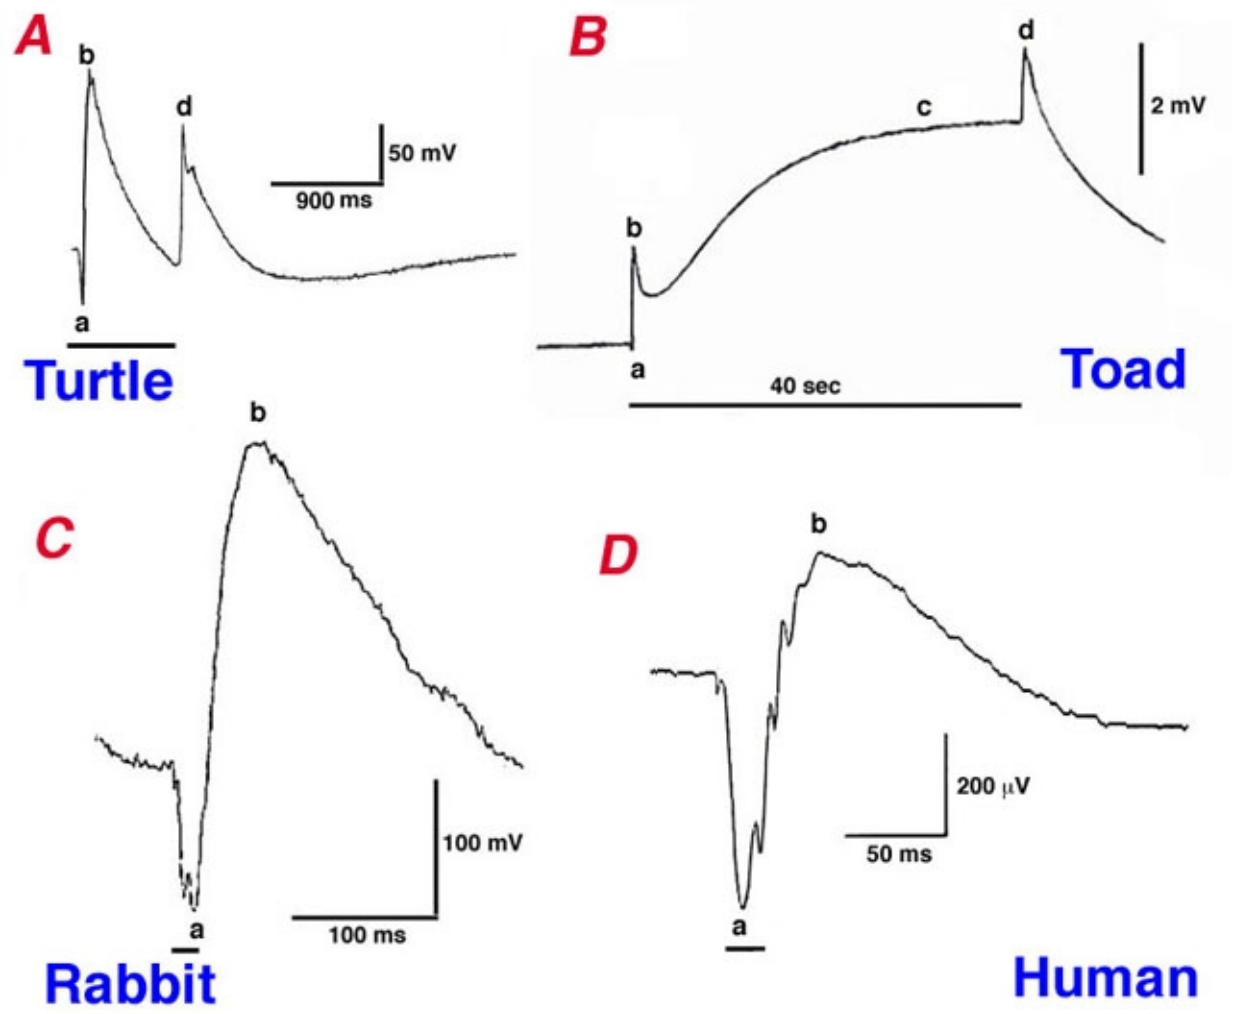

Figure 1. A, ERG response of turtle *Pseudemys scripta elegans* elicited by a 900-ms light stimulus to separate the a-wave and b-wave from the d-wave. B, the ERG of the bullfrog elicited by a long (40-sec) light stimulus to show the c-wave in addition to the a-, b-, and d-waves (4). C, the ERG response of a rabbit to a flash (20 μs) flash of white light. D, the ERG response from a human as typically recorded in the clinic. Note the fast oscillations on the ascending limb of the b-wave. Calibration bars are denoted separately for each ERG response.

$$V_C - V_D = I_B * R_4 \text{ (Equation 2)}$$

or

$$V_C - V_D = I_A R_1 - I_B(R_2 + R_3 + R_5 + R_6) \text{ (Equation 3)}$$

This is the ERG: the light-induced potential change that is related to light-induced electrical activity within the retina. In general, when retinal function deteriorates, the light-induced electrical activity in the retina reduces. The currents I_A and I_B will be smaller and the ERG will be smaller, too, thus indicating retinal pathology.

However, we have to remember that the magnitude of the different resistances, and more so, the relationships between them, can also affect the ERG that is measured with extraocular electrodes. The division of the current originating from the light-induced retinal activity into the local and remote pathways depends upon the relative resistances of the two pathways. From Equation 1, we can derive the following relationship:

Figure 2a. Ragnar Granit, winner of the Nobel Prize for Physiology and Medicine in 1954.

$$I_A/I_B = (R_2 + R_3 + R_4 + R_5 + R_6)/ R_1 \text{ (Equation 4)}$$

Any change in one of the resistances will cause a change in the magnitude of the current in the extraocular pathway (I_B) and the ERG ($V_C - V_D$) can change irrespective of retinal function. Therefore, knowledge of the different resistances and understanding the factors that affect them is needed for proper use of the ERG for clinical and/or research purposes.

The pigment epithelium layer (R-membrane) offers the highest resistance to electrical current along the ocular tissues (7-10) as denoted by a large resistor R6 in Fig. 3b. Therefore, any change in the magnitude of this resistor will affect the distribution of currents between the retinal pathway (I_A) and the remote pathway (I_B). This change will be reflected in the ERG responses that are measured with extraocular electrodes. Such changes in the distribution of resistances may account for species differences in the magnitude of the ERG responses and for intrasubject differences within a given species. The importance of the resistances of the ocular tissues has been recognized by Arden and Brown (11). They replaced the vitreous humor of cats with heavy oil to abolish current flow from the retina to distant sites and thereby ensured large potential recordings of local ERG from the retinal

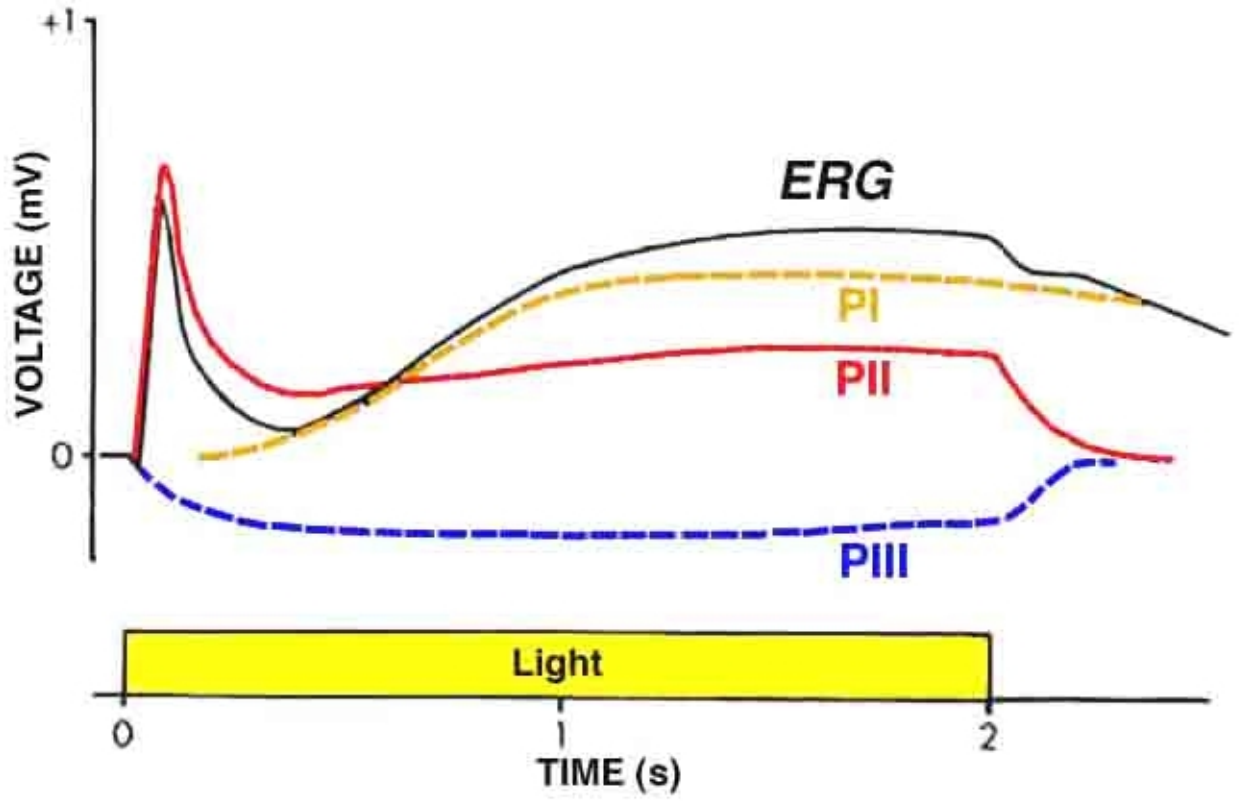

Figure 2b. The ERG of a cat in response to a 2-sec light stimulus. The components, P-I, P-II, and P-III, have been isolated by deepening the state of anesthesia (5).

surface. In the clinical environment, it is well documented that the ERG can be reduced significantly in patients with giant retinal tears who have undergone vitrectomy surgery and injection of silicon oil into the vitreous. Since silicon oil does not conduct electric currents, the resistance of the vitreous increases by several folds causing the current I_B to be so reduced that the ERG becomes very small in amplitude (12-14).

The Origin of the Major ERG Waves

Granit (5) divided the cat's ERG into three components; P-I, P-II and P-III (Fig. 2a and Fig. 2b). From his analysis, we know that the negative a-wave is the leading edge of the negative P-III component; the positive b-wave reflects the summation of P-II and P-III, whereas the slow c-wave is the summation of P-I and P-III. However, the cellular origin of the different components needs to be understood. Basically, two types of approaches, physiological and pharmacological, have been used to dissect out these cellular origins. The physiological experiments are based on the assumption that the generators of specific ERG components are located in specific retinal layers, and therefore, when these are passed by the intra-retinal microelectrode, the polarity of the specific ERG waves will reverse. These current source-density analyses have indeed revealed the anatomical location within the retina of the different ERG components. The pharmacological approaches to ERG analyses are based on retinal physiology and biophysics. In these experiments, specific agonists and antagonists of cellular mechanisms are applied and their effects on the ERG then analyzed.

In the following section, the sources of the a-, b-, and c-waves will be discussed, not according to the order of their timing in the ERG response but according to the retinal level at which they are generated, starting from the most distal layer, the pigment epithelium.

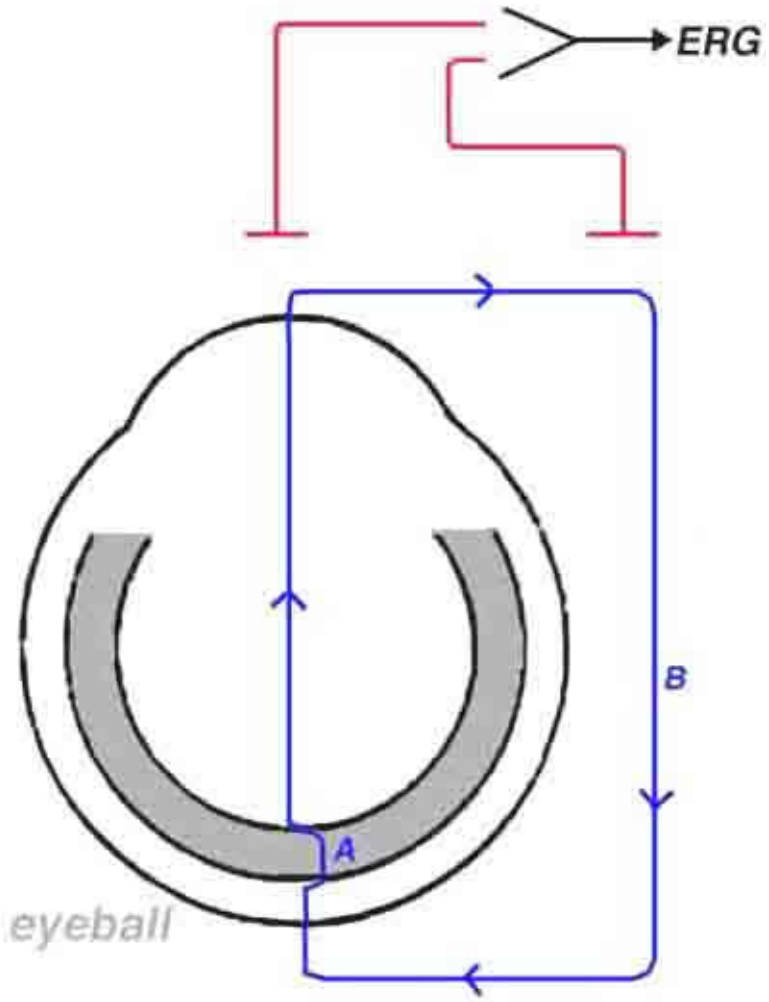

Figure 3a. A schematic representation of the extracellular currents that are formed after light stimulation. Pathway A represents local currents within the retina, whereas pathway B shows the currents leaving the retina through the vitreous and the cornea and returning to the retina through the choroid and the pigment epithelium. ERG recording in human is done along the B path.

The c-Wave

The c-wave, which corresponds to the P-I component of Granit (Fig. 2a and Fig. 2b), is now known to originate in the pigment epithelium. The first indication of this was reported by Noell (15). He showed that systemic injection of sodium azide elicited an electrical potential from the retina similar to the ERG c-wave. The azide-induced potential was not influenced by iodoacetic acid, which is known to destroy photoreceptors, or by cutting the optic nerve, which causes degeneration of the ganglion cells. This interpretation of the c-wave origin was proven directly when intracellular recordings were made from pigment epithelial cells. The potential changes that were recorded from these cells in response to light stimuli were identical in shape and temporal properties to the ERG c-wave (16). Furthermore, when the retina was separated from the pigment epithelium, the ERG response contained normal a- and b-waves, but the c-wave disappeared. Fig. 4 shows ERG recording from the skate eyecup that consists of a-wave, b-wave, and c-wave (upper trace). When the retina is separated from the sclera and pigment epithelium, the ERG response contains only the a- and b-waves. Furthermore, aspartate, by blocking transmission from photoreceptors to bipolar cells, completely removes the b-wave (Fig. 4) (17).

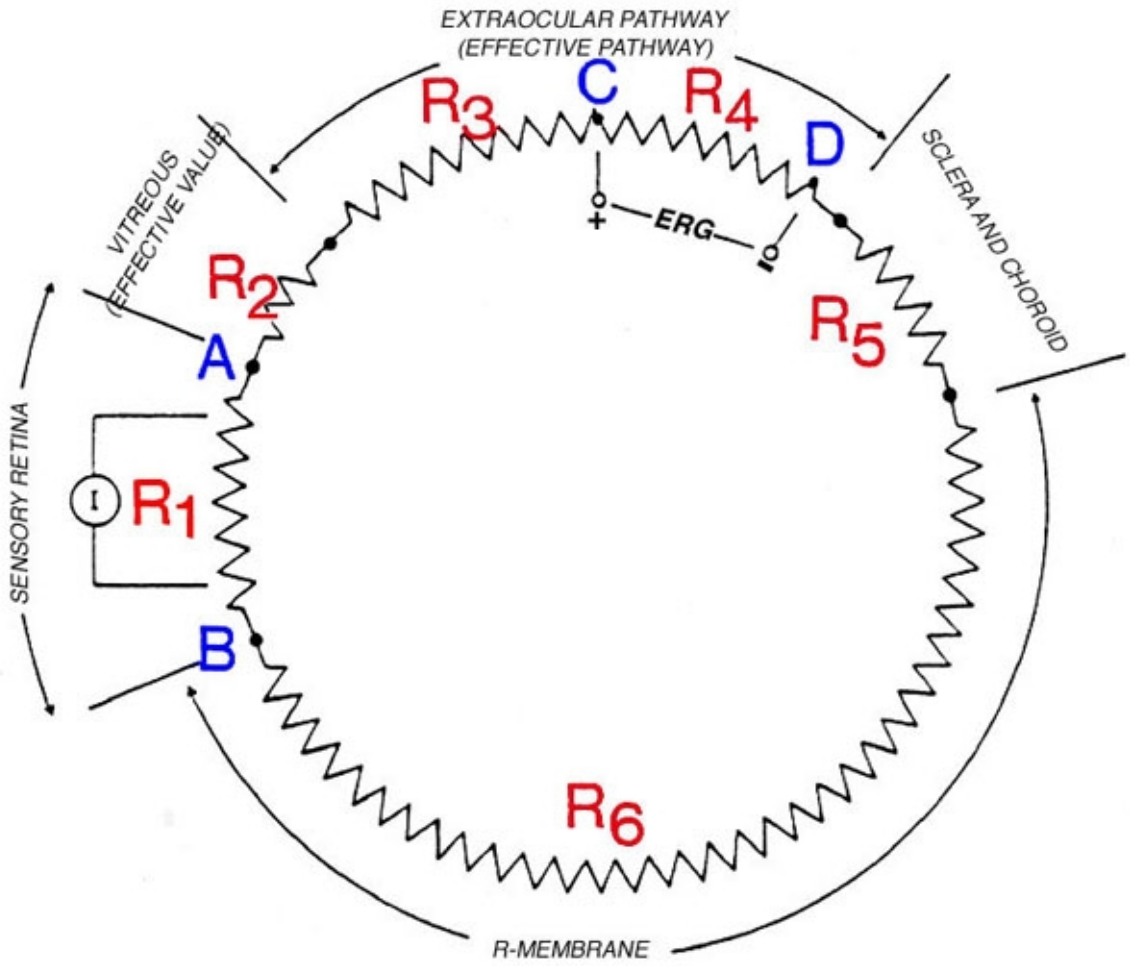

Figure 3b. An electrical scheme of the resistances through which currents IA and IB (Fig. 3a) flow when the retina is stimulated with light. The current source I represents the electrical current that is generated in the retina in response to a light stimulus. Pathway A is the local intra-retinal route of current flow, and pathway B is the remote route going from the retina and through the vitreous, lens, cornea, extraocular tissues, and back to the retina through the sclera, choroid, and pigment epithelium.

The exact mechanisms whereby the pigment epithelial cells generate the c-wave were revealed only when potassium-sensitive microelectrodes were developed. The pigment epithelium cells are functionally asymmetrical cells with their basal membrane (toward the choroid) less permeable to potassium ions than the apical membrane (retinal side). This asymmetry causes a constant potential difference between the retina and the choroid with the retinal side positive relative to the choroidal side. This is also called "the standing potential of the eye". The standing potential is very sensitive to the extracellular concentration of potassium ions. Any change in concentration of potassium ions at one side will be expressed in a change in the whole trans-epithelial potential. Measurements with potassium-sensitive microelectrode in the photoreceptor layer shows a light-induced decrease in the extracellular concentration of potassium ions, due to light-induced electrical activity in the photoreceptors. The reduction in the extracellular concentration of potassium ions near the apical membrane of the pigment epithelial cells is expressed as an increase in the trans-epithelial potential with the retinal side becoming more positive relative to the choroidal side. This is the ERG c-wave when recorded with a corneal electrode (4, 18). Fig. 5 shows simultaneous recordings of the ERG and the potassium retinogram (KRG) in the frog retina. To simplify the comparison, the KRG responses are inverted; thus, a positive deflection in this figure means a reduction in the extracellular concentration of potassium ions. The intensity series (Fig. 5A) indicates that the temporal properties of the KRG match closely with those of the ERG c-wave. The intensity-response

curves show excellent correlation between peak amplitude of the c-wave and peak reduction in potassium concentration (Fig. 5B).

Although the c-wave originates from the pigment epithelium, it depends upon the integrity of the photoreceptors, because light absorption in the photoreceptors triggers the chain of events leading to the decrease in extracellular concentration of potassium ions. Therefore, the ERG c-wave can be used to assess the functional integrity of the photoreceptors, the pigment epithelial cells, and the interactions between them.

The a-Wave

The ERG a-wave is the leading part of Granit's P-III component. It has now been shown that P-III can be divided into two components: a fast P-III and a slow P-III (19, 20). The most important information on the origin of these waves was obtained from ERG recordings with intra-retinal microelectrodes (21-25). These studies suggested the photoreceptor layer as the origin of the fast P-III wave. Differential recording in the rat retina using two microelectrodes revealed that the a-wave resulted from extracellular radial current. This is the "light" current and basically reflects the reduction in the "dark" currents because of light absorption in the photoreceptor outer segments and closure of cGMP-gated cationic channels (see the chapter on photoreceptors) (26, 27).

A pharmacological approach to the study of the origin of the ERG a-wave became possible when the identity of the neurotransmitter released from the photoreceptors became known. Because L-glutamate is the neurotransmitter of the photoreceptors, exposing the retina to agonists or antagonists of L-glutamate can effectively block synaptic transmission from the photoreceptors and isolate the contribution of the photoreceptors to the ERG. This can be achieved by exposing the isolated skate retina to L-aspartate, an excitatory, acidic amino acid (Fig. 4, lower trace). Fig. 6 shows ERG responses from dark-adapted rabbits that were recorded 3 hours after intravitreal injection of L-glutamate or 2-amino-phosphonobutyric acid (APB) into one eye and saline into the fellow control eye (A and B, respectively). Both drugs effectively isolated the P-III component of the ERG in the experimental eye, compared with the control eye. These and numerous other studies indicate that the P-III component of the ERG, or more specifically the fast P-III, reflects light-induced activity of the photoreceptors. This component of the ERG is also referred to as "the receptor component".

The slow component of the P-III cannot be identified in a regular ERG response because of the large-amplitude, positive P-I wave. However, by separating the retina from the pigment epithelium, P-I can be eliminated; and by exposing the retina to drugs, such as aspartic acid, which blocks synaptic transmission from the photoreceptors to the neurons in the inner nuclear layer, the P-III component can be isolated and studied (28). Measurements of the extracellular concentration of potassium ions and of the isolated P-III component of the ERG at different retinal depths reveal the involvement of retinal glial (Müller) cells in the generation of the slow P-III. The Müller cells are highly permeable to potassium ions. Therefore, the reduction in the extracellular concentration of potassium ions in the photoreceptor layer, due to light absorption in the photoreceptors, elicits changes in the trans-membrane potential of the Müller cells and is expressed as the slow P-III component of the ERG.

The b-Wave

The ERG b-wave has been the subject of extensive research by many groups because it is the major component of the human ERG recording as used in clinical and experimental analysis of retinal function. The data in Fig. 4 and Fig. 6 clearly indicate that the b-wave originates in retinal cells that are post-synaptic to the photoreceptors. Blocking synaptic transmission from the photoreceptors to second-order retinal neurons by saturating the post-synaptic receptors with L-aspartate (Fig. 4) or L-glutamate (Fig. 6A) eliminates the ERG b-wave and isolates the P-III component. In fact, any procedure that blocks synaptic transmission from the photoreceptors, such as superfusion with cobalt ions or with high magnesium, low calcium solutions, will eliminate the ERG b-wave (20, 29, 30). The b-wave is also eliminated when the blood flow through the central retinal artery is blocked either

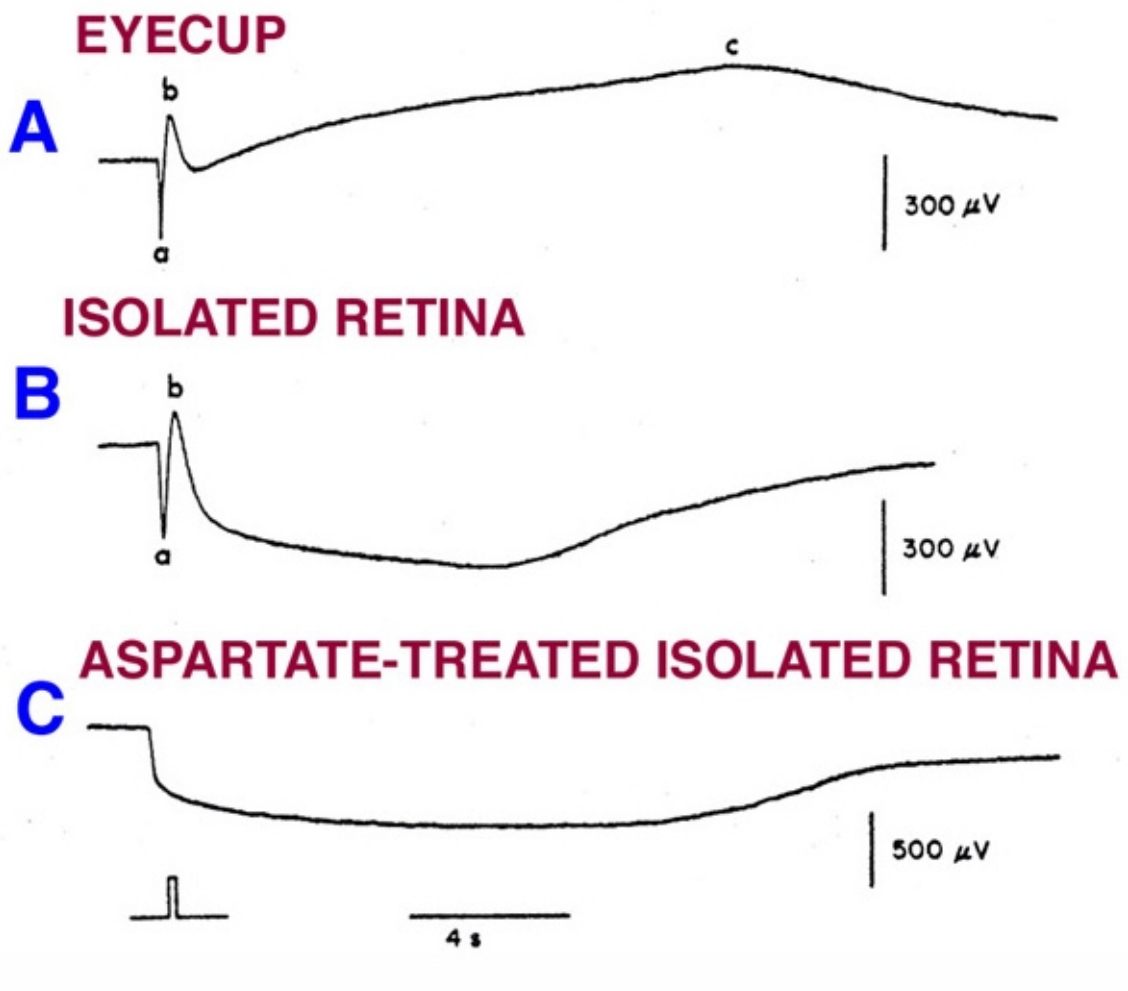

Figure 4. ERGs recording from the skate. The recording was done from the whole eyecup (upper trace), following the separation of the retina from the pigment epithelium (middle trace) and after exposing the retina to aspartic acid (lower trace) (17).

intentionally in laboratory animals (15, 31) or in human patients (32). Because the neural retina is supplied by the retinal vasculature and the photoreceptors by the choroidal plexus, this experimental manipulation, or pathological cases, effectively eliminate light-induced electrical activity in the neural retina from the photoreceptors.

Applying sink-source analysis to electrophysiological recordings of the intra-retinal ERG responses at different retinal depths further reveals the location of the b-wave (P-II) generators. Faber (33) was the first to calculate the extracellular currents that underlie the ERG b-wave of the rabbit eye. He reported that a sink for the b-wave was in the distal part of the retina, most probably in the outer plexiform layer, whereas the source was distributed proximally and distally to the sink. The only retinal elements that have a spatial distribution similar to the b-wave sources and sinks are the Müller glial cells. Indeed, intracellular recording from Müller cells in the Nectars retina supported Faber's ideas (34). The slow depolarizing response of Müller cells to a light stimulus followed a temporal pattern, similar to that of the ERG b-wave recorded from the same retina. Furthermore, the amplitude-stimulus intensity relationship was similar for the Müller cell photo responses and the ERG b-wave. On the basis of these observations, Miller and Dowling (34) suggested that depolarization of the Müller cell membrane in the distal retina resulted in extracellular currents that were expressed as the b-wave. A change in the extracellular concentration of ions that permeate through the Müller cells' membrane may cause a change in membrane potential. The most effective are potassium ions (35).

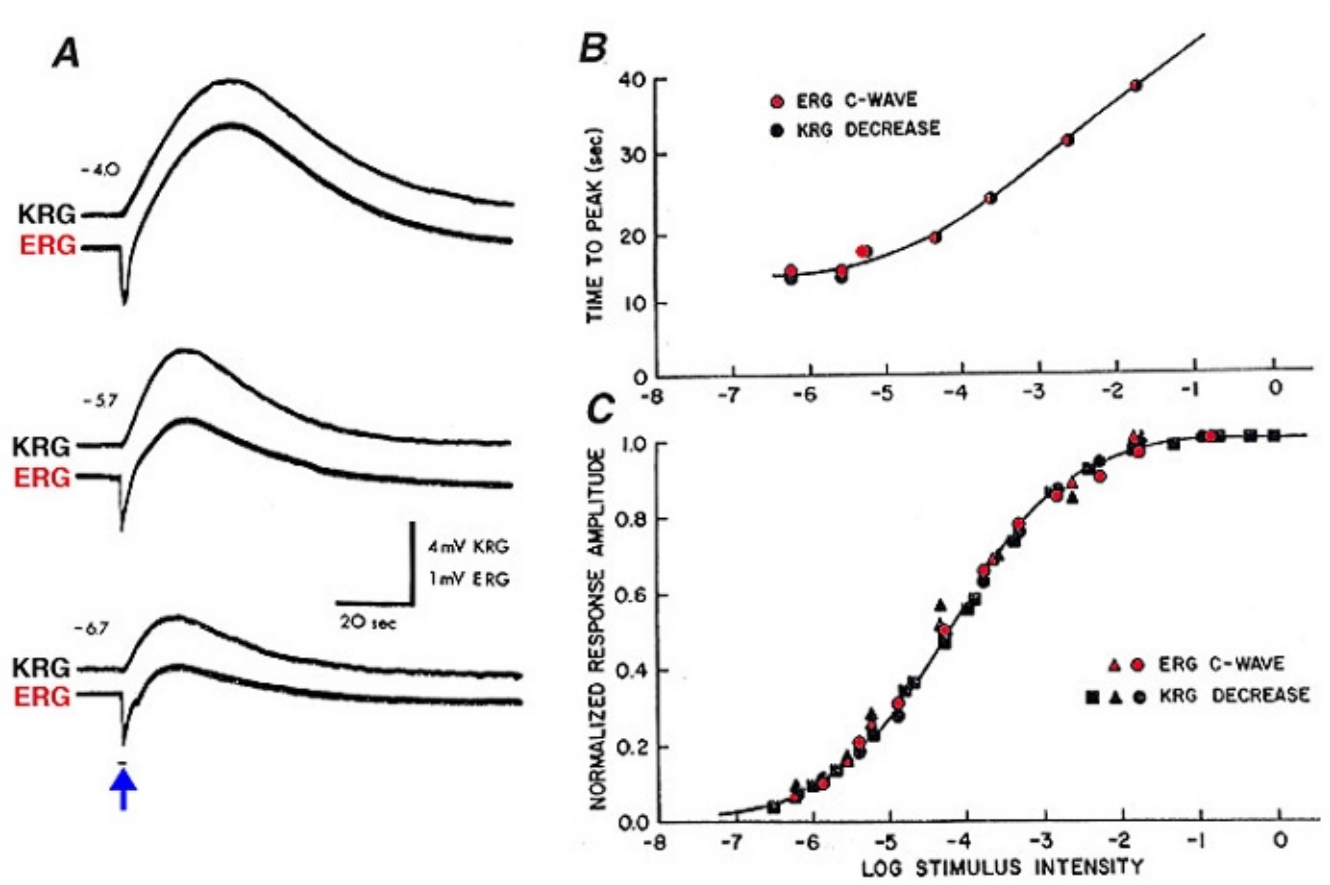

Figure 5. A, simultaneous recordings with double-barrel microelectrode of the ERG and the changes in the KRG from the distal retina of the frog. The KRG responses were inverted in polarity to compare with the ERG c-wave. Three different intensities of the light stimulus were applied. B, comparing time-to-peak (upper panel) and peak amplitude (lower panel) of the ERG c-wave and the KRG (18).

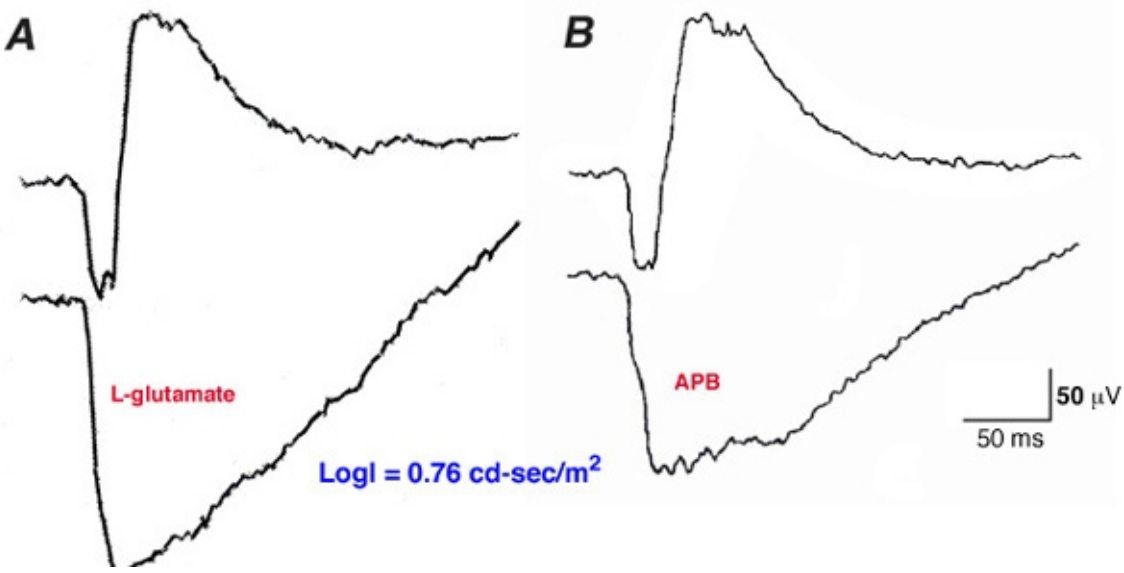

Figure 6. Elimination of the ERG b-wave (P-II) in rabbits by intravitreal injection of L-glutamate (A) or 2-amino-phosphonobutyric acid (APB) (B). The experimental drug was injected into the right eye (lower trace) and saline into the left eye (upper trace) as a control. In both experiments, the drugs successfully eliminated P-II, thus revealing the entire time course of the P-III component.

The idea that the b-wave results from changes in the membrane potential of the Müller cells due to light-induced changes of extracellular potassium concentration underlies the basis for the "Müller-cell hypothesis". Since first proposed, this idea has been tested by many investigators using intracellular recordings from Müller cells, measurements of extracellular concentrations of potassium, and recording of the ERG at different retinal depths. Studies were done in mudpuppy (36, 37), frog (38-40), fish (41, 42), rabbit (43, 44), cat (11, 23, 24), and monkey (45, 46). These and other studies reported a light-induced increase in extracellular potassium in the outer and inner plexiform layers. This increase was thought most likely attributable to leakage from depolarizing retinal neurons. It was assumed that the origin of potassium increases in the outer plexiform layer was bipolar cells, most specifically ON-center bipolar cells that were depolarized by light (47). In the inner plexiform layer, the increase in extracellular potassium resulted from light-induced activity of amacrine and ganglion cells (47, 48). The change in potassium alters the membrane potential of Müller cells, generating electrical currents in these two regions of the Müller cell and exiting through its distal and proximal ends (49). Depth recordings of extracellular concentration of potassium and of local field potentials are shown in Fig. 7a (36). The reduction of $[K^+]_o$ in the photoreceptor layer and the increase in the outer and inner plexiform layers are clearly seen. Current source-density analysis of data like these (Fig. 7a) led to the current pathways shown in Fig. 7b (40).

More evidence concerning the source of the ERG b-wave was gained with specific agonists and antagonists to glutamate receptors. Exposing the vertebrate retina to 2-amino-4-phosphonobutyric acid (APB), a specific agonist of glutamate metabotropic receptors, eliminates the ERG b-wave (50) as shown in Fig. 6B. Because APB-sensitive metabotropic glutamate receptors are found only in ON-center bipolar cells (51), this finding constitutes a clear indication of the involvement of these bipolar cells in the generation of the b-wave. Further support came from experiments in which the effects of 6,7-dinitroquinoxaline-2,3-dione (DNQX) upon the ERG were tested. This drug is a specific antagonist to AMPA/KA type glutamate receptors and enhances the b-wave, probably by removing current sources that oppose those forming the b-wave. In primates, Sieving and coauthors (52) proposed that the b-wave of the photopic ERG response is mainly contributed by the ON-center bipolar cells but is opposed by OFF-center bipolar cells. This leads to a "push-pull model" of these cell types (52). More recent detailed sink-source analyses (44), pharmacological dissection of the ERG (53), and experiments with mGluR6 knockout mice (54) (mGluR6 is the specific receptor for photoreceptor to ON-bipolar transmission in the retina; see the chapter on bipolar cells) points directly to the ON-center bipolar cells as generating the ERG b-wave without the Müller cells.

Experiments with injection of barium ions into the vitreous of rabbits did not eliminate the ERG b-wave. Under certain conditions, barium ions even caused augmentation of the b-wave as shown in Fig. 8 (55). Because barium ions block almost completely the potassium permeability of Müller cells (56-58), the dose used was expected to abolish the ERG b-wave if the Müller cell hypothesis for the b-wave generation was correct. This was not the case as shown by the ERG response in Fig. 8. The effects of barium chloride solution injected into the vitreous of one eye, while saline was injected into the vitreous of the other eye, were tested. The ERGs of the experimental eye that was being injected with barium chloride are augmented compared to those of the control eye. This observation opposes the Müller cells hypothesis for the ERG b-wave and thus supports the ON-center bipolar cell hypothesis.

Even more recent studies have searched for inner retina contributions to the ERG b-wave. Using tetrodotoxin (TTX) to block action potentials in third-order retinal neurons (amacrine and ganglion cells) and specific antagonists to GABA and glycine receptors, it was concluded that third-order neurons contributed to the amplitude and kinetics of the ERG b-wave (59). Because the a-wave is the sum of P-III and P-II, the a-wave is also affected by TTX application. In Fig. 9A, bright flash ERG responses from the rabbit are shown in control conditions and after intravitreal injection of bicuculline and strychnine to block, respectively, $GABA_A$ and glycine receptors, and after addition of TTX. The basic waveform of the ERG (a-wave b-wave complex) was not changed by these drugs; however, after bicuculline and strychnine, the b-wave was augmented, indicating removal of inhibitory contributions. After TTX, the b-wave was slightly reduced but was mainly delayed,

indicating the removal of a fast component. Averages (± s.d.) of the effects of the above drugs in five rabbits are shown in Fig. 9B. The data indicate that the amplitude of the b-wave is significantly increased by the mixture of bicuculline + strychnine, whereas TTX significantly delays the time-to-peak. The above conclusions are supported by another study on the retina-eyecup preparation of the tiger salamander, showing that drugs disrupting the activity of third-order neurons cause enhancement of the b-wave (60). The b-wave is also found to be affected by drugs that modulate $GABA_C$-type receptors, indicating that negative feedback from amacrine cells onto bipolar cells can shape the photoresponses of the bipolar cells and thus the amplitude and kinetics of the ERG b-wave (61). $GABA_A$ and $GABA_C$ pathways are also found to affect the ERG b-wave of the rat retina (62). Bicuculline, the antagonist for $GABA_A$-type receptors, augments the b-wave, whereas 3-aminopropylphosphono acid (3-APMPA), the antagonist for $GABA_C$-type receptors, reduces it.

Additional Minor Components of the ERG

In addition to the three major waves (a, b, and c), other components can be identified in the ERG, depending upon the experimental recording conditions. Some of these serve for evaluation of human retinal function in the clinic, whereas others are mainly used for research purposes.

The Early Receptor Potential (ERP)

This component of the light-induced activity of the eye was first revealed when a very bright light flash was used to stimulate the monkey eye (22, 63), the rat eye (64), or the human eye (65). This electrical response appears immediately after stimulus on set and has a biphasic pattern as shown in Fig. 10. The ERP in humans ends within 1.5 ms and is followed by the a-wave. Depth recordings of the ERP with microelectrodes and intracellular recordings led to the conclusion that the ERP originated in the photoreceptors (66, 67). The amplitude of the ERP depends directly upon stimulus intensity and the concentration of visual pigment in the outer segments of the photoreceptors. Therefore, the ERP is believed to reflect dipole changes in the visual pigment molecules because of conformational changes that are elicited by photon absorption. The ERP has been used in research to follow non-invasively the concentration of the visual pigment during light adaptation and in the dark after an exposure to bright light that causes substantial pigment bleaching (68). In humans, ERP recording have been done only occasionally to estimate rhodopsin density in patients suffering from retinitis pigmentosa, a disease of the photoreceptors (69, 70). Furthermore, it was shown that carriers of X-linked retinitis pigmentosa, who had no visual defects, could be identified by their reduced ERP recordings (70).

The Oscillatory Potential (OP)

When a bright light stimulus is used to elicit the ERG in humans or in animals, low-amplitude oscillating waves can be identified on the rising phase of the b-wave. These wavelets are much faster than the complex of the a- and b-waves. Their frequency is in the range of 100-150 Hz, and they are best isolated by using a band-pass filter on the ERG wave to eliminate the slow, large amplitude a- and b-waves. An example is shown in Fig. 11 (71). The small-amplitude, fast wavelets can be seen in the ERG response (Fig. 11a), but they cannot be measured. When an appropriate digital filter is applied and the amplification increased, the oscillatory potentials are isolated (Fig. 11b). A Fast Fourier Transform (FFT) can be applied to derive the power spectrum (Fig. 11c) and quantitative assessment of the amplitude and frequency of these potentials.

Depth recordings reveal that the OPs attain maximum amplitude when the microelectrode is in the inner retina (21). Because the amplitude-stimulus intensity of the OPs differs significantly from that of the b-wave, it is thought that these waves are generated in the inner plexiform layer (72, 73). The exact cellular origin of OPs is not yet known for certain. Pharmacological studies and depth recordings lead us to believe they reflect extracellular electrical currents generated by negative feedback pathways between amacrine cells, ganglion cells, and bipolar cells (73-75).

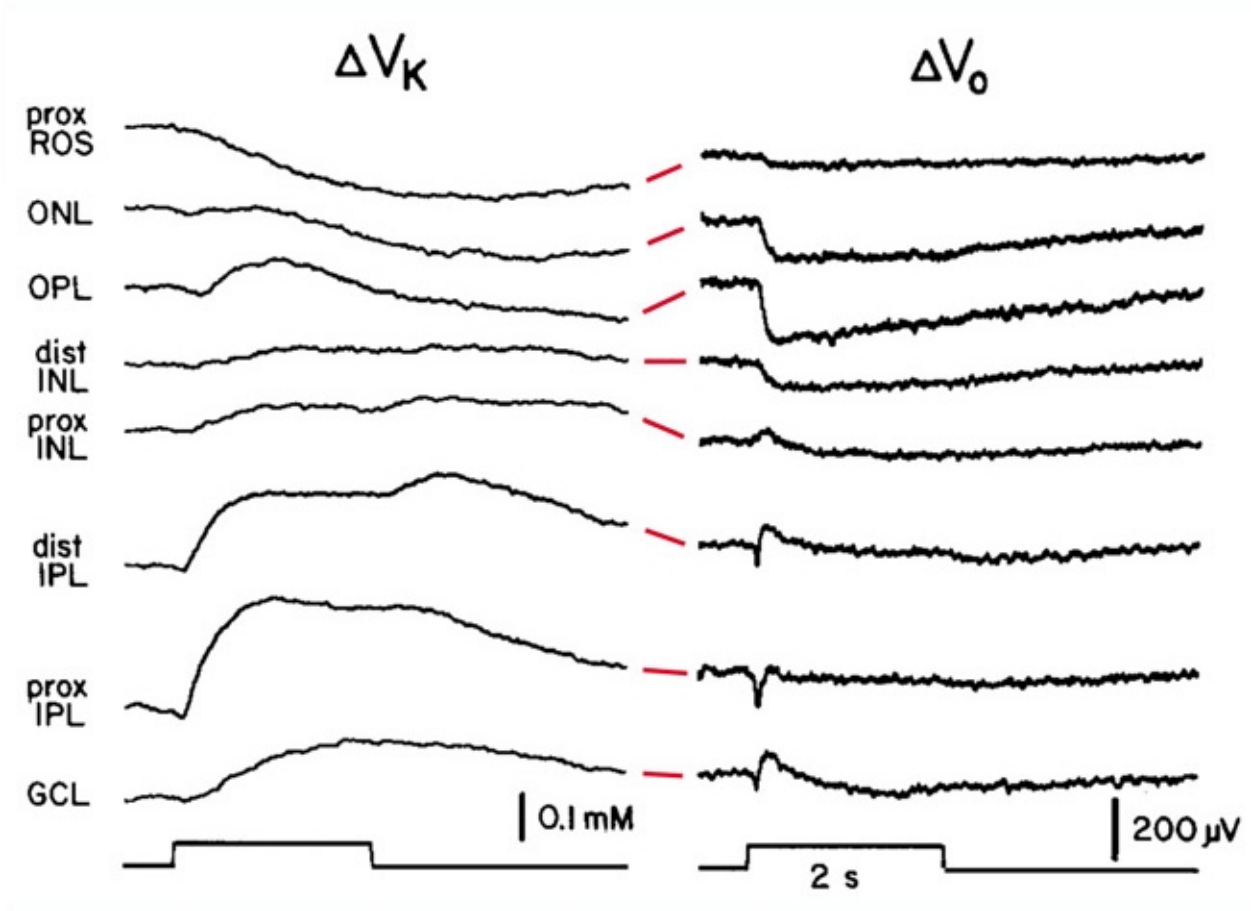

Figure 7a. The Muller cell hypothesis of the ERG b-wave. Depth profile of light-induced changes in the extracellular concentration of potassium ions (ΔVK) and of local field potential (ΔV0) (36).

OPs are very sensitive to ischemia in localized retinal areas. Therefore, in situations where the a- and b-waves remain normal in waveform and amplitude, OP recording scans indicate mild retinal ischemia in the inner retina (76). This occurs in diabetic retinopathy. Thus, OP recordings have sometimes been used as an indicator of background diabetic retinopathy (71, 77-79).

The d-Wave

The d-wave is seen only when the ON and OFF phases of the ERG response are separated in time, by using light stimuli of relatively long duration (>100 ms). Current source-density analysis shows its source to be the OFF-center bipolar cells (80, 81). Pharmacological studies in amphibian retinas (50, 82, 83) and in primates (52), using selective blockers for ON bipolar cell glutamate metabotropic receptors and OFF bipolar cell AMPA/KA type receptors, have shown that the d-wave of the ERG depends entirely on AMPA/KA type synaptic transmission, i.e., between photoreceptors and OFF-center bipolar cells (Fig. 12).

In Fig. 12, responses were recorded with a microelectrode in the distal retina, and therefore, the polarities of the waves are opposite to that obtained with the active recording in the proximal retina or vitreous or cornea. The a-wave is positive, the b-wave negative, and the d-wave negative. After exposure to DNQX, a specific antagonist for AMAP/KA-type glutamate receptors, the a-wave is reduced, the b-wave enhanced, and the d-wave reverses in polarity (Fig. 12b). The enhancement of the b-wave reflects the removal of opposing contribution from third-order retinal neurons (59, 60). The reduction in the amplitude of the a-wave does not reflect a direct action of DNQX but rather the enhancement of P-II that usually opposes P-III. The reversal in polarity of the d-wave

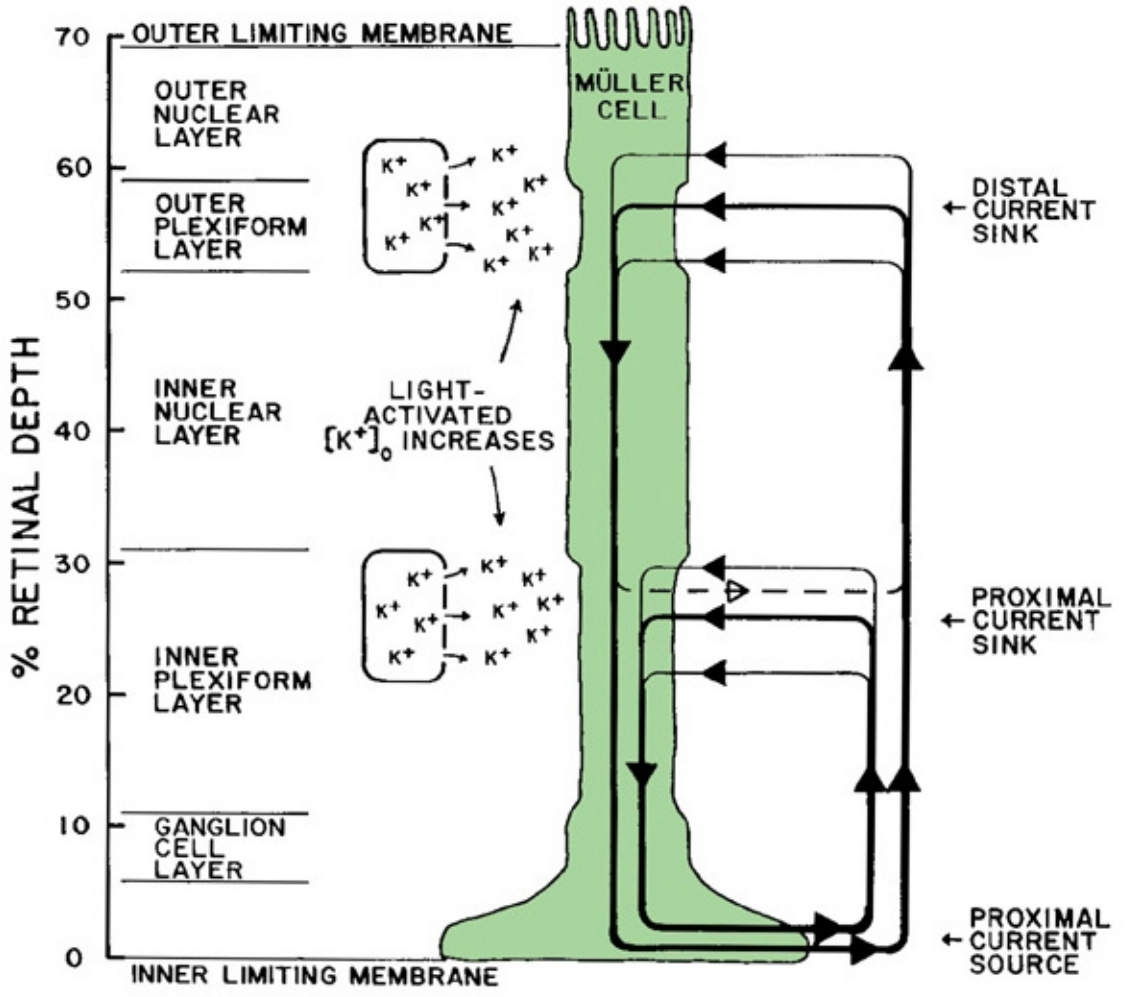

Figure 7b. The pathways of the extracellular currents that have been suggested to underlie the generation of the ERG b-wave. The two sinks (OPL and IPL) reflect the increase in extracellular potassium ions attributable to light-induced electrical activity. The vitreous serves as a large current source due to the high potassium conductance of the end feet of the Muller cells (40).

reflects its origin in OFF-center bipolar cells. Third-order retinal neurons may also contribute to the ERG d-wave (60).

The d-wave can be recorded only with prolonged light stimuli. With light stimuli of shorter durations, the d-wave tends to combine with the b-wave. This phenomenon led early studies of patients with congenital stationary night blindness (CSNB) or with melanoma-associated retinopathy (MAR) to conclude that the cone system was functioning normally and only the rod system was affected. The use of light stimuli of long duration revealed that the ON pathway in both rod system and cone system was affected, and only the OFF pathway of the cone system exhibited normal function (see the chapter on bipolar cells) (84, 85).

Scotopic Threshold Response (STR)

When very dim light stimuli (below the P-II threshold) are applied in the dark-adapted state, a slow corneal negative potential is recorded from toad (86), cat (11, 87), sheep (88), monkey (89), and humans (90, 91). This potential was called the scotopic threshold response (STR) to indicate that it was recorded with light stimuli near rod threshold. Simultaneous recording of field potentials and potassium concentrations with double-barreled electrodes, at different retinal depths of the dark-adapted cat retina, indicates that the STR originates from light-induced changes in the extracellular concentration of potassium ions in the proximal retina (affecting the

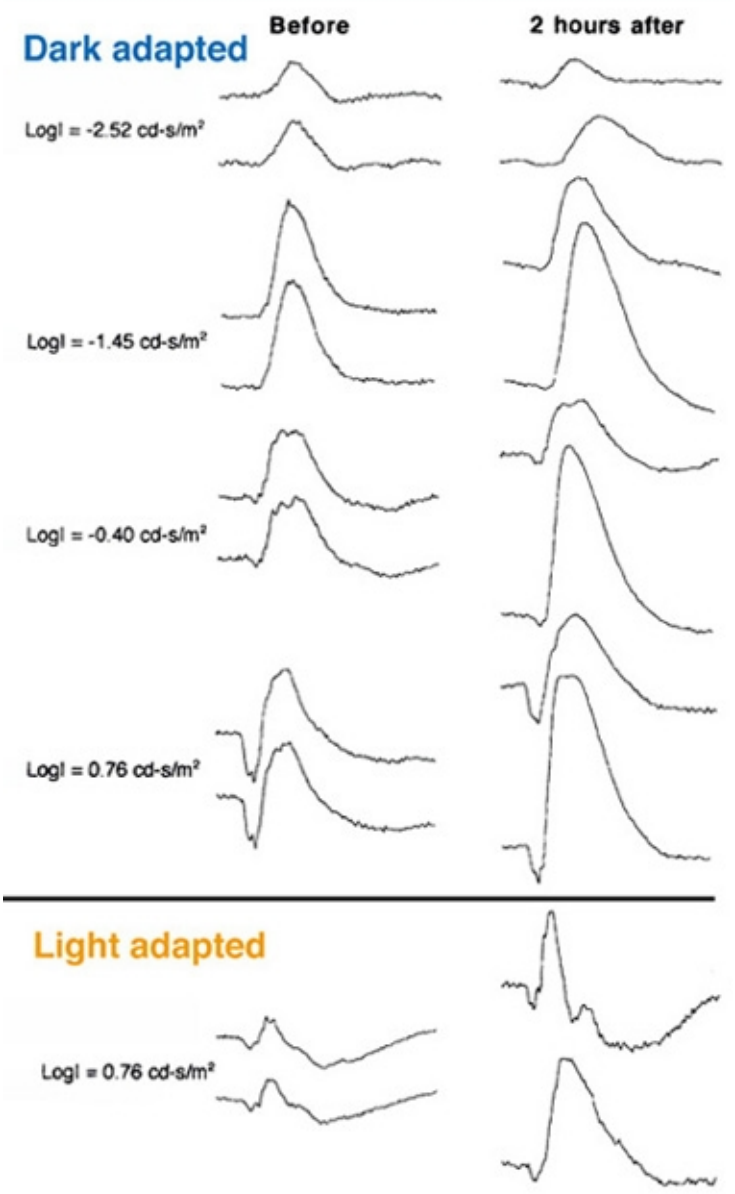

Figure 8. The effects of barium ions on the ERG responses of the rabbit. Saline solution containing barium chloride was injected into the vitreous of the right eye and saline into the vitreous of the left eye (lower and upper traces, respectively). The ERG responses after 2 hours were augmented in the eye injected with barium ions (55).

membrane potential of Müller cells) (87, 92). Barium ions that block potassium conductance of the Müller cells, but not light-induced increase in extracellular potassium concentration, also eliminate the STR as shown in Fig. 13 (92).

Because the STR is a corneal negative component that is sometimes followed by a positive component, it resembles the ERG a-wave/b-wave complex and can be misinterpreted. In a detailed study in cat and monkey, it was found that the STR could be eliminated by aspartate while the a-wave that was elicited by bright light stimuli was spared, supporting the post-receptoral origin of the STR (89). Fig. 14 compares amplitude-intensity (A) and latency- intensity (B) data for cat STR and a-wave in normal conditions and after intravitreal injection of L-aspartate (89). The STR responses were recorded with light stimuli that were dimmer by more than 3 log units. L-Aspartate eliminated the STR but did not affect the a-wave.

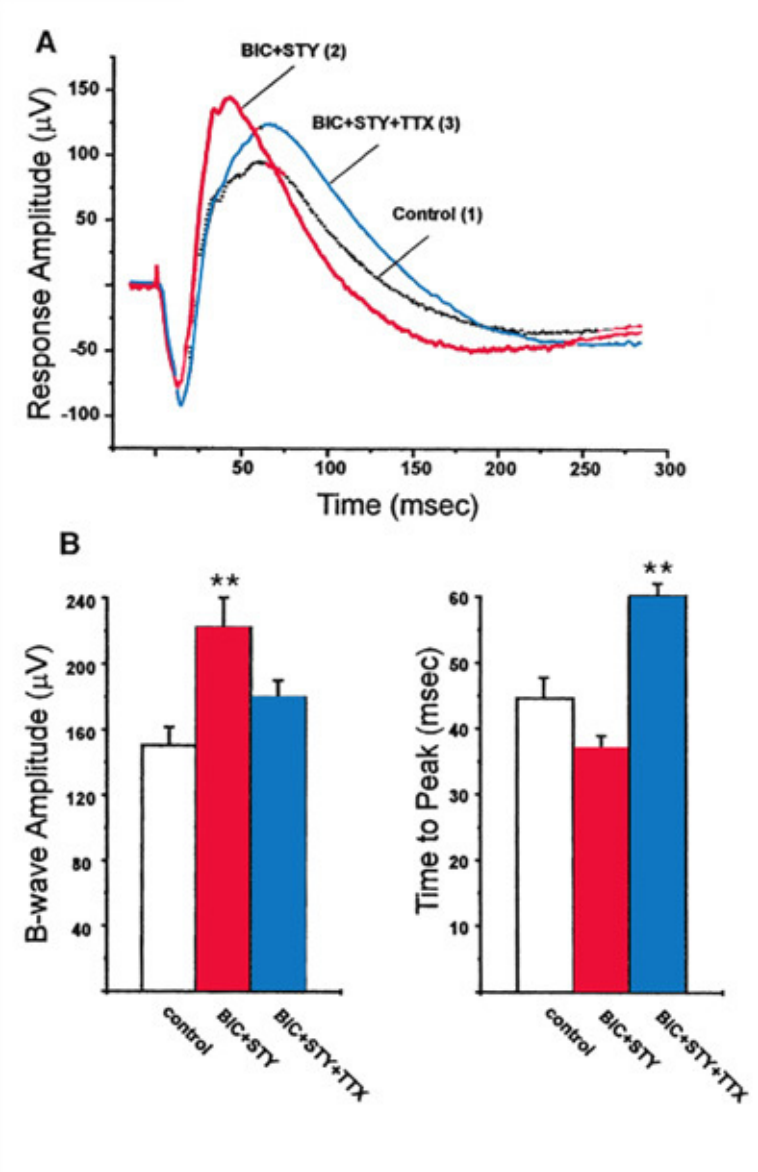

Figure 9. A, the effects of a mixture of bicuculline + strychnine on the ERG, response of one rabbit (trace 2). Then, TTX was added to the mixture to block spiking activity (trace 3). The drugs were injected into the vitreous of the rabbit eye. B, average effects of the different drugs on the b-wave amplitude (left) and time-to-peak (right). Significant difference at the $p<0.01$ level is denoted by two asterisks (59).

The M-Wave

The M-wave was first described in cold-blooded vertebrates as a negative-going potential change at stimulus onset and offset (48). The M-wave has also been described in the light-adapted retina of the cat (93, 94). It was proposed to represent changes in membrane potential of Müller cells due to light-induced increases in the extracellular potassium in the proximal retina (37, 48). This suggestion was later supported by experiments in which barium ions, used to block the potassium conductance of Müller cells, eliminated the M-wave (95).

We can learn more about the M-wave from simultaneous recordings of field potentials and potassium concentrations at different retinal depths under changing light stimulation and by modulating the activity of the ON- and OFF-channels by specific drugs. Fig. 15 compares the M-wave to potassium changes for different spot sizes of light. The M-wave is composed of ON and OFF waves that decrease in amplitude as the stimulus diameter is increased. The light-induced potassium increases are of similar waveform; transient increases occur

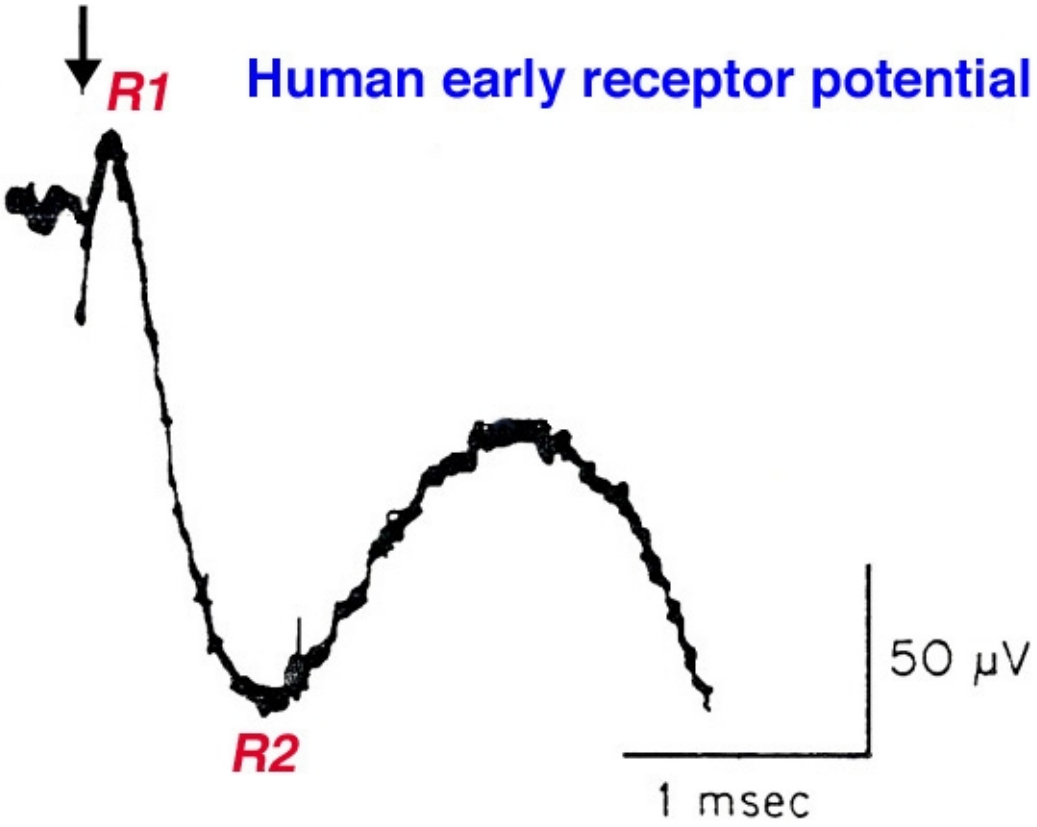

Figure 10. A typical early receptor potential (ERP) of the human eye that was elicited by a very bright light flash (arrow). Two waves are identified, the positive R1 followed by the negative R2 (65).

at stimulus onset and offset. The relationship to the diameter of the stimulating light is similar. These experiments support the hypothesis that the M-wave, in the light-adapted cat retina, is attributable to changes in extracellular potassium concentration in the proximal retina and to activity in both ON and OFF channels (93). Adding barium ions to block potassium conductance of the Müller cells does not completely eliminate the M-wave. A small, sustained depolarizing component is seen at light onset plus a negative OFF component. Evidently, direct neuronal contributions cause the M-waves, and the major contribution is to the OFF wave (93).

The ERG results discussed here and in the previous section indicate similarities between the STR and the M-wave. Both are negative-going field potentials that reflect the effects of light-induced potassium changes upon the Müller cells in the proximal retina. The difference between these field potentials arises from their photoreceptor basis. Whereas the STR reflects rod-mediated vision, the M-wave is dominated by the cone system. Therefore, the former is a slow potential at stimulus onset recorded in the dark-adapted retina, whereas the latter contains ON and OFF components and is recorded in light-adapted conditions (compare Fig. 13 and Fig. 15). Furthermore, the STR seems to be solely dependent upon potassium-Müller cell interactions, whereas the M-wave reflects also direct contributions from neuronal activity, particularly to its OFF component.

Summary of the ERG Components

The ERG is an electrical response of the eye and is made up of several components. In the previous sections, the major and minor components of the ERG were described, and their cellular origins were discussed. Researchers and clinicians who are interested in objective assessment of retinal function need to become familiar with the

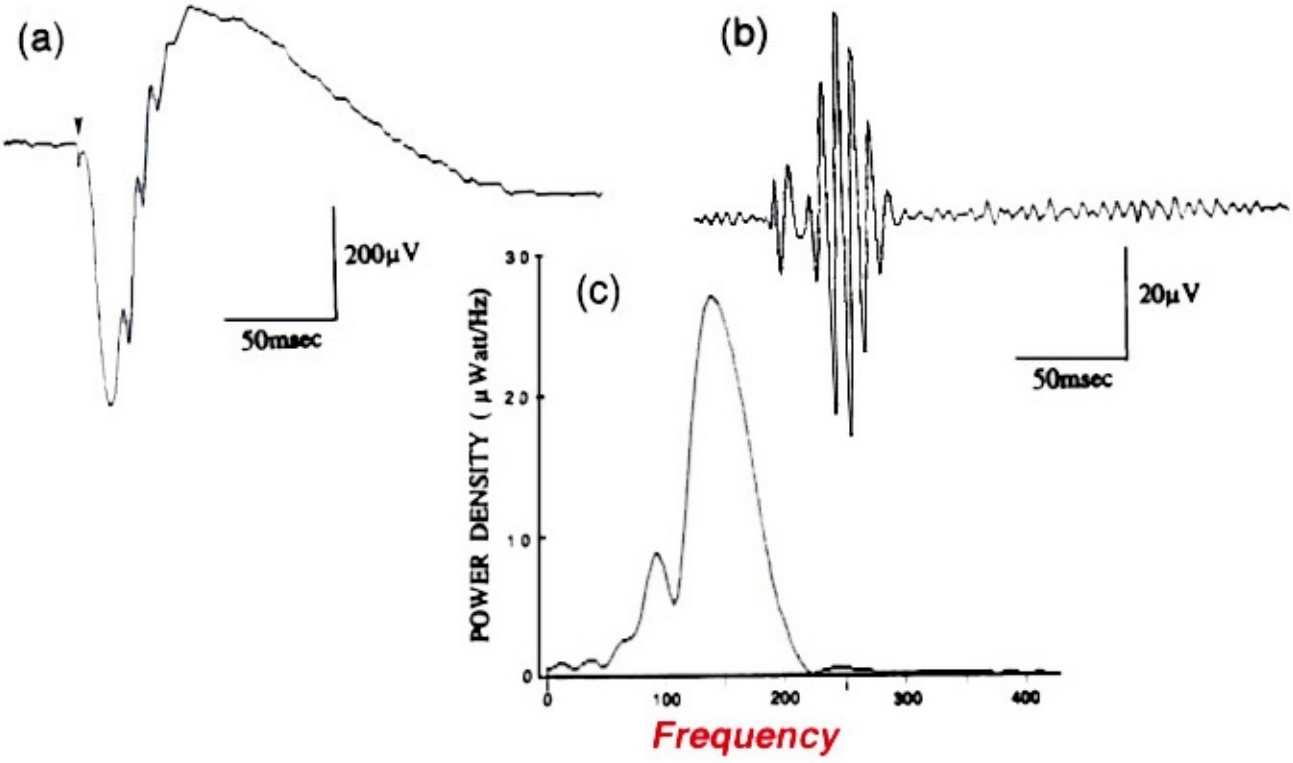

Figure 11. Isolating the oscillatory potentials from the bright flash ERG response of the human eye (a) by applying a digital filter (b). An FFT procedure was applied to the isolated oscillatory potential to obtain the power spectrum (c) (71).

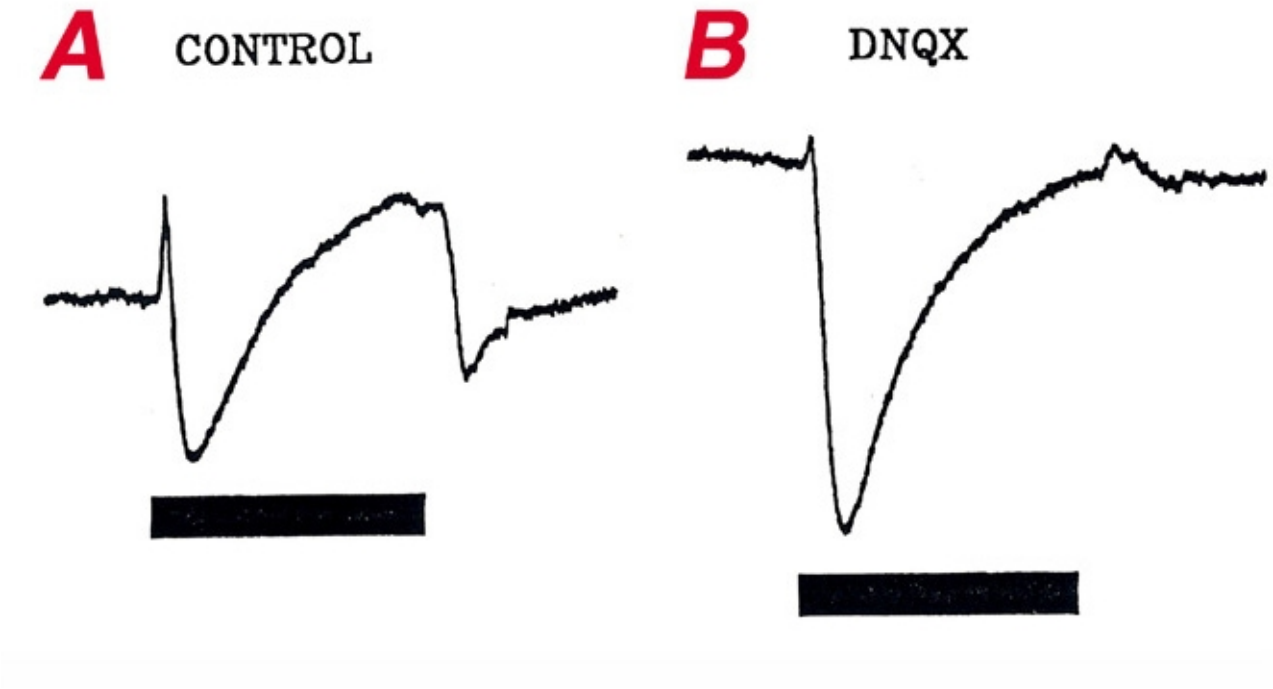

Figure 12. The effects of DNQX, a specific antagonist of AMPA/KA-type glutamate receptors, upon the ERG response of the tiger salamander. The polarity of the waves is reversed; the a-wave is positive, the b-wave negative, and the d-wave negative (50).

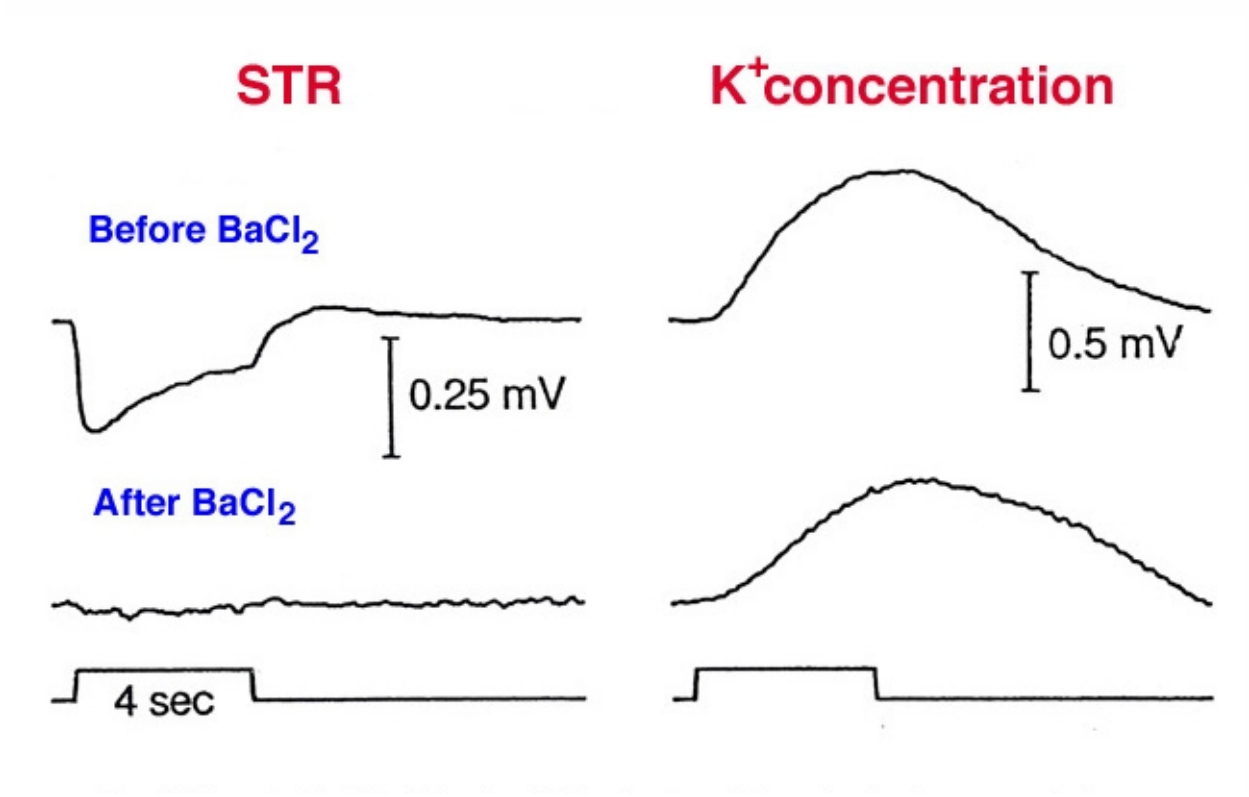

Figure 13. The effects of $BaCl_2$ on the STR and extracellular potassium ion concentration recorded from the proximal retina of the dark-adapted cat. Barium ions eliminate the STR but have no effect on the light-induced increase in extracellular potassium concentration in the proximal retina (92).

ERG waves. With proper analysis, the functional integrity of different retinal structures can be dissected out, and we are able to understand information processing mechanisms and/or the sites of retinal disorders.

The ERG originates from extracellular currents that are generated in response to a light stimulus. In the ophthalmic clinic, the most common recording of ERG responses contains the negative a-wave and the positive b-wave. Light absorbance by the visual pigment molecules in the outer segments of the photoreceptors reduces the "dark" current and, therefore, can be viewed as eliciting a "light" current. This current is expressed as a negative wave when recorded from the vitreous or the cornea and constitutes the fast P-III (the receptor potential). The a-wave of the electroretinogram is the leading edge of the fast P-III and, therefore, reflects the functional integrity of the photoreceptors. However, the amplitude of the a-wave also depends upon the development of the positive Granit's P-II component. Early development of P-II will result in a subnormal a-wave, whereas a slow P-II will be expressed in a supernormal a-wave. Any analysis that allows separation of P-III from the overall ERG response will provide valuable information about the photoreceptors.

The exact source of the ERG b-wave is still under dispute. The major contribution comes from light-induced activity in ON-center bipolar cells. The extracellular currents that generate the b-wave either originate directly in these cells or reflect potassium-induced changes in the membrane potential of the Müller cells enveloping them. Regardless of the exact mechanism, the b-wave is telling us about light-induced electrical activity in retinal cells post-synaptic to the photoreceptors. The b-wave is also affected by OFF-center bipolar cells and by light-induced activity in third-order retinal neurons (amacrine and ganglion cells). This contribution can be isolated in the laboratory by using specific drugs, but in the clinical environment, the ERG b-wave of patients reflects all contributions summed together. In the future, more sophisticated analytical approaches may allow separation of the different contributions and allow identity of more exact sites of retinal diseases.

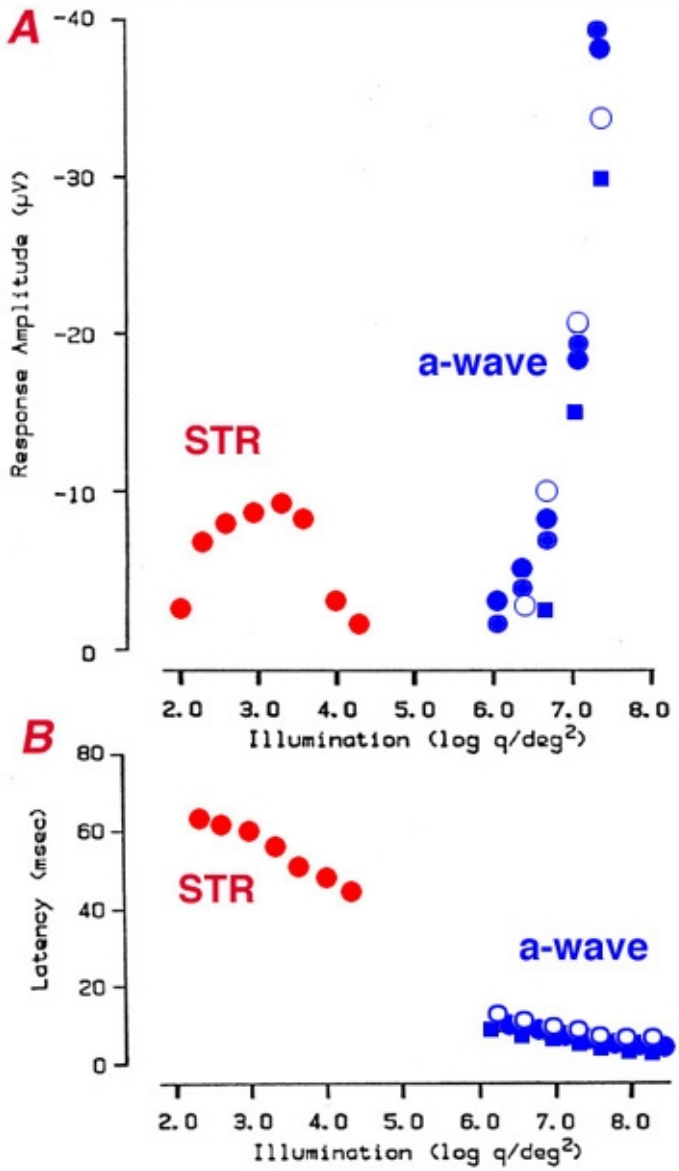

Figure 14. Amplitude-intensity (A) and latency-intensity (B) for the STR and a-wave that were recorded in the dark-adapted cat. Measurements obtained before and after intravitreal injection of L-aspartate are compared (open circles and filled symbols, respectively) (89).

Under special conditions of ERG recordings, the c-wave can be observed in patients. As has been discussed above, the c-wave reflects light-induced decrease in the extracellular concentration of potassium ions in the photoreceptor layer due to light-induced activity in the photoreceptors. The c-wave itself is a manifestation of the change in the trans-epithelial potential. Therefore, the c-wave can be used to assess the functional integrity of the pigment epithelial cells, the photoreceptors, and the interactions between the two.

Among the minor components of the ERG, only the oscillatory potentials and the d-wave are used for clinical assessment of retinal function. The OPs are often used to assess the balance between retinal metabolic needs and retinal vascular supply, because in many retinal vascular disorders, they are the first to be affected (75, 76). The d-wave is used only when the cone ON- and OFF-channels need to be separated to identify defects specific to ON-channels (84, 85).

The other components of the ERG—the early receptor potential (ERP), scotopic threshold response (STR), and M-wave—are more difficult to isolate in the routine clinical setup and are measured only for research purposes.

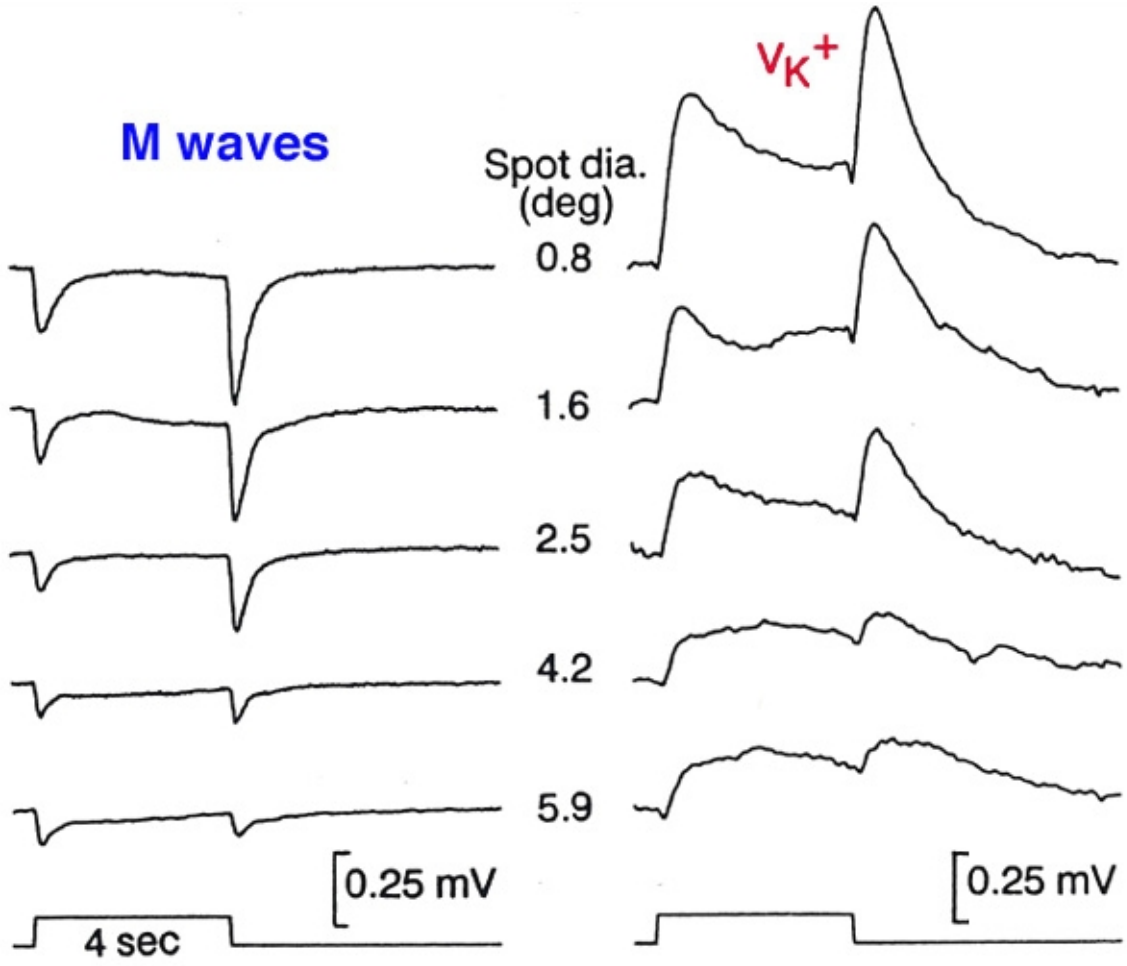

Figure 15. The effects of changing the diameter of the stimulating light upon the M-wave (left column) and the extracellular potassium concentration (right column). The field potential and the potassium concentration were recorded simultaneously with a double-barreled electrode from the proximal retina of the dark-adapted cat (93).

Factors Affecting the ERG

To use the ERG in the most efficient way for retinal research and for electrodiagnosis of retinal function, the parameters that affect the ERG response need to be known.

State of Adaptation

The visual system in vertebrates can be roughly divided into two subsystems, the rod system (night vision) and the cone system (day vision). Both systems operate independently with very few interactions between them. The most sensitive system under particular conditions is the one that determines vision. In some species, the rod system dominates (e.g., skates, rats), whereas in others, the cone system is the dominant one (e.g., some fresh water turtles, ground squirrels). However, in most species including humans, both systems are found. These are duplex retinas. Rod-mediated vision is very sensitive to dim light stimuli in the dark-adapted state; while under background illumination, it saturates and does not respond to light increment or decrement (96). In contrast, the cone system is not as sensitive but is characterized by the ability to adapt to bright lights—processes that allow vision to adapt to background illumination over a wide range of intensities. To separate cone function from rod function, we can modulate the state of adaptation as shown in Fig. 16. When a given light stimulus is applied under background illumination that saturates the rod system, the ERG reflects activity in the cone system. The

ERG under these conditions is of small amplitude but of very fast kinetics—time to peak is about 30-32 ms (Fig. 16, left). In contrast, if the same light stimulus is applied after the subject is kept in darkness for about 30 min, the ERG is of considerably larger amplitude (about 4 folds) and is characterized by slow temporal properties—time to peak of the b-wave is about 60 ms (Fig. 16, right). This ERG response is a mixed rod-cone response (the cone system is operational, too) but mainly reflects the activity in the rod system because the cone system contribution is considerably smaller.

Light Intensity

In Fig. 17, dark-adapted ERG responses of one volunteer are shown to light stimuli of different intensities covering a range of about 5 log units. With a dim light stimulus, the ERG is a slow positive wave of small amplitude. This is the b-wave. As the stimulus intensity is increased, the ERG b-wave increases in amplitude and becomes faster in kinetics. With yet brighter stimuli, a negative wave (the a-wave) precedes the positive b-wave. With further increase in the flash intensity, both the a-wave and the b-wave increase in amplitude and become faster. With the brightest flash used here, fast wavelets (oscillatory potentials) are seen on the rising phase of the b-wave.

It is clear from Fig. 17 that the ERG responses of humans and of other vertebrate species depend upon the intensity of the light stimulus used. Therefore, it is crucial for a research laboratory as well as a clinical set-up to control the light intensity of the ERG system and to verify that technical factors will not contaminate the data and, therefore, the conclusions. The size of the pupil is the major determinant of light intensity to the retina. A 3-fold change in pupil diameter means a 9-fold change in light intensity reaching the retina (almost 1 log unit). Opaque optical media should also be considered. Mature cataract or vitreal hemorrhage will absorb some of the impinging light and will, therefore, reduce the light intensity reaching the retina. These latter factors usually absorb about 50% of the light, thereby reducing light intensity by 0.3 log units.

Color of Light Stimulus

Fig. 18 shows the spectral sensitivity curves of cone-mediated vision and of rod-mediated vision in human observers. The rod curve peaks at the blue-green region of the visible spectrum (around 500 nm). The spectral sensitivity curve of cone-mediated vision is the sum of all three spectral types of cone: long-wavelength sensitive (red), medium wavelength-sensitive (green), and short wavelength-sensitive (blue), and, in net, has peak sensitivity in the orange range of the visible spectrum (around 560 nm). Throughout most of the visible spectrum (less than 620 nm), the rod system is more sensitive than the cone system by as much as 3 log units (a factor of 1000). For wavelengths longer than 620 nm, the sensitivity of both systems is similar, and cone vision may even exhibit a slightly higher sensitivity than rod vision.

Therefore, light stimuli of different spectral content can elicit ERG responses that are dominated by one or the other systems as shown in Fig. 19. These ERG responses were recorded in a volunteer in the dark-adapted state using dim blue or bright red light stimuli. The blue stimulus elicits a slow positive ERG of the more sensitive rod system (A). The red light stimulus produces an ERG response composed of two parts: a fast wave peaking around 30 ms, and a slow wave peaking at 100 ms (B). This ERG is a combination of rod and cone contributions, with the cone-mediated response being of fast kinetics and the rod-mediated response of slow time-to-peak. The fast cone-mediated ERG is sometimes referred to as the x-wave (97, 98). The two light stimuli were balanced to produce equal rod excitation as evidenced by the equality in the slow ERG component (Fig. 19C). With this procedure, cone-mediated function can be isolated from the large-amplitude rod ERG and allows analysis of the cone *versus* rod system in the dark-adapted state.

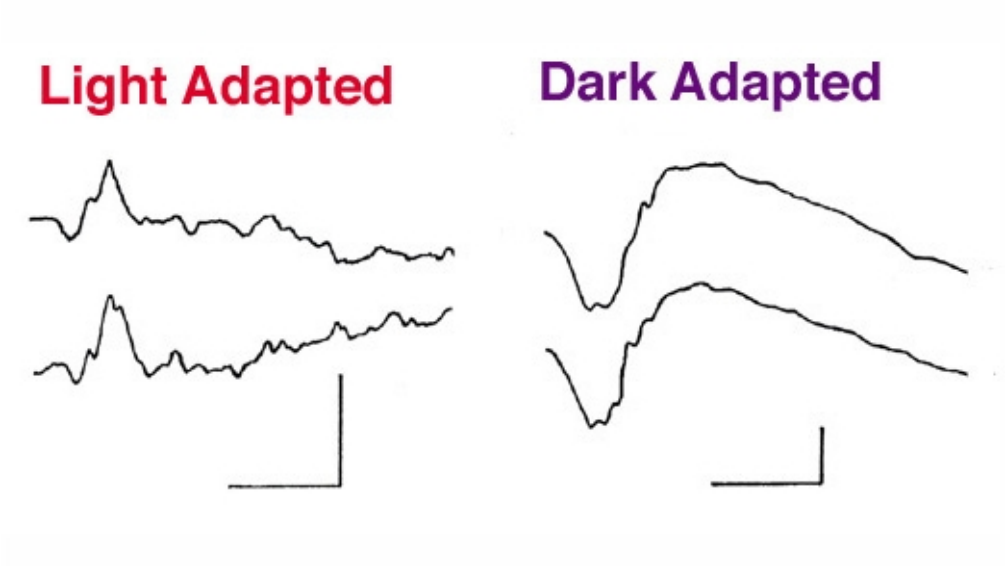

Figure 16. The ERG responses of a volunteer that were elicited with the same light stimulus during continuous background illumination (A) and after 30 min in the dark (B). Note the different temporal properties and amplitudes of the two responses.

Frequency of Photostimulation

Another experimental approach to separate rod-mediated vision from cone-mediated vision is based upon the differences in temporal properties between these two visual systems. Measurements of critical fusion frequency (CFF), the maximal frequency of stimulation that can be perceived as flickering, show low CFF in dim illumination that rises with stimulus intensity until a plateau phase of about 15 Hz is reached. Under cone vision conditions, high-intensity stimuli can be perceived as flickering at frequencies of 30 and even 50 Hz (99). However, when special care is taken to selectively desensitize the cones and thus reveal the rod function under bright illumination, flicker fusion frequencies are achieved at 28 Hz (99).

In ERG recording, CFF is determined by the frequency of photic stimulation that just elicits flickering electrical signal. The relationship between the ERG-determined CFF and stimulus intensity shows a discontinuity that marks the transition from rod vision to cone vision. The highest CFF for rod vision is about 15 Hz, whereas the cones can follow flickering stimulations up to 50 Hz (100). Recent, more careful ERG recordings reveal that rod-mediated electrical activity can follow flickering frequencies higher than 15 HZ, reaching as high as 28 Hz (101). It has been argued, based on recent findings on the rod system in mammals and primates, that rod signals can be transmitted via two pathways. The first one involves the rod bipolar cells. This is the slow pathway that can follow flickering stimuli up to 15 Hz. The second pathway involves rod-to-cone gap junctions that transmit rod-mediated signals via the cone bipolar cells that can follow flickering stimuli up to 28 Hz (101).

To reveal the fast flicker of the rod signals, special care is needed for recording conditions. Under regular recording conditions of the ophthalmic clinic, it can be accepted that rod-mediated electrical signals can follow flickering stimuli up to 15 Hz. Therefore, it is customary to apply bright light stimuli at a frequency of 30 Hz to isolate the cone system from the rod system. The responsiveness of the cone system and its ability to follow fast flickering stimuli depend upon the level of ambient illumination as shown in Fig. 20 (102). In this figure, ERG recording was performed from one subject using 31.3 Hz flicker of constant intensity while changing the level of ambient illumination. The responses are of larger amplitude and are characterized by faster rise times as the irradiance of the adapting field is raised. This observation is consistent with the notion that the cone system is suppressed in the dark-adapted state and that light adaptation removes this inhibitory action. However, by using scotopically matched backgrounds, one can see that mechanisms intrinsic to the cone system itself are also involved (102).

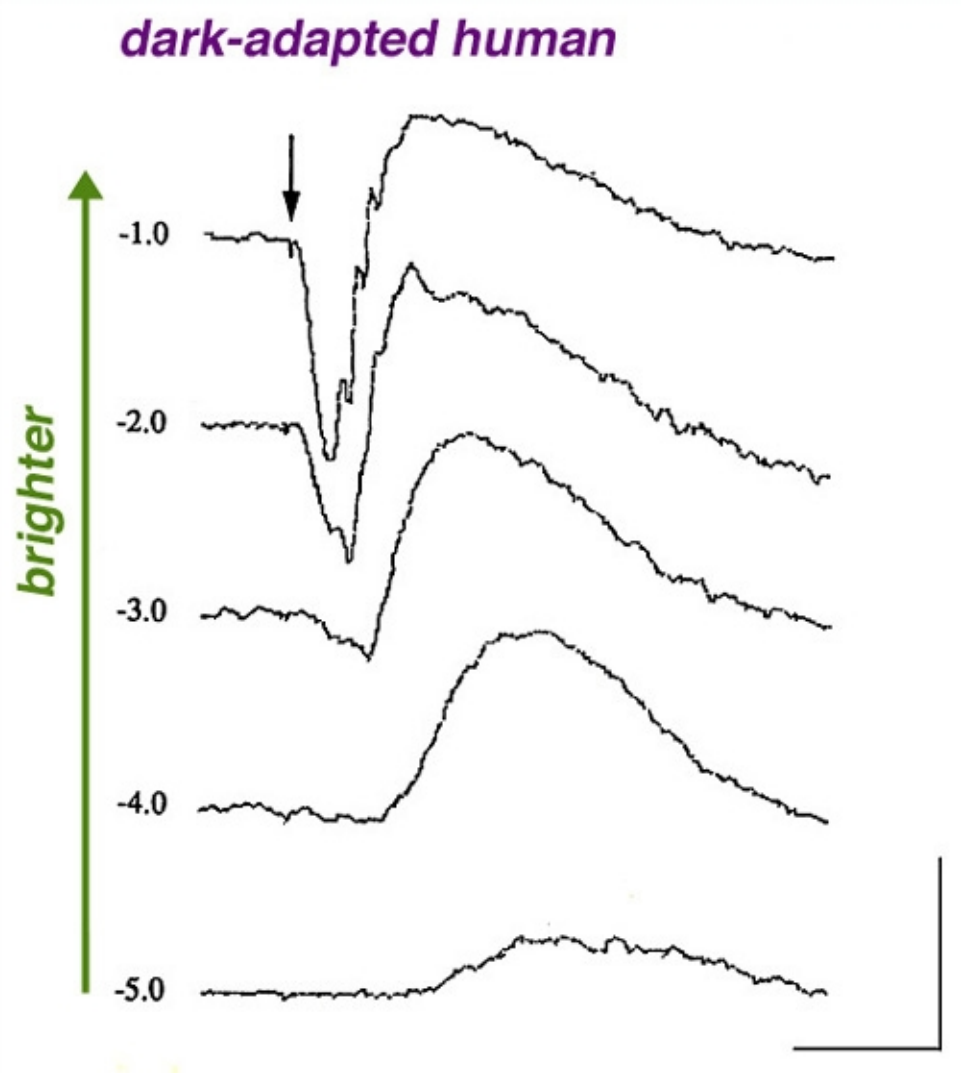

Figure 17. ERG responses that were recorded from one subject with corneal electrode in the dark-adapted state. Several intensities were used covering a range of 4 log units.

Analysis of the ERG

Over the years, since the first recording of the ERG responses and with greater understanding of retinal function at the cellular and molecular levels, more advanced analytical approaches have been developed. In this section, the more classical means of analysis and some of the recent approaches to clinical ERG analysis will be discussed.

Amplitude and Implicit Time Measurements

The most common ERG response from a human, which is elicited with a full-field (Ganzfeld) flash of light, contains the a-wave and the b-wave as shown in Fig. 21. The amplitude of the a-wave is measured from a baseline that is monitored before the light stimulus, to the trough of the negative wave. Because the b-wave reflects the sum of the negative P-III component and the positive P-II component, its amplitude is measured from the trough of the a-wave to the peak of the b-wave. The temporal properties of the ERG response are usually defined by the time-to-peak (implicit time) of the b-wave and are measured from stimulus onset to the peak of the b-wave (L_b in Fig. 21). In some laboratories, the time-to-peak of the a-wave is also measured (L_a in

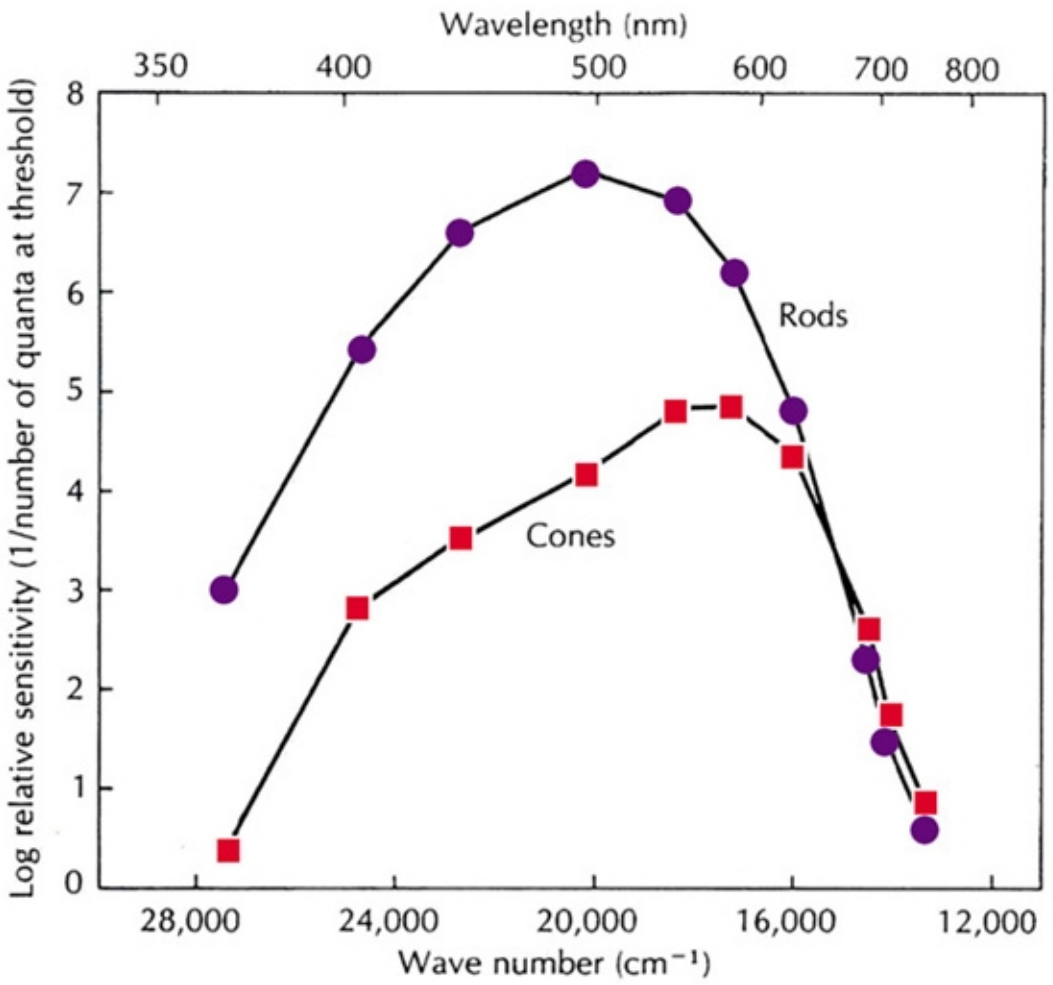

Figure 18. Spectral sensitivity of rod vision (purple circles) and cone vision (red squares).

Fig. 21). These ERG parameters change with the intensity of the light stimulus (Fig. 17) and with the state of adaptation (Fig. 16), as we have seen earlier.

Fig. 22 shows the dependency of the ERG amplitudes and temporal properties upon stimulus intensity (A and B, respectively). These curves were constructed from ERG measurements in 20 volunteers with no visual defects and were conducted in the dark-adapted state. Data represent average (± s.d.) of the amplitude and time-to-peak of the a-wave and the b-wave. For dim light stimuli, the ERG consists of only the b-wave (Fig. 22A). As stimulus intensity is increased, the b-wave increases in amplitude until a plateau is reached at intensities brighter by about 2 log units than that needed to elicit the smallest recordable b-wave. At these intensities, the a-wave becomes evident. With further increases in intensity, both a- and b-waves grow in amplitude. The effect of stimulus intensity upon the kinetics of the ERG response is clearly seen in the dependency of the a- and b-wave time-to-peaks upon stimulus intensity (Fig. 22B). The brighter the flash stimulus, the faster the ERG response and the shorter the time-to-peaks of both waves are. This type of analysis can give valuable information about retinal function in a clinical set-up where all conditions of measurements are maintained at a constant.

The relationship between amplitude and intensity of the ERG waves can be described by the following hyperbolic function (103, 104).

$$V/V_{max} = I/(I + \sigma) \text{ (Equation 1)}$$

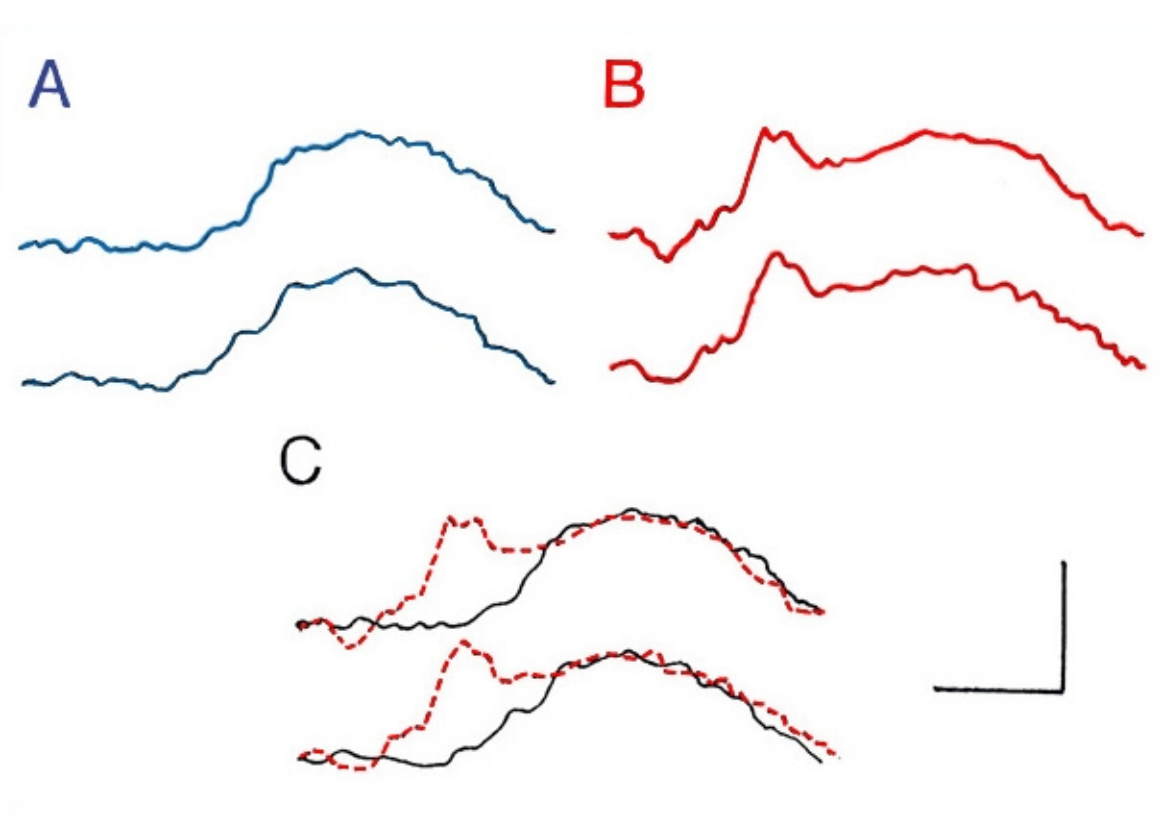

Figure 19. The effects of color on the dark-adapted ERG response of human. Dim blue (A) and bright red (B) light stimuli were used to elicit the ERG responses. These light stimuli were matched for rod-mediated vision, as can be appreciated from the comparison in part C. The slow, positive wave in both responses represents rod function and, therefore, exhibits a good match. The early, positive wave is sometimes referred to as the x-wave and represents cone function.

In this equation, V and V_{max} are the amplitudes that are measured with light stimulus of intensity I and with super-saturating stimulus, respectively. The parameter σ is the semi-saturation constant and is the stimulus intensity needed to elicit a response of half-maximal amplitude. This parameter also describes the location of the intensity-response curve along the intensity axis. When very dim light stimuli are used ($I < \sigma$), Eq. 1 can be reduced to:

$$V/V_{max} = I/\sigma \text{ (Equation 2)}$$

Namely, the amplitude V is linearly related to the light intensity I with a slope of V_{max}/σ. Thus, the semi-saturation constant is also used as a measure of sensitivity.

The values V_{max} and σ have been calculated for normal subjects under different conditions to study retinal mechanisms during adaptation or development (103, 105-107). In patients, these parameters provide quantitative assessment of retinal function during the progress of retinal diseases and the success of treatment (108, 109). Furthermore, these parameters indicate the nature of the disease: progressive or static; affecting the entire retina or only patches; and the site of the disorder (106, 108, 110, 111).

Ratio of b-Wave to a-Wave

ERG analysis that is based only upon amplitude measurements may lead to erroneous conclusions if the pupil is not maximally dilated. Furthermore, exchange of information between laboratories that use different recording conditions has always been problematical. One way to circumvent this difficulty is to compare a series of ERG

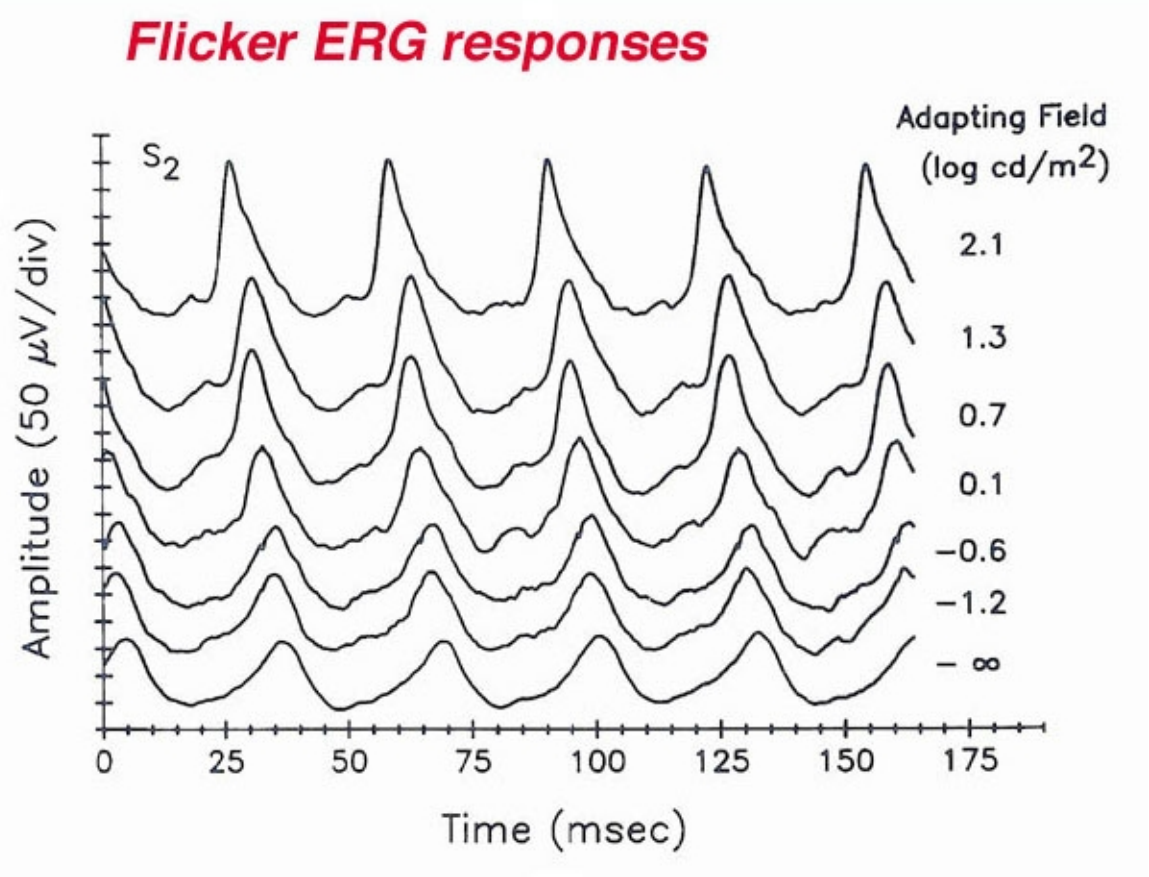

Figure 20. Flicker ERG responses to stimulation at 31.1 Hz with a stimulus intensity of 0.8 log cd-s/m2. The lowest trace was obtained in the dark-adapted state. Other traces were recorded after 30 min adaptation to white background of intensity denoted on the right (102).

responses for the relationship between the a-wave and the b-wave (112). This analysis is based upon our understanding of retinal physiology and the origin of the ERG waves. If the a-wave reflects activity in the photoreceptors and the b-wave originates from post-synaptic neurons, than normal signal transmission in the distal retina will be expressed in a normal relationship between the b-wave and the a-wave. Such analysis can also be used to compare ERG data between laboratories as shown in Fig. 23. The figure was constructed from ERG data of 20 volunteers with normal vision who were tested in the dark-adapted state with light stimuli of different intensities. The relationship between the b- and a-waves was derived for each subject, and the normal mean (continuous line) and range (± s.d., dashed lines) are shown in the figure. ERG data from two other laboratories that use different corneal electrodes and different light sources are shown (red dots, blue triangles). The data points from these laboratories fall within our normal range, indicating normal retinal function.

This type of analysis can also help in understanding the site of disorder. Any disorder that is localized to the photoreceptors and does not involve more proximal sites will be expressed in abnormal a-wave amplitude but normal b-wave:a-wave ratio. In contrast, a defect in signal transmission in the outer plexiform layer will show abnormal b-wave:a-wave ratio, but the amplitudes of the ERG waves may even increase. This is illustrated in Fig. 24 for two cases. In this figure, the b-wave:a-wave ratio is plotted in a different manner. The a-wave is used as the independent variable and is used together with the normal b-wave:a-wave ratio (of Fig. 23) to derive the expected b-wave. Then, the ratio of the measured b-wave:expected b-wave tells us about signal transmission in the OPL. In Fig. 24, the mean (± s.d) of the b-wave ratios for 20 volunteers with normal vision is plotted as a function of the a-wave amplitude. The data from normal subjects that were recorded in another two laboratories (red and blue symbols) fall well within the normal range of my laboratory. The b-wave ratios of a patient with

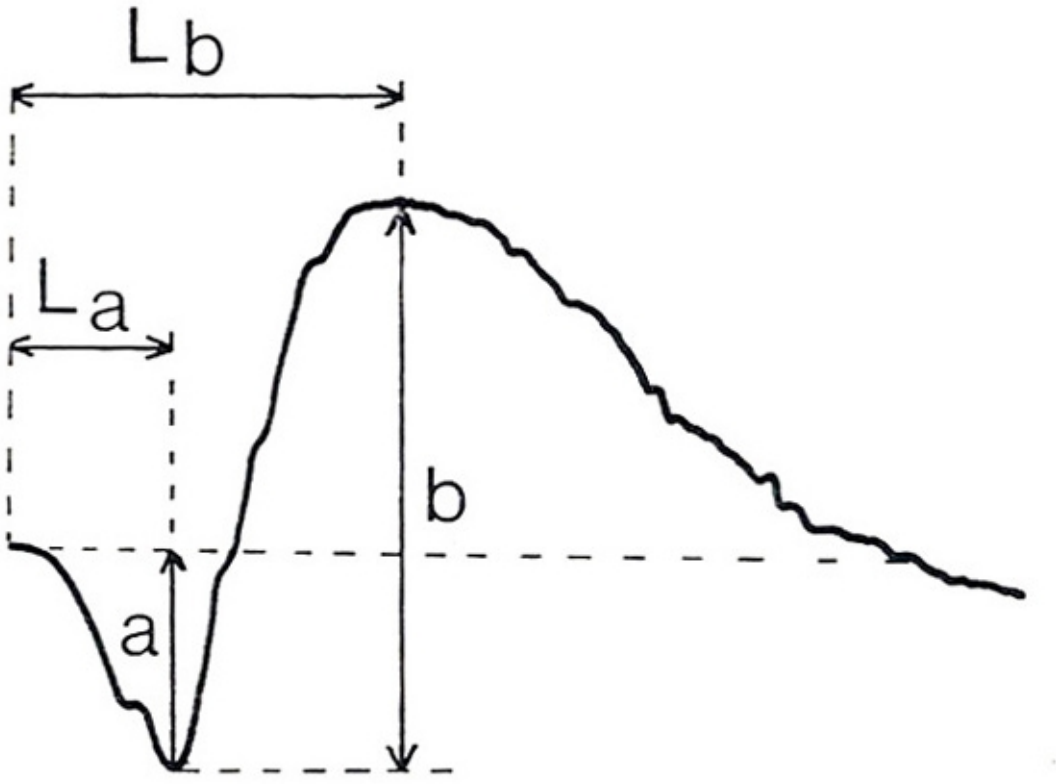

Figure 21. The ERG parameters that are customarily measured in the ophthalmic clinic for electrodiagnosis. The size of the a-wave is measured from the baseline to the trough of the wave. The size of the b-wave is measured from the trough of the a-wave to the peak of the b-wave. The time-to-peak for both waves (La and Lb) is determined from stimulus onset to the trough or peak of the waves.

high myopia and of a patient suffering from congenital stationary night blindness (CSNB) are compared with the normal range. The patient with high myopia is characterized by subnormal ERG responses because of the reduced function of the photoreceptors. However, the b-wave ratio is normal, indicating normal signal transmission. The CSNB patient is characterized by subnormal b-wave ratio, in agreement with the known defect in synaptic transmission from rods to bipolar cells.

Reconstruction of P-III

For over 50 years, since the analysis by Granit (5) of the ERG components, the a-wave has been used to assess the functional integrity of the photoreceptors. Extracellular recordings of the photoreceptors currents (113) and the introduction of the suction electrode technique to record the photocurrents from individual photoreceptors (114) allows creation of a mathematical model to fit to the ERG a-wave. This describes the entire contribution of the photoreceptors to the ERG- the P-III component (115, 116). The model is based upon the two-component model of the light-induced currents of mammalian rods (114, 117, 118) and is given by the following equation:

$$P_3(i, t) = \{1 - \exp[-iS(t- t_d)^2]\}R_{mP3} \quad \text{(Equation 3)}$$

In this equation, P_3, the amplitude of Granit's P-III component, is a function of flash energy i and time of measurement t after light onset. S is a sensitivity parameter, R_{mP3}, is the maximum amplitude of P-III, and t_d is a delay.

To derive the relationship between P_3 and time for the entire ERG range, very bright flashes that saturate the photoreceptors (i.e., shut down the "dark" current completely) are needed (Fig. 25A). As can be seen in these

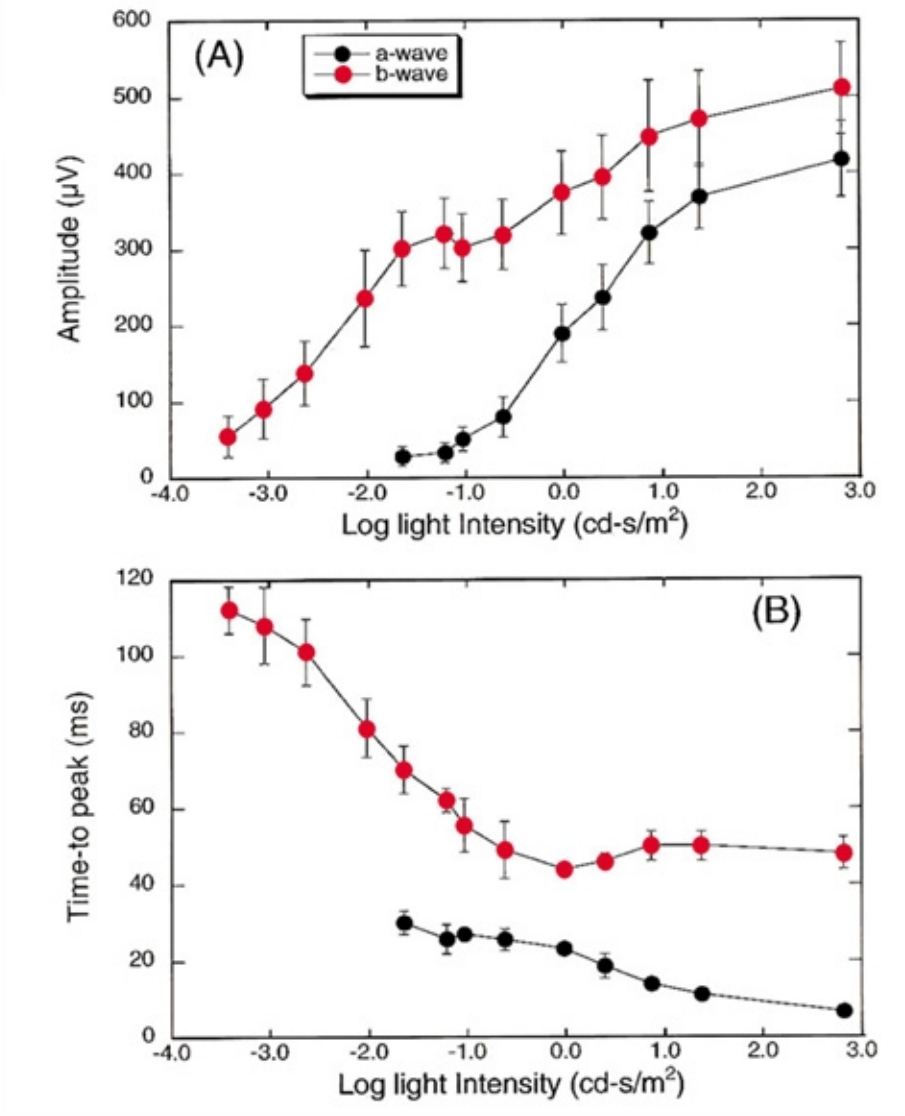

Figure 22. The ERG parameters for a normal range (N = 20) as determined in the dark-adapted state. The dependencies of amplitudes (A) and of time-to-peaks (B) of the a-wave and the b-wave upon log stimulus intensity are shown.

ERG records, the a-wave saturates for the two brightest light stimuli. Time of analysis is limited to the period before b-wave intrusion, as shown by the two dashed vertical lines (Fig. 25A). Application of Eq. 3 to these ERG data is shown in Fig. 25B. The data points are the amplitude measurements of the ERG responses, and the continuous curves are the fitted model. The fit of the theoretical curves to the actual data is quite good for the first 25 ms of the ERG responses. Longer intervals cannot be compared because the positive P-II component starts to develop and to affect the ERG recordings.

The bright-flash ERG response predominantly reflects rod function with a small contribution of the cone photoreceptors. To derive the isolated rod P-III wave and allow analysis of rod function alone, a procedure for a rod-isolating technique has been suggested (115). ERG responses are also elicited by long-wavelength light stimuli (>605 nm). These responses reflect mainly cone contribution and can be subtracted from the responses to white light stimuli and thus isolate the rod ERG responses.

A model, similar to that suggested for the rod P-III, has also been suggested for the cone P-III (116, 119). However, to construct the cone P-III from the a-wave of the bright flash photopic ERG response, a low-pass, exponential filter needs to be added, after the phototransduction process (116). This filter represents membrane

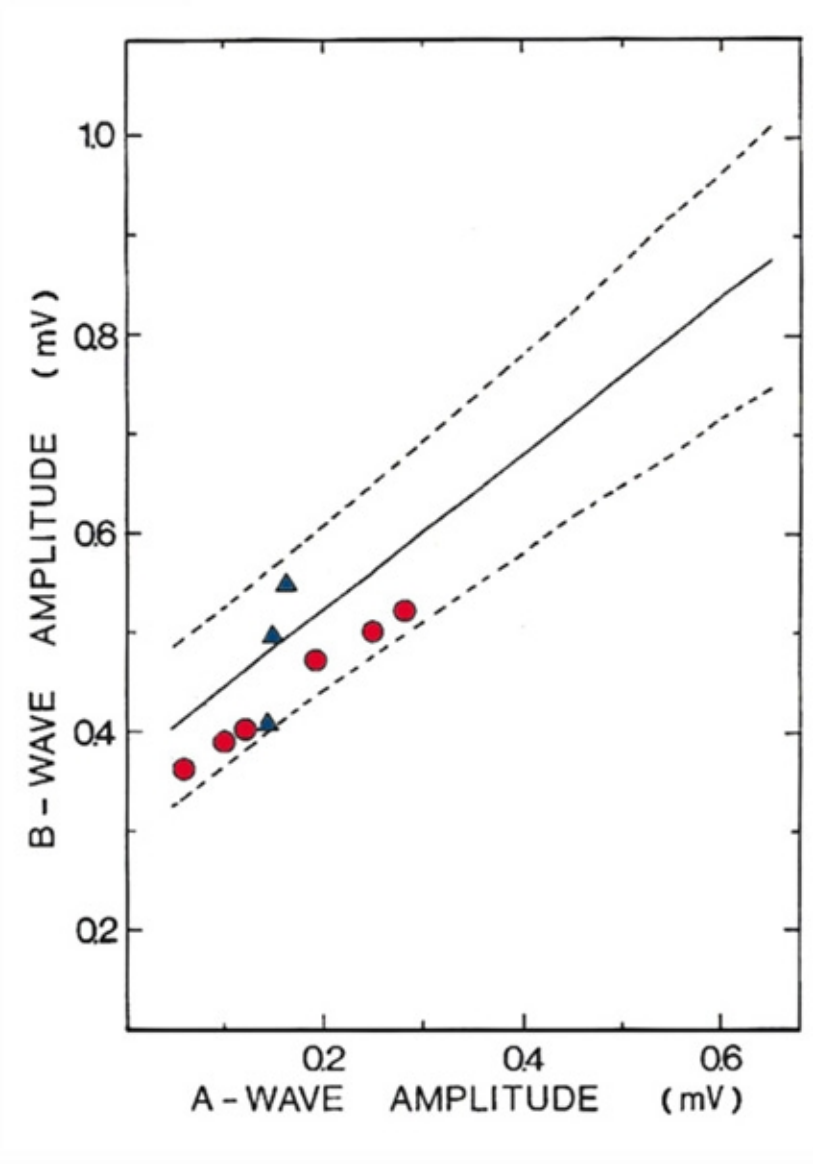

Figure 23. The relationship between the a-wave amplitude and the b-wave amplitude for 20 subjects with normal vision. The average (continuous line) and the range (dashed lines) are given. The data points (red circles and blue triangles) represent data from normal subjects recorded in two different laboratories (112).

capacitance that determines the rate at which the photocurrent is translated into membrane potential. With the rods, the membrane capacitance is relatively small and, therefore, the development of membrane potential follows quite accurately the development of photocurrent. This is not true for the cone photoreceptors, probably because of the in-foldings of the plasma membrane that make the outer segment discs and contribute to membrane capacitance. The importance of adding this low-pass filter to fit the phototransduction model to the cone a-wave is illustrated in Fig. 26. The ERG responses were elicited by a series of red light stimuli of moderate to bright intensities that were applied during background illumination. When the rod model (Eq. 3) was fitted to the cone a-wave (Fig. 26A), a substantial discrepancy between the theoretical curves and measured ones was seen (dashed and continuous curves, respectively). However, when a low-pass filter with t = 1.8 ms was added, a good fit was obtained between the theoretical and measured responses (Fig. 26B, dashed and continuous traces, respectively).

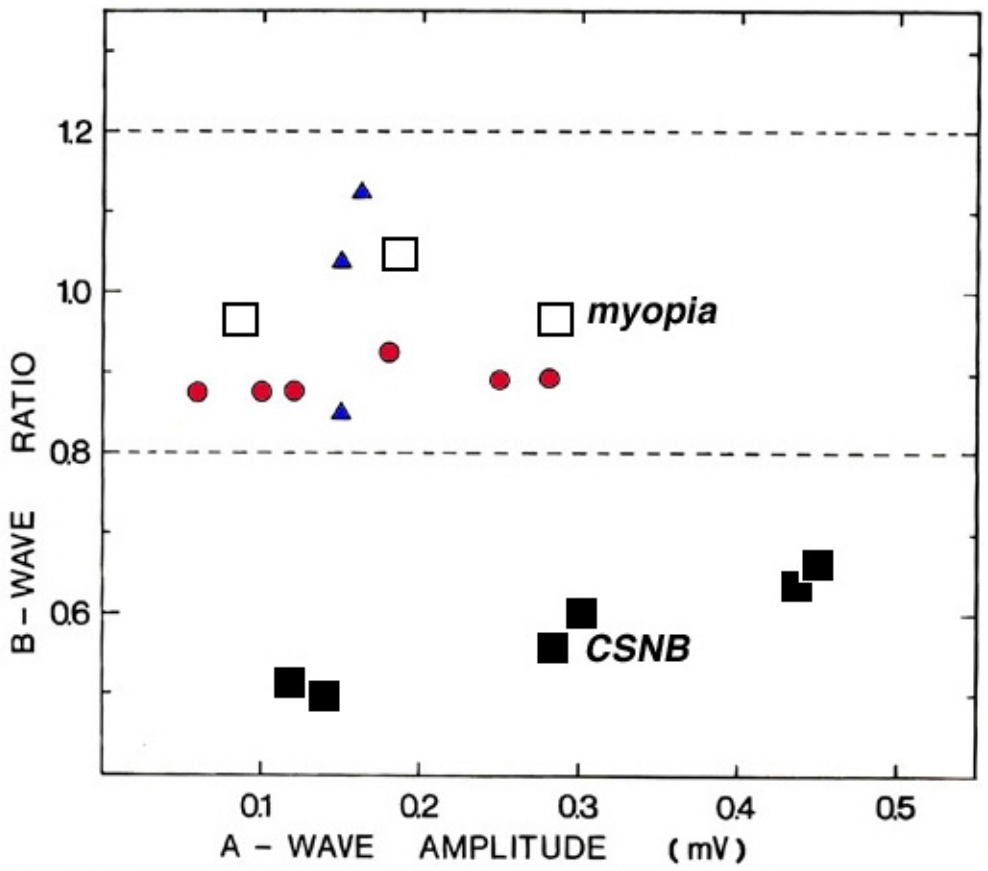

Figure 24. The b-wave ratio was computed from Fig. 23 as follows. For a given a-wave, there is an expected b-wave if synaptic transmission is normal and the b-wave generators function properly. The b-wave ratio is the ratio of the measured b-wave relative to the expected b-wave. The continuous and dashed lines represent the average ± s.d. of 20 subjects with normal vision. The colored symbols represent normal ERG data from two other laboratories. The myopic patient (open squares) exhibits reduced a-wave, but the b-wave ratio is normal, indicating normal synaptic transmission and normal functioning of the second-order neurons (ON-center bipolar cells). The patient with congential stationary night blindness (CSNB) exhibits reduced b-wave ratio, indicating abnormal signal transmission in the rod pathway (black squares) (112).

The model discussed above, or an extension of it using bright light stimuli to elicit ERG responses (120), can be used to analyze biophysical mechanisms of the phototransduction process. These can be used for research purposes to study non-invasively and in a chronic manner, photoreceptor function in primates (121), or to analyze the disorder locus in patients with retinal diseases (122, 123). By fitting rod a-waves to the phototransduction model (Eq. 3), it is possible to isolate disorders that affect the sensitivity of the rods from disorders that affect their maximum response. A more simple approach is to record the ERG to bright white flash and compare the patient ERG to the normal range. A disease that leads to a reduction in the maximum response (R_{mP3}) will show as a smaller maximum a-wave in the ERG that can be scaled up to fit the normal one. In contrast, a disorder that affects the sensitivity (S) will cause a smaller or even normal amplitude a-wave, but when scaled to the normal one, a delay in its development will be seen (123). An example is shown in Fig. 27. The thick continuous traces show the range of a-waves that were recorded from 10 volunteers with normal vision in the dark-adapted state using a white light stimulus of 664 cd-s/m^2. The colored traces are the actual ERG responses of a patient who was diagnosed with enhanced short-wavelength cone syndrome (enhanced SWS cones). His dark-adapted a-wave is smaller in amplitude than that of the normal range and when scaled up exhibits considerably slower kinetics. Thus, the dark-adapted a-wave of this patient is characterized by smaller maximum response and reduced sensitivity. This patient also complained of difficulty at night and had an abnormal dark-adaptation curve with only cone adaptation and no rod function (124).

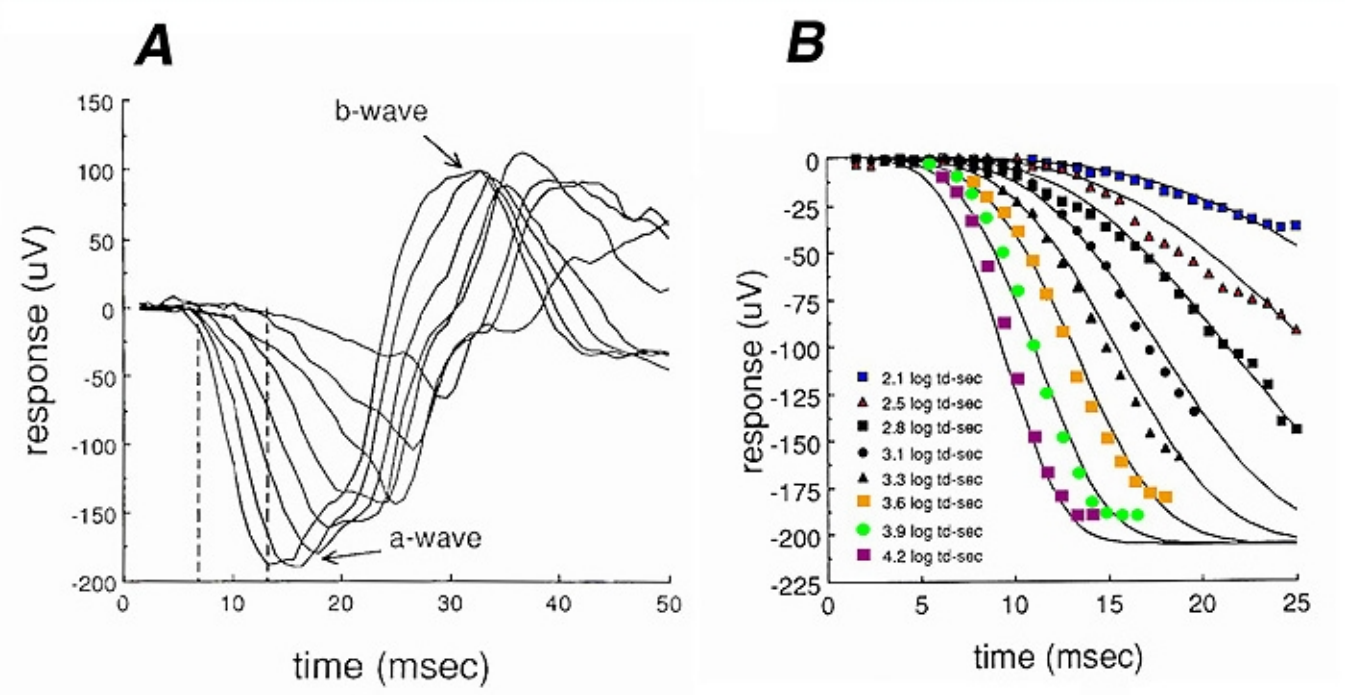

Figure 25. A, the ERG responses of one subject in the dark-adapted state by bright short-wavelength light stimuli. These are rod responses that were obtained by computer subtraction of the cone contribution as described in the text. The vertical dashed lines represent the time frame used to derive the theoretical rod P-III component. B, the data points (different symbols describe different intensities) represent the first 25 ms of the records in A. The continuous traces were obtained by fitting the phototransduction model (Eq. 3) to the data points (115).

Reconstruction of P-II

Granit's P-II component is generated in the neural retina mainly by ON-center bipolar cells with minor contributions from OFF-center bipolar cells and third-order neurons. Accurate measurement of the P-II amplitude can supply valuable information to the clinician on the functional integrity of the retina. However, the b-wave of the ERG is the sum of the positive P-II and the negative P-III. Therefore, changes in the b-wave can reflect changes in either of these components. The best estimate of the b-wave is by measuring it from the trough of the a-wave to the peak of the b-wave; however, this method will always underestimate the amplitude of P-II. Furthermore, the temporal properties of P-II are of value to the clinician. However, the time-to-peak of the ERG b-wave is not the time-to peak of the isolated P-II component but rather depends upon the summation of P-II and P-III (104).

Because the ERG P-III component can be reconstructed from bright flash ERG responses using the phototransduction model (Eq. 3), P-II can be estimated for any stimulus intensity by subtracting the estimated P-III from the measured ERG (Fig. 28) (104). Dark-adapted ERG responses of a normal subject were elicited by a standard series of light stimuli (Fig. 28A). The dashed traces are the theoretical rod responses that were derived from bright flash responses as described above. By subtracting the rod responses from the measured ERG responses, the P-II components can be isolated (Fig. 28B). From this set of data, the actual amplitude and time-to-peak of the ERG P-II component can be obtained and used to understand retinal changes (125).

Paired-Flash Analysis of the Rod Response

A test flash of fixed intensity induces a rod response that reflects the degree to which the "dark" current is reduced, and the time course of closure, followed by opening, of the cGMP-gated channels. This rod response underlies the receptor component (P-III) of the ERG. It is normally masked throughout most of its period by the

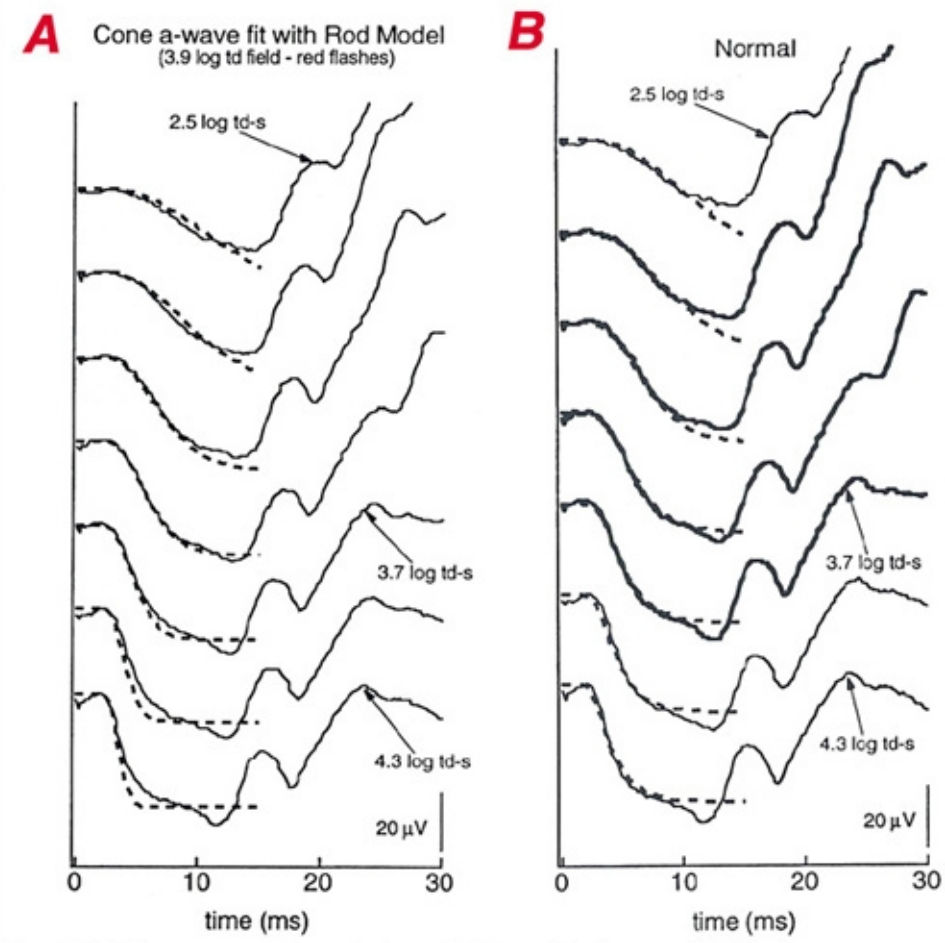

Figure 26. Fitting cone a-waves to the phototransduction model. A, cone a-waves that were elicited in the light-adapted state using long-wavelength light stimuli of different intensities. The rod model (Eq. 3) could be used to fit the a-waves that were recorded in response to light stimuli of moderate intensities (upper four traces) but failed with bright stimuli. The theoretical traces (dashed) are faster than the measured responses (continuous). B, adding a low-pass filter after the phototransduction process to the theoretical equation to account for the large membrane capacitance (long time constant) of the cones improved the fitting of the cone a-wave (continuous traces) to the phototransduction model (dashed traces) (116).

large, positive b-wave. The paired-flash technique has been developed to reconstruct the P-III component (126, 127). The concept of the paired-flash approach is that a super-bright flash delivered after a test flash will completely shut down the remaining "dark" current, and therefore, the amplitude of the a-wave, which is elicited by the probe flash, can be used as a measure of the prevailing rod "dark" current at that time. Thus, two stimuli are applied at variable time intervals. A test flash of fixed intensity (I test) that is given at t = 0 and a bright probe flash (I probe) that is expected to shut down the "dark" current and is delivered at a variable time interval, t probe, after the test flash. For long time intervals, the a-wave of the probe flash will be large and constant, because the rods have recovered from the effects of the test flash, and the probe flash induces an a-wave of saturating amplitude. However, with short inter-flash intervals, the probe flash can only shutdown the "dark" current that exists at that time, and therefore, the amplitude of the a-wave will be smaller. Such an experiment is illustrated in Fig. 29. The a-waves elicited by probe flashes at different time intervals after the test flash are shown in Fig. 29A. The shorter the inter-flash interval, the smaller the a-wave that is elicited by the probe flash. These a-waves are corrected for cone contributions in Fig. 29B. Fig. 29C illustrates the construction of the rod response underlying the test flash. The a-waves elicited by the probe flashes are arranged according to their inter-flash interval so that all of their peaks reach the same level—the level where all of the "dark" current is shut off. Connecting the baselines of the probe a-waves gives the time course of the rod response of the test flash.

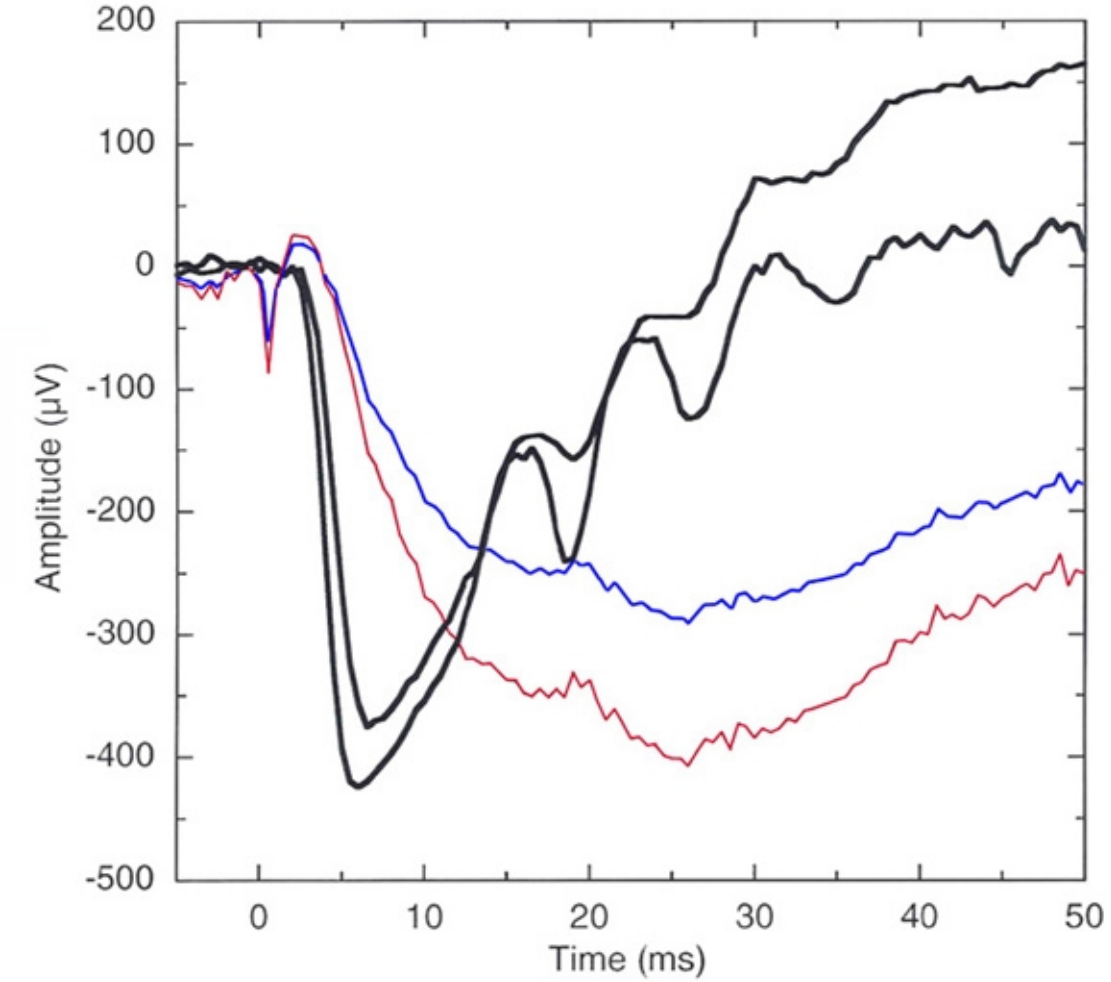

Figure 27. Analyzing the rod phototransduction in a patient with enhanced SWS cone syndrome. The range of bright flash, dark-adapted ERG a-wave of 10 normal subjects is given by the thick continuous traces. The patient's maximum ERG a-wave is smaller in amplitude and slower in kinetics after normalizing the a-wave to the normal range.

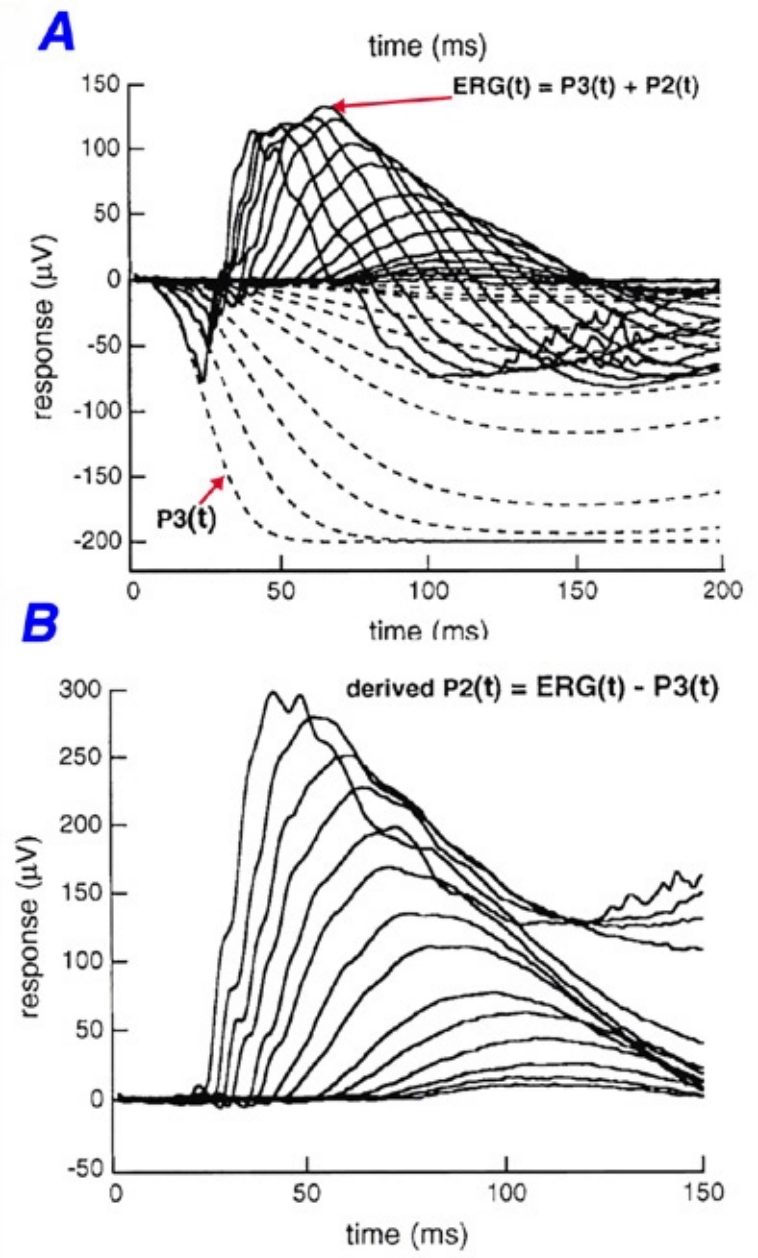

Figure 28. Reconstructing the P-II component of the human ERG response. A, the ERG responses that were elicited in the dark-adapted state using light stimuli of different intensities. The dashed traces are the reconstructed P-III component of each ERG response according to the method described in the text (Eq. 3). B, reconstructed P-II components of the ERG responses of part A by subtracting the reconstructed P-III from the measured ERG (128).

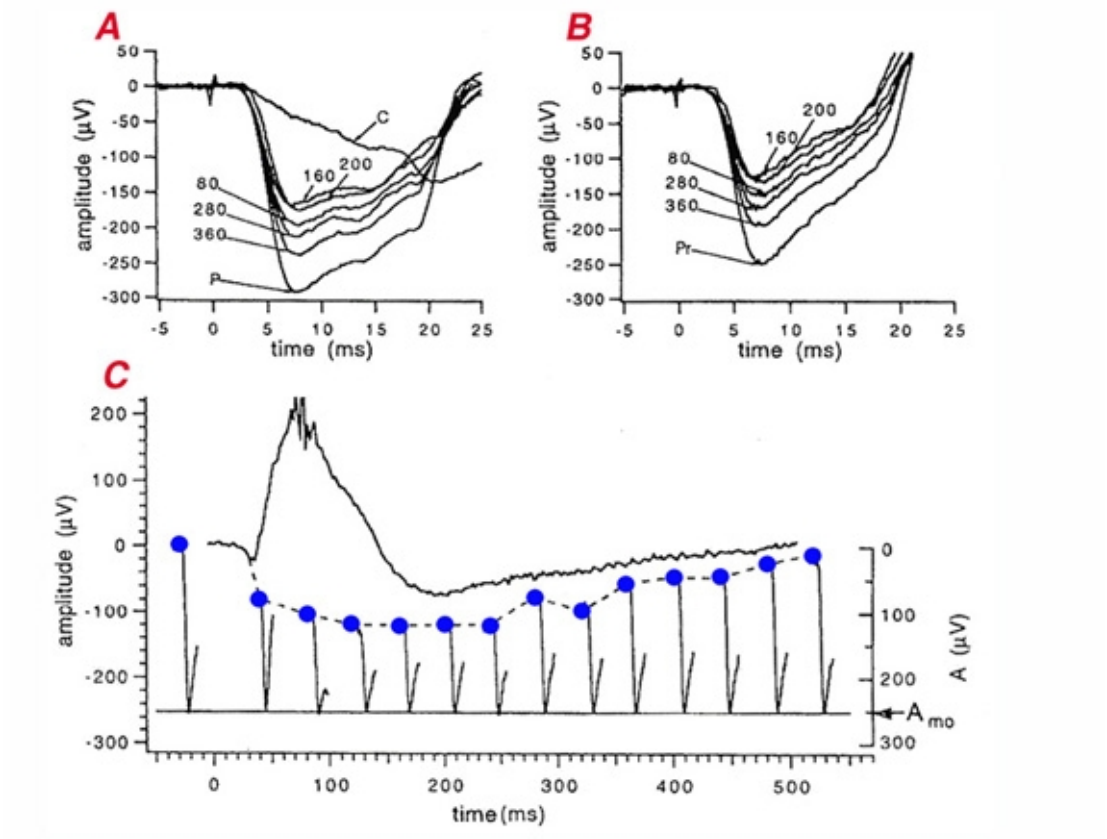

Figure 29. The paired-flash technique to reconstruct the rod response from the ERG response. A test flash of fixed intensity was followed at different time intervals by a probe flash of super-saturating intensity. A, the a-wave part of the ERG responses that were elicited by the probe flash at different time intervals after the test flash. The trace marked P is the effect of the probe flash alone. The trace marked C is a photopically matched long-wavelength probe flash. B, the responses in A were corrected for cone contribution. C, reconstruction of the rod response underlying the ERG response to the test flash (continuous trace). The responses to the different probe flashes were arranged such that they all reached the same low level (Amo), denoting the shutdown of the "dark" current. The trace connecting the baselines of the probe a-waves (dashed trace) is the rod response of the test ERG response (127).

About the Author

Dr. Ido Perlman was born in Haifa, Israel. He received his B.S. from the Technion-Israel, Institute of Technology, Haifa, in Chemistry in 1970 and his Ph.D. in Physiology from the University of Michigan, Ann Arbor, in 1976 under the mentorship of Dr. Matthew Alpern. Dr. Perlman then pursued postdoctoral studies with Dr. Richard Normann at the National Institutes of Health, on aspects of information processing in the turtle retina. He returned to Israel and became a professor of physiology at the Rappaport Faculty of Medicine, Technion-Israel in Haifa, Israel. His research interests have continued to be information processing in the vertebrate retina with a particular interest in horizontal cell physiology. Ido has always run an advanced, scientifically based, clinical ERG service for patients with visual disorders in northern Israel and has made major contributions to the field of clinical ERG work.

Clinical Electrophysiology

Donnell J. Creel

Created: May 1, 2005; Updated: July 2, 2007.

Introduction

Electrophysiological testing of patients with retinal disease began in clinical departments in the late 1940s. Under the influence of the great Swedish pioneers, Holmgren (1) and Granit (2), the electroretinogram was being dissected into component parts, and early intraretinal electrode studies were beginning to tell which cells or cell layers gave rise to the various components. A detailed discussion of the electroretinogram, or ERG as it is commonly abbreviated, is found in the accompanying chapter by Ido Perlman. A little after the introduction of the ERG as a test of the state of the patient's retina, another diagnostic test called the electrooculogram (EOG) was introduced to the clinic (3). The EOG had advantages over the ERG in that electrodes did not touch the surface of the eye. The changes in the standing potential across the eyeball were recorded by skin electrodes during simple eye movements and after exposure to periods of light and dark. Over the years, ERG recording techniques have become progressively more sophisticated, even in the clinical setting. With the advent of perimetry and pattern ERG techniques, more precise mapping of lesioned areas of the retina is now possible. The most recent advance in ERG technology is the multifocal pattern ERG, analysed and mapped by computer averaging techniques. It allows a detailed assessment of the state of the macular area.

Where the previous chapter (The Electroretinogram: ERG) presents the basic science behind the waveforms and components of the massed ERG response, in this chapter the intention is to show purely the clinical use of the various electrophysiological tests. The chapter is based on experience in the ERG clinic of the Moran Eye Center.

The Electroretinogram (ERG)

The global or full-field electroretinogram (ERG) is a mass electrical response of the retina to photic stimulation. The ERG is a test used worldwide to assess the status of the retina in eye diseases in human patients and in laboratory animals used as models of retinal disease.

The basic method of recording the electrical response, known as the global or full-field ERG, is by stimulating the eye with a bright light source, such as a flash produced by a strobe lamp. The intense flash of light elicits a biphasic waveform recordable at the cornea similar to that illustrated in Fig. 1. The two components that are most often measured are the a- and b-waves. The a-wave is the first large negative component, followed by the b-wave, which is corneal positive and usually larger in amplitude.

Two principal measures of the ERG waveform are taken: 1) the amplitude (a) from the baseline to the negative trough of the a-wave, and the amplitude of the b-wave measured from the trough of the a-wave to the following peak of the b-wave; and 2) the time (t) from flash onset to the trough of the a-wave and the time (t) from flash onset to the peak of the b-wave (Fig. 2). These times, reflecting peak latency, are referred to as "implicit times" in the jargon of electroretinography.

The a-wave, sometimes called the "late receptor potential," reflects the general physiological health of the photoreceptors in the outer retina. In contrast, the b-wave reflects the health of the inner layers of the retina, including the ON bipolar cells and the Muller cells (4). Two other waveforms that are sometimes recorded in the clinic (see the previous chapter) are the c-wave originating in the pigment epithelium (5) and the d-wave indicating activity of the OFF bipolar cells (Fig. 3a). Later, we shall discuss some wavelets that occur on the rising phase of the b-wave known as oscillitatory potentials (OPs). OPs are thought to reflect activity in amacrine cells.

The ERG of a normal full-term infant looks similar to a mature ERG. The ERG attains peak amplitude in adolescence and slowly declines in amplitude throughout life (6). After age 55-60 years, the amplitude of the ERG declines even more. Implicit times slow gradually from adolescence through old age as well. Below are two figures illustrating how the b-wave attenuates in amplitude with age and slows in its implicit time (Fig. 3a and Fig. 3b). There is considerable variation among individuals, but the linear regression line in each figure indicates the trend of aging affects on the ERG.

ERG Recording Electrodes

The ERG can be recorded several ways. The pupil is usually dilated. There are a number of corneal ERG electrodes that are in common use. Some are speculum structures (Fig. 4) that hold the eye open and have a contact lens with a wire ring that "floats" on the cornea supported by a small spring (7). Some versions use carbon, wire, or gold foil to record electrical activity. There are also cotton-wick electrodes (Fig. 4) (8).

There are yet other simpler ERG recording devices (Fig. 5) using gold Mylar tape that can be inserted between the lower lid and sclera/cornea. Most electrodes are monopolar, i.e., are referred to another electrode site most commonly on the forehead. Some are bipolar with the reference electrodes built into a metal surface on a speculum.

Each of these electrodes records large voltage responses directly from the cornea, and each has advantages and disadvantages. We use Burian speculum electrodes when possible. Sizes are available down to a size that fits in the eye of most full-term babies. When the eye is too small for speculum recording electrodes, we use the ERG Jet type most of the time. When the eye is very small, such as in some microphthalmic eyes or cases of trauma to tissue surrounding the eye, we use a carbon-wick or gold Mylar tape.

The ERG can also be recorded using skin electrodes placed just above and below the eye, or below the eye and next to the lateral canthus. Because skin electrodes are not in direct contact with the cornea, there is significant attenuation in amplitude of the ERG, so a number of individual responses to flash stimulation must be averaged by computer. Pictured in Fig. 6 is a comparison of bright white flash ERGs recorded from the same person using three types of recording devices and an averaged ERG from skin electrodes.

If electrodes are to be reused, they must be sterilized with a solution that neutralizes prion-transmitted diseases such as Creutzfeldt-Jakob disease (CJD). We use household bleach, e.g., Chlorox (active ingredient, sodium hypochlorite), diluted to a 10% solution with distilled water. The electrodes need only be submerged in this solution for 1 minute. Do not leave electrodes in this solution more than a few minutes.

Light Stimulation for ERGs

There are also several methods of stimulating the eye. Some laboratories use a strobe lamp that is mobile and can be easily placed in front of a person whether sitting or reclining (Fig. 7). The mobility of a strobe lamp or an array of LEDs is a necessity in some situations, such as at the hospital bedside or in the operating room.

For patients over 5 years of age, most laboratories use a Ganzfeld (globe) with a chin rest and fixation points (Fig. 8). The Ganzfeld allows the best control of background illumination and stimulus flash intensity. Either strobe lamp or Ganzfeld methods of flash presentation can be used to record the ERG after a single flash or to average responses to several flashes with the aid of a computer. Clinical decisions can be made from ERGs generated by either methodology.

Testing Infants for ERGs

Infants up to about 2 years of age can usually be tested without sedation by the parent holding them bundled in a blanket. It is difficult to get a child less than 5 years of age to allow a contact lens or speculum recording

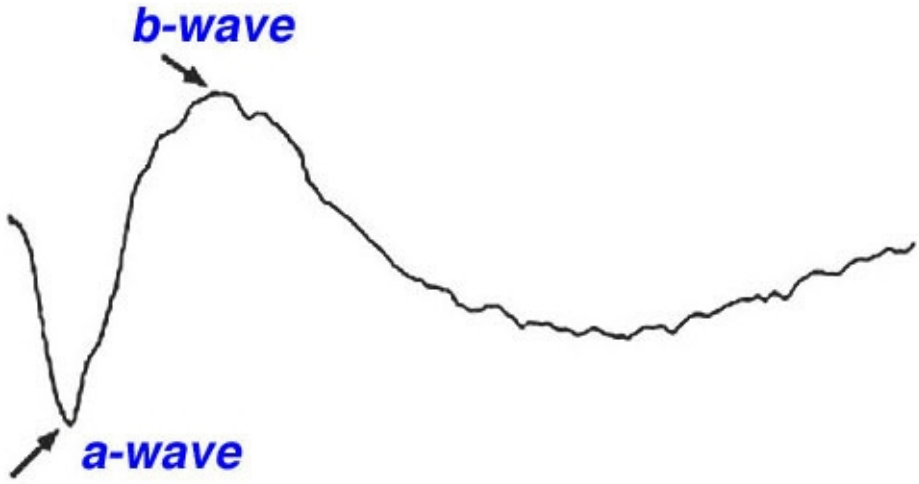

Figure 1. The biphasic waveform of the typical normal patient.

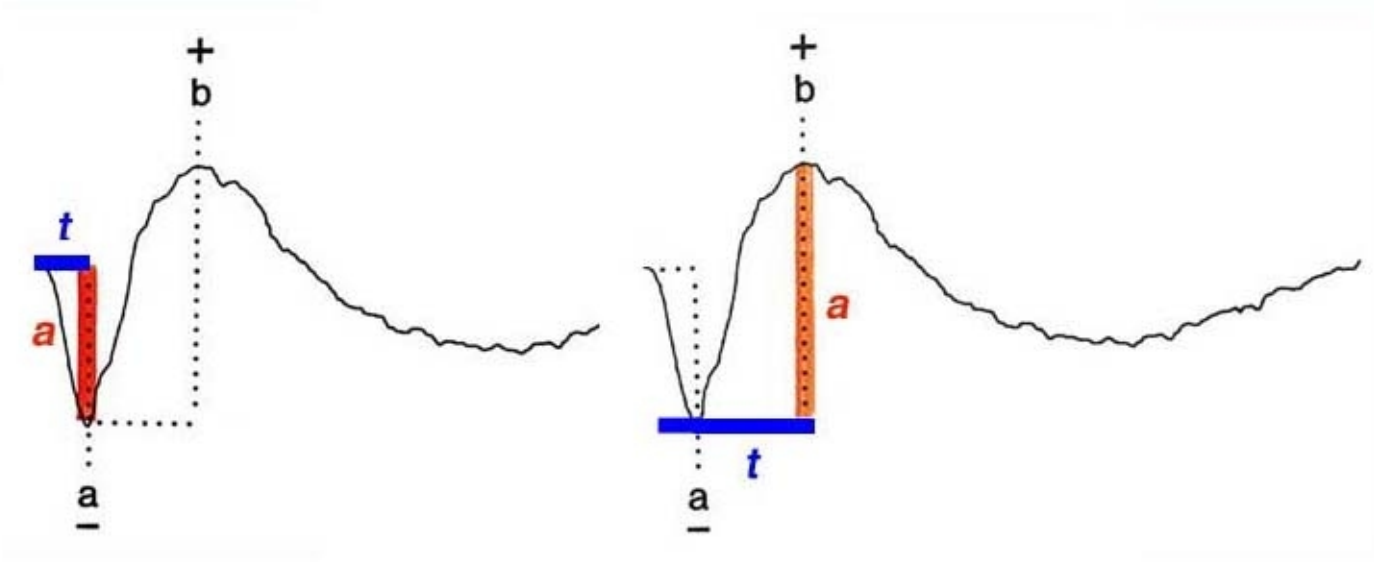

Figure 2. Amplitude and implicit time measurements of the ERG waveform.

electrode in the eye, so skin or scleral electrodes can be used, with their limitations. Alternatively, the child is sedated or anesthetized. Many clinics use chloral hydrate or the 3-in-1 "cardiac cocktail" to sedate pediatric patients. Chloral hydrate has several limitations, including that dose restrictions limit the use to patients weighing less than about 15 kg.

Both of these sedatives have little effect on the ERG. ERG testing is also sometimes performed as part of a more extensive exam under anesthesia (EUA). Few laboratories have Ganzfeld stimulators that can be tilted and placed over the face of a sedated patient, and it is difficult to use such equipment in the operating room. Thus, flash stimuli with sedated patients are usually delivered with a strobe lamp (Fig. 7). In an ERG laboratory, the sedated patient can be dark adapted, and a more or less normal series of stimuli can be used, although the length

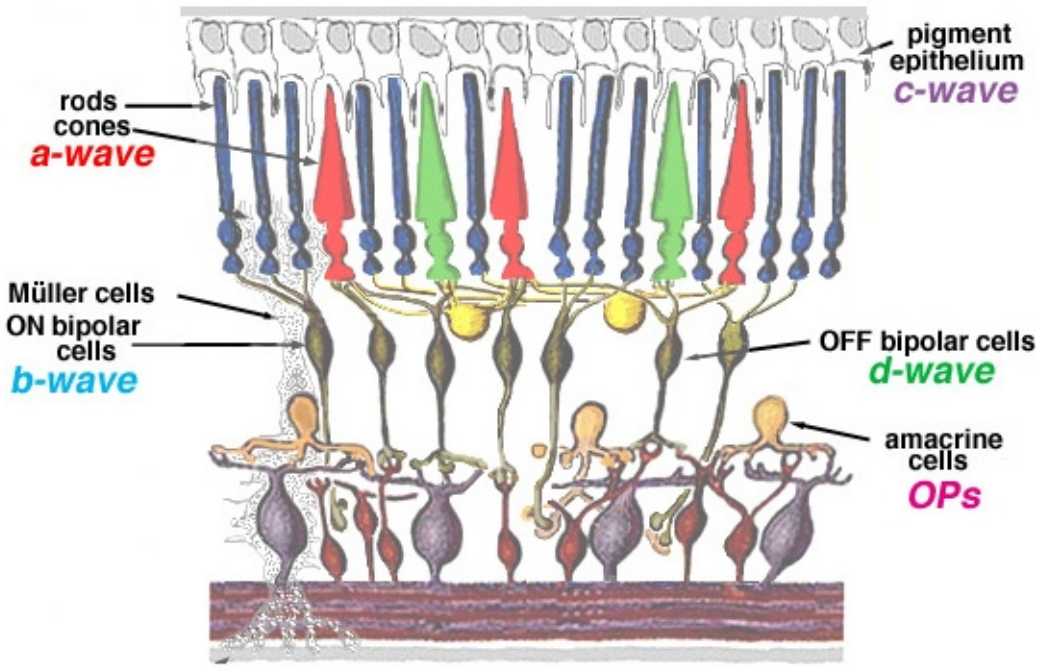

Figure 3a. Schematic of the retina to show where the major components of the ERG originate.

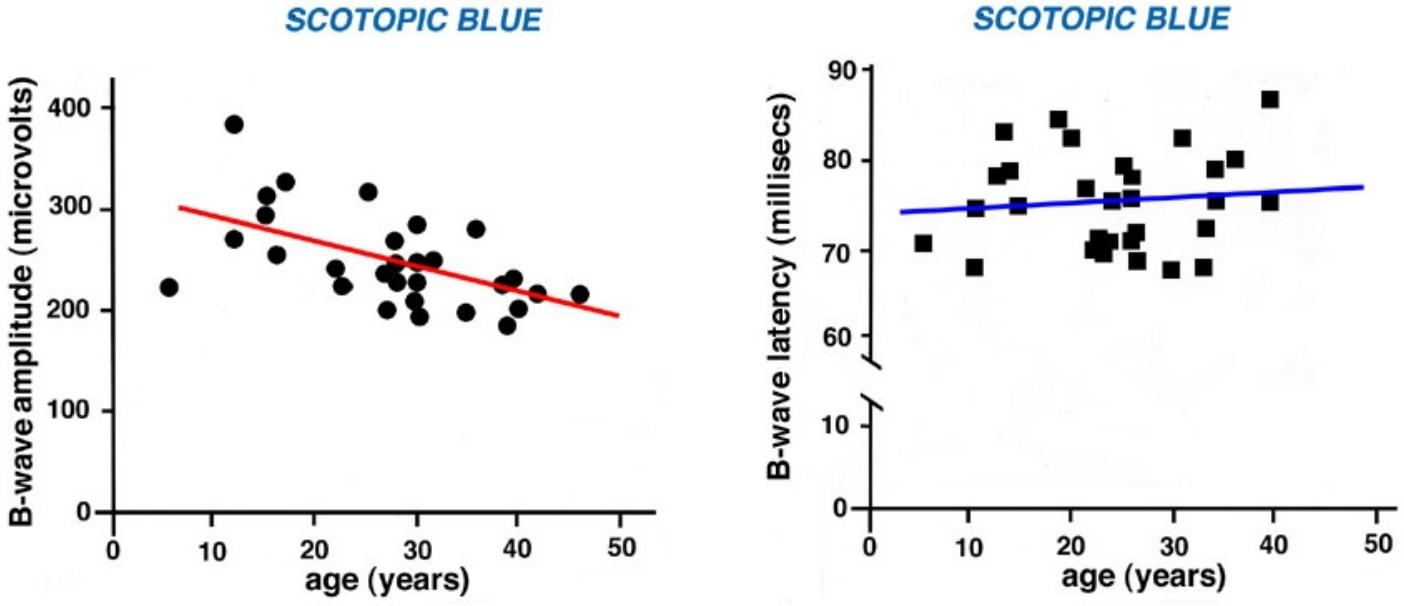

Figure 3b. Scatter plot of b-wave amplitudes and latencies with age with regression lines to show the aging effects.

of effect of the sedative usually necessitates that the method be abbreviated to just three or four stimuli. Dark adaptation, even for a few minutes, followed by single flashes of white or blue will assess scotopic ERG function. Photopic single flashes and 30 Hz flicker can be used to evaluate cone function.

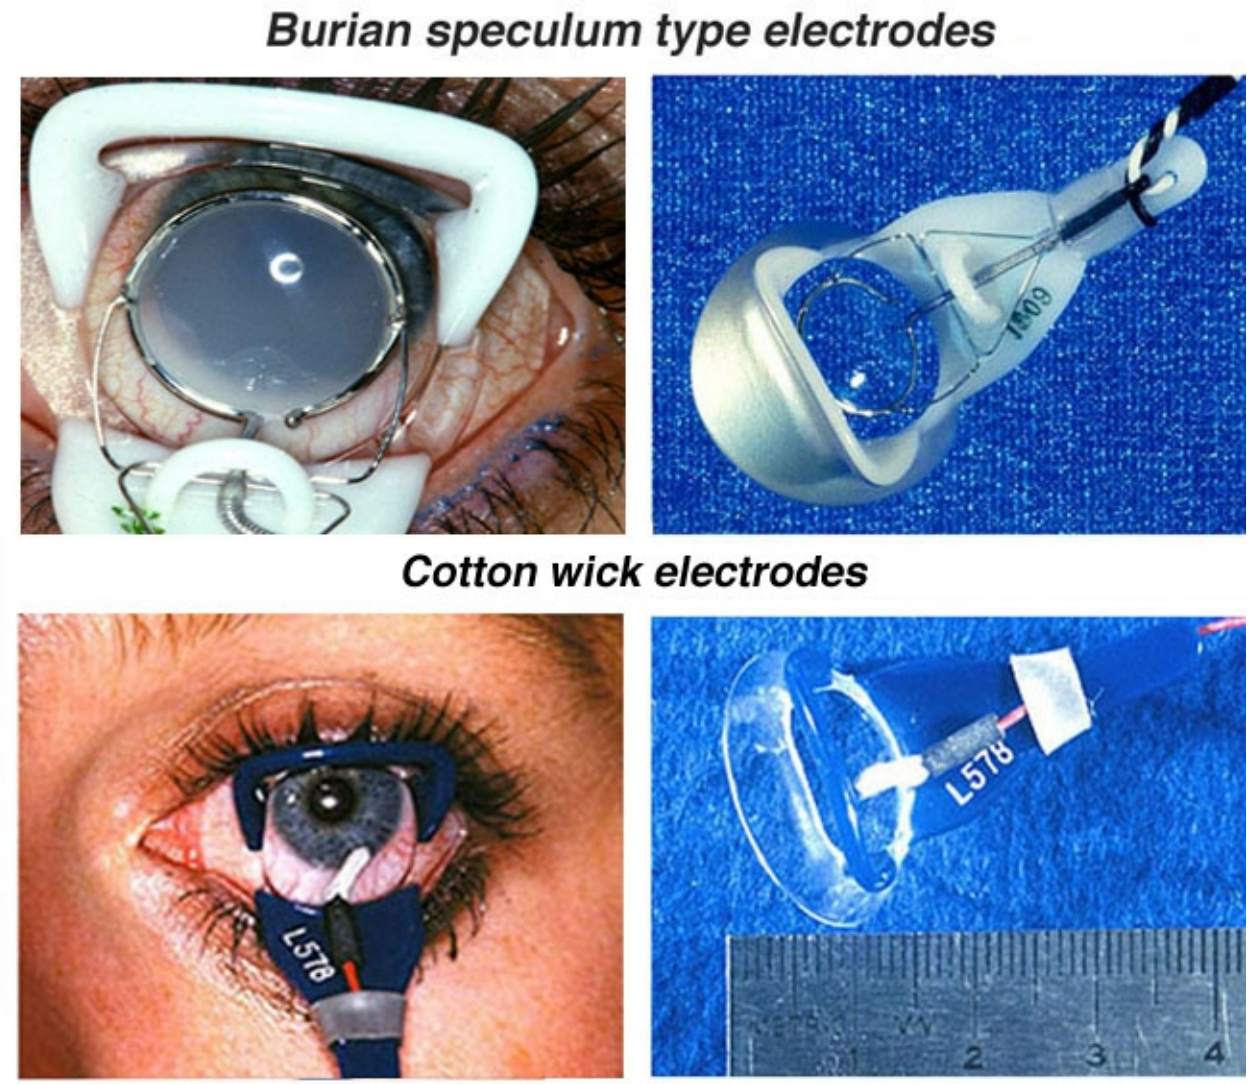

Figure 4. Speculum or Burian-type electrodes used to record the human ERG.

It is usually not possible to completely darken the operating room, so abbreviated testing is accomplished under mesopic and photopic light conditions. Anesthesia affects the ERG, varying with type and depth of anesthesia. Some anesthetics can attenuate b-wave amplitude as much as 50%. Light levels of anesthesia have little affect, and most anesthetics do not usually affect a-waves or implicit times.

Separating Rod and Cone ERGs

Most disorders of the retina are detected by an attenuation of amplitude. Implicit times, of both a- and b-waves, are also affected in some conditions. Implicit times and amplitudes vary, depending upon whether the eye is dark adapted, and brightness and color of the light stimulus. These parameters allow separation of rod and cone activity in any duplex retina.

Rods and cones differ in number, peak color sensitivity, threshold, and recovery. There are about 120 million rods in each retina, and about 6-7 million cones (see the Facts and Figures chapter). Because of sheer numbers, the ERG following a white flash is dominated by the mass response of the rods. By manipulating adaptation level and background illumination, flash intensity, color of the flash, and rate of stimulation, rod and cone activity can be significantly isolated.

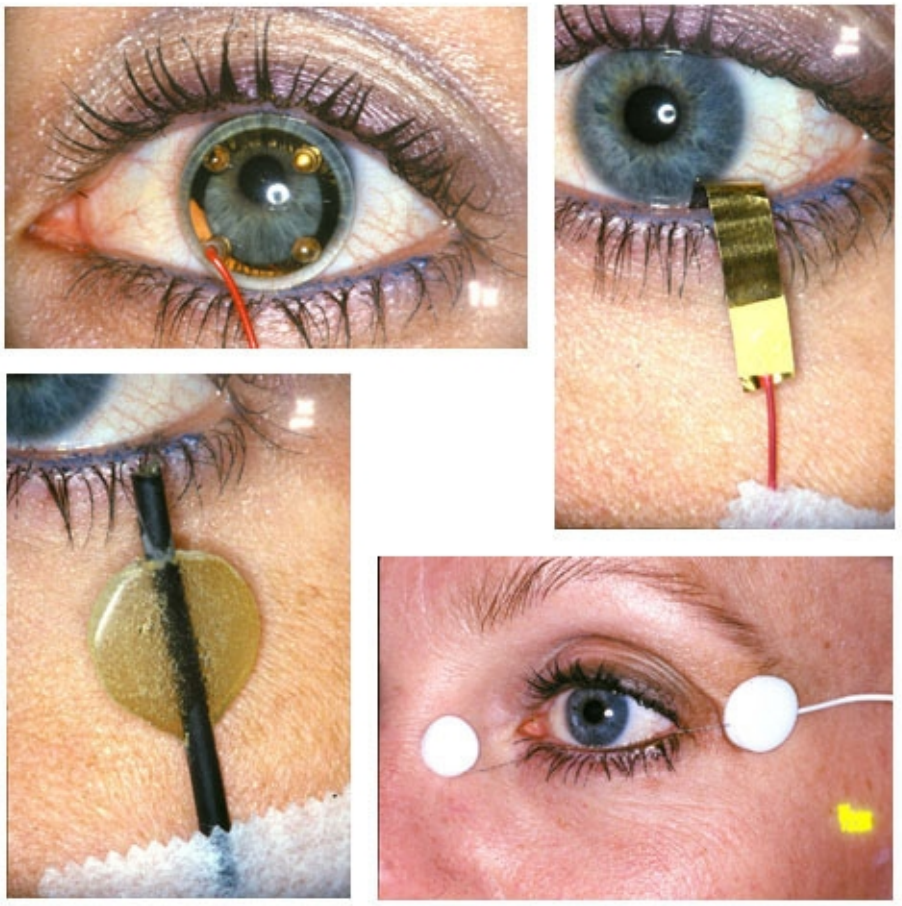

Figure 5. Other simple types of electrodes used to record the human ERG.

Using Color Stimuli

Peak wavelength sensitivity for rods is around 510 nm, and the peak sensitivity of cones as a group is about 560 nm (tennis ball yellow). By using color filters such as the Kodak Blue and Red Wratten series shown in Fig. 9a, you can essentially isolate rod and cone ERGs using dim flash stimuli into photopic (cone) and scotopic (rod) signals as illustrated in Fig. 9b. Dim red analyses both rod and cone function by identifying b_x and b-wave. Rods are about three log units more sensitive than cones. However, cones recover faster than rods.

Using different rates (flicker) of stimulus presentation also allows rod and cone contributions to the ERG to be separated. Even under ideal conditions, rods cannot follow a flickering light up to 20 per second, whereas cones can easily follow a 30-Hz flicker, which is the rate routinely used to test if a retina has good cone physiology (Fig. 9c).

ERG Recording Methods

There are many ways of recording ERGs from patients (9, 10). I recommend reviewing ISCEV standards before recording ERGs (11). Most procedures give similar results but vary mainly in sequence. Some laboratories record the light-adapted state first, and others dark-adapt first. Some laboratories use only white flashes, and others included colored flashes. Many laboratories use a scotopic intensity series as well. Supplemental analysis, such as Perlman's (12) relationship between the ratio of a- and b-wave amplitudes, can be extracted from this intensity series. If only bright white flash stimuli are used, subtle abnormalities will be missed.

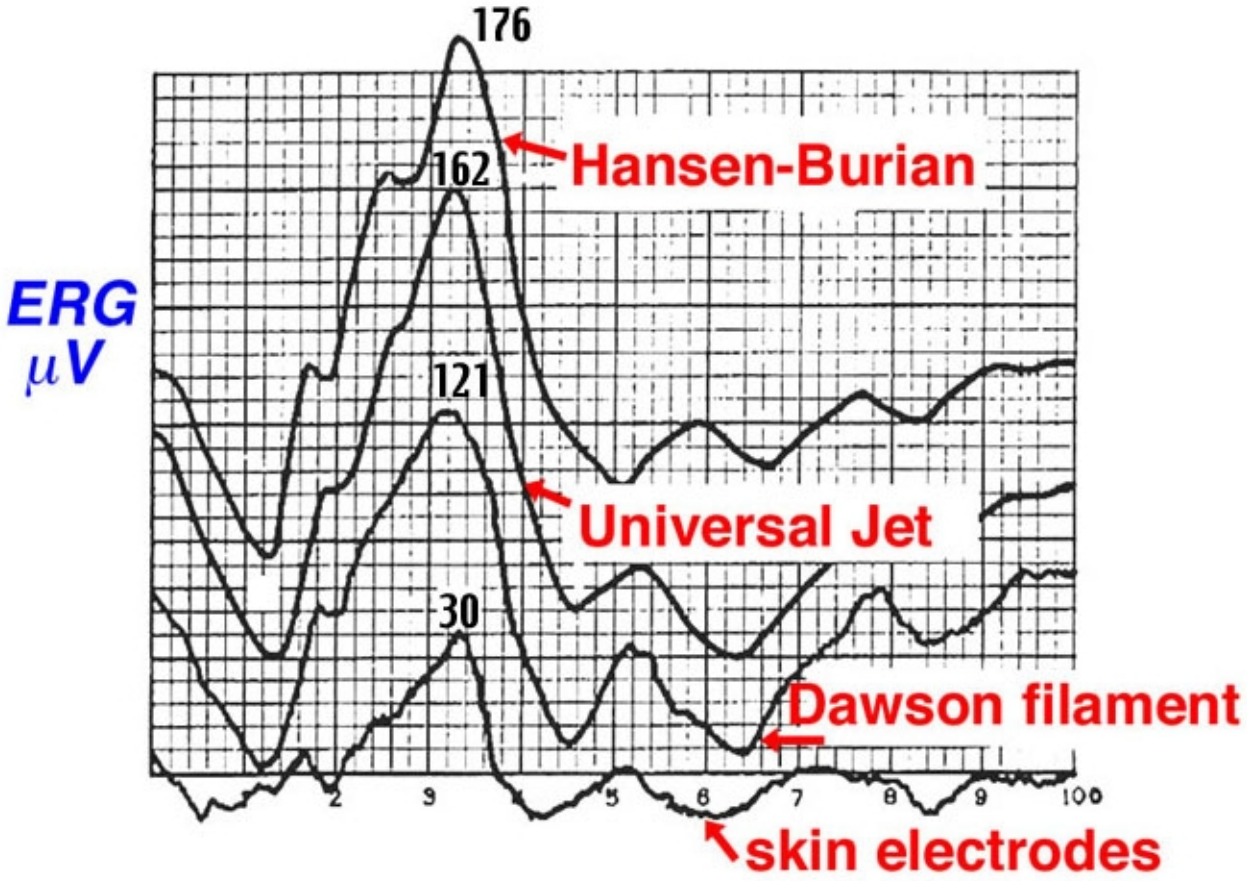

Figure 6. Typical ERGs as recorded with different electrodes.

The method we use in our clinic is:

1. Dark adapt patient for a set time of 30 minutes.
2. Attach electrodes using dim red illumination. We use an indirect headlamp with several Wratten 26 red filters so that a mobile dark room "safe" light is simulated.
3. Record ERG using single, scotopically balanced, dim blue and red flashes and bright white flashes, as illustrated in the sample ERGs of Fig. 9b. Some laboratories average several responses.
4. Turn on moderately high background illumination of about 10 ftL for about 10 minutes and record ERGs using 30-Hz flicker and bright white flashes (Fig. 9c). Responses recorded using moderately high background illumination accentuate the cone system by bleaching the rods, and only cones can recover fast enough between flashes to accurately follow a flickering 30-Hz light.

Recording Scotopic ERGs

Thirty minutes or more in the dark produces a state of 98% or more dark adaptation in most individuals. The use of two or more log unit filters to reduce flash intensity and dim blue filters limits the ERG to reflecting rods only. "Scotopically balanced" blue and red filters (Fig. 9b) mean that deep blue and red filters with transmission spectra that do not overlap are matched through trial and error addition of neutral density filters until the ERGs produce b-wave amplitudes of the same size. The purpose of this is to establish a standard so that differences between rod and cone physiology can be more easily detected. We do this routinely for all patients tested in our clinic. The scotopic dim blue ERG is the most sensitive, not only to rod disorders but also to systemic metabolic aberrations and retinal toxicity.

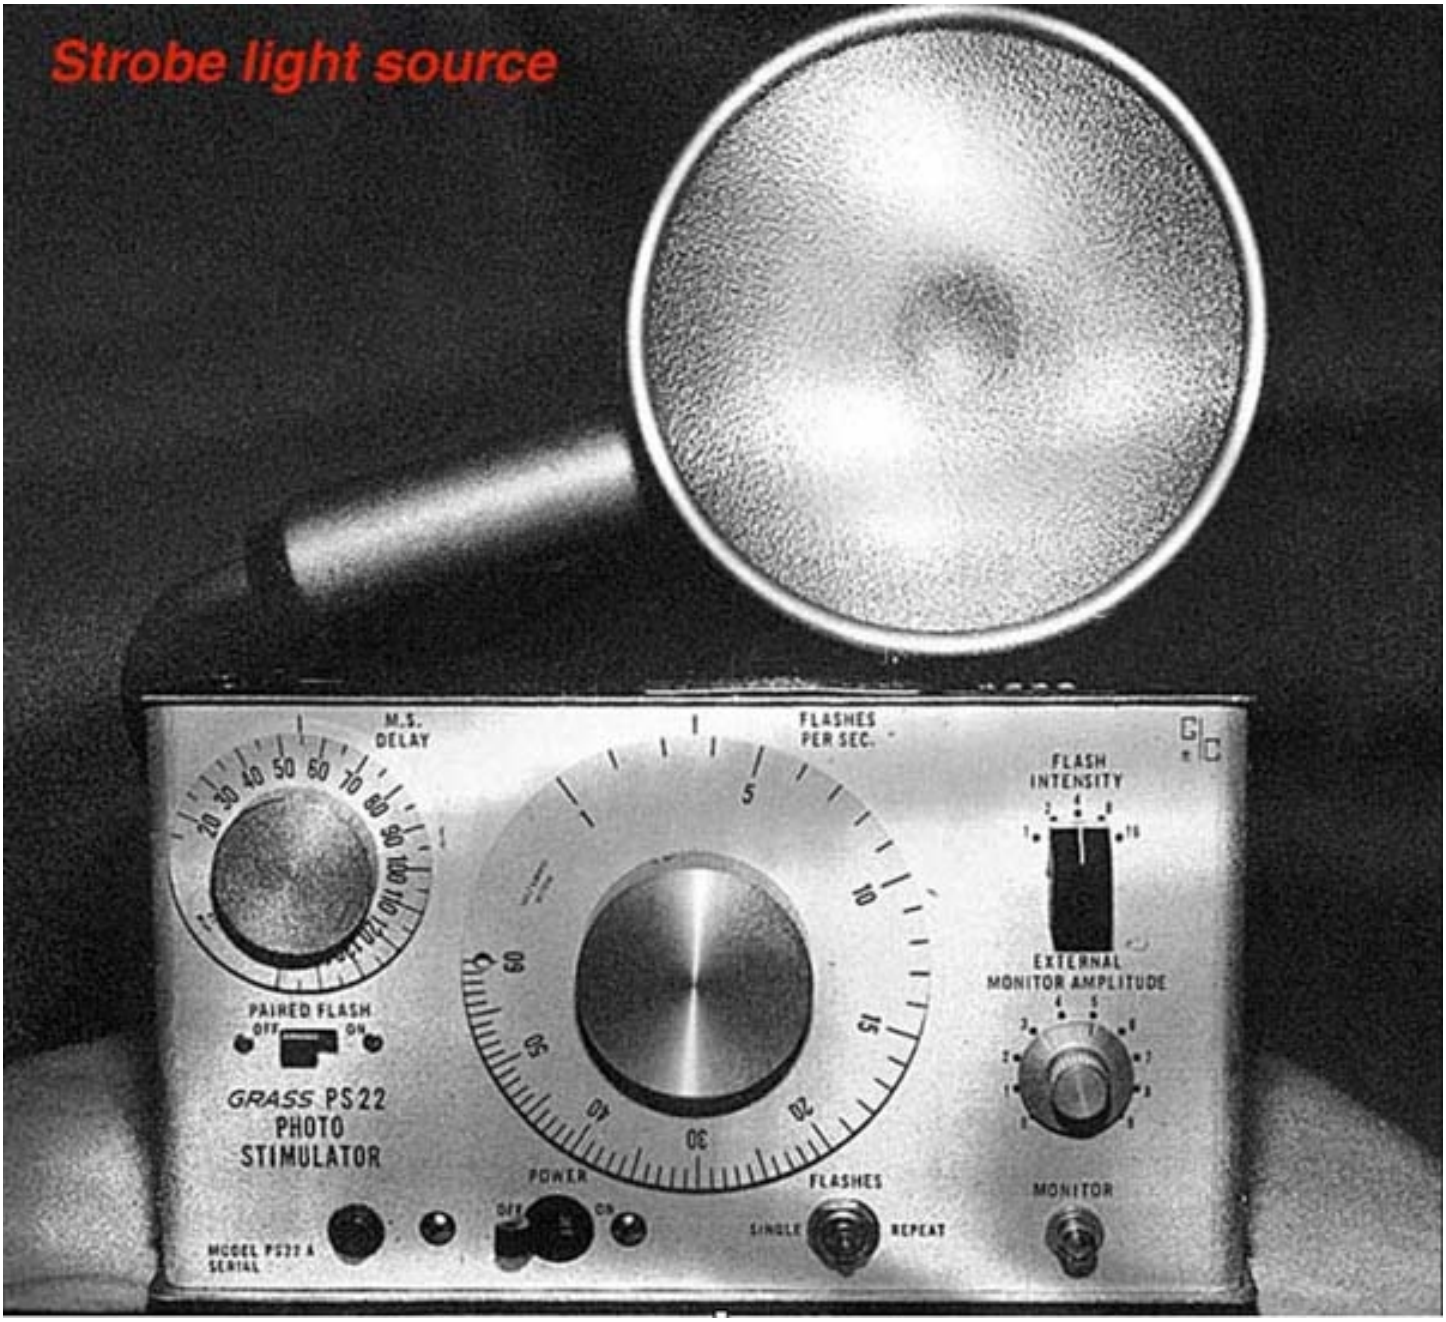

Figure 7. Portable strobe light source.

Oscillatory Potentials (OPs)

Some laboratories also include recording oscillatory potentials (OPs). OPs seen on the ascending limb of most b-waves, in both scotopic and photopic bright flash ERG recordings, were first described by Cobb and Morton (13). By raising the low bandpass from the usual <1 Hz up to around 100 Hz, the slower a- and b-wave components are filtered out, leaving a burst of cone OPs following a bright white flash between about 15 and 40 msec (Fig. 10). Scotopic rod OPs produced by dim blue flash appear later between about 25 and 55 msec. OPs are thought to reflect activity initiated by amacrine cells in the inner retina (14).

This brings up an interesting clinical anecdote that also indicates the vulnerability of the ERGs to changes in retinal chemistry. For over 50 years, the irrigating solution of choice when removing enlarged prostate glands

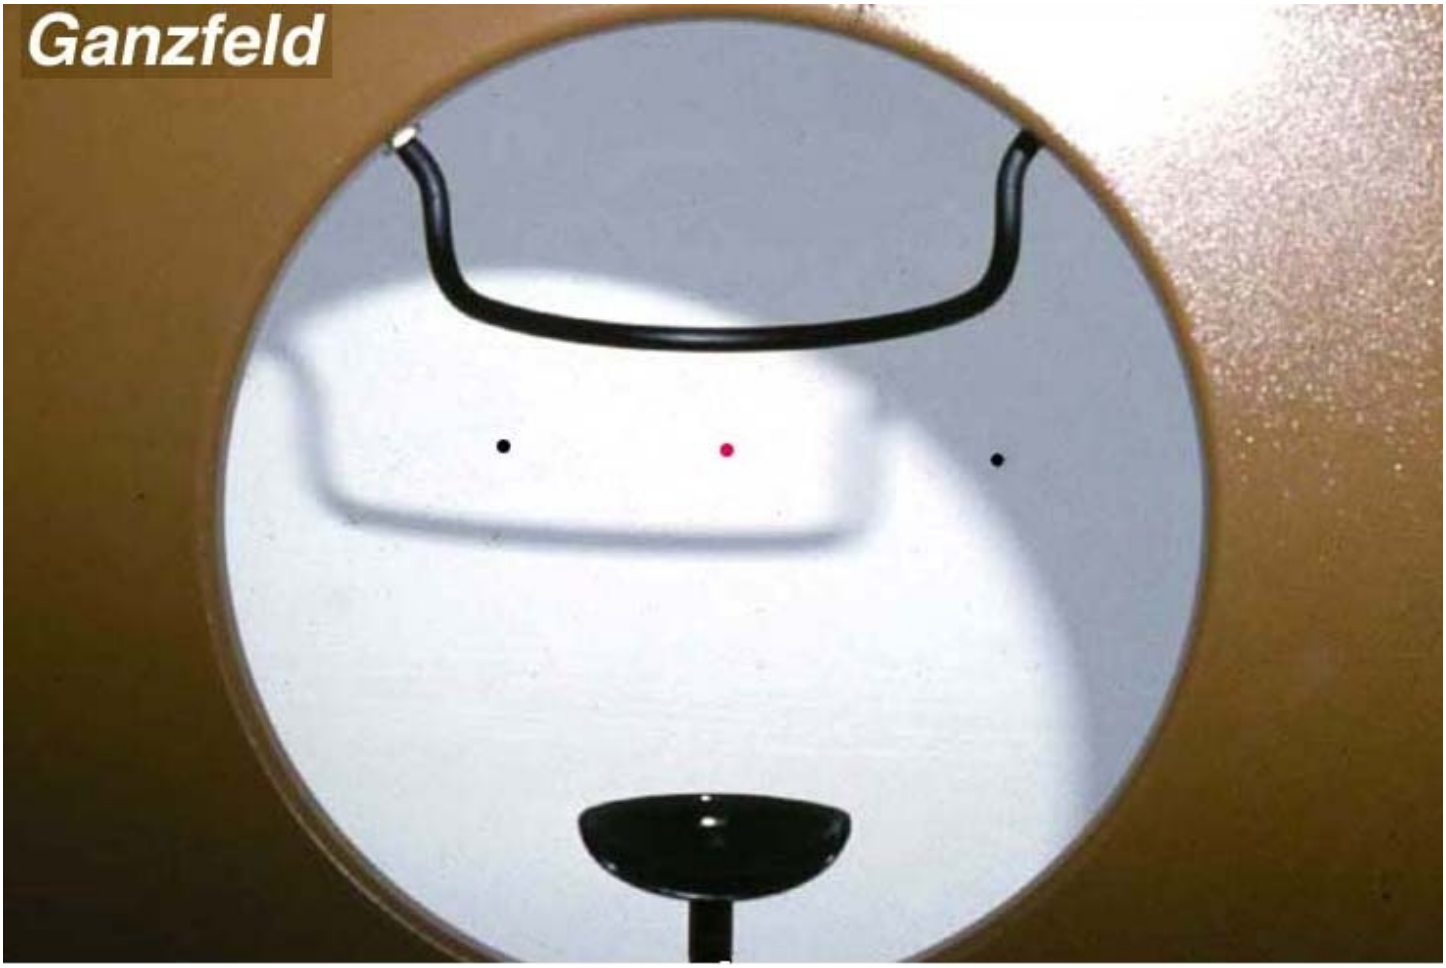

Figure 8. The Ganzfeld stimulation globe.

has been glycine. When the procedure takes a long time or the surgeon cuts deeply into the venous beds surrounding the prostate gland, an awake patient under spinal block anesthesia has said, "Why did you turn the lights off?" This can create considerable consternation among personnel in a brightly illuminated operating room. Glycine is an inhibitory transmitter in the retina, particularly associated with amacrine cells. When the glycine reaches retinal circulation, it short circuits the amacrine cell pathways in the retina and turns off the source of OPs (15). OPs specifically disappear from the ascending limb of the b-wave. OPs and vision return to the patient over several hours as the glycine is metabolized (Fig. 11).

OPs are significantly attenuated in various retinal degenerations, among them are the following:

- Retinitis pigmentosa
- Central serous retinopathy
- CSNB type 2
- Birdshot choroidopathy
- Retinoschisis
- Carriers of X-linked CSNB
- Diabetic retinopathy
- Hypertensive retinopathy
- CRVO and CRAO
- Takayasu's (pulseless) disease

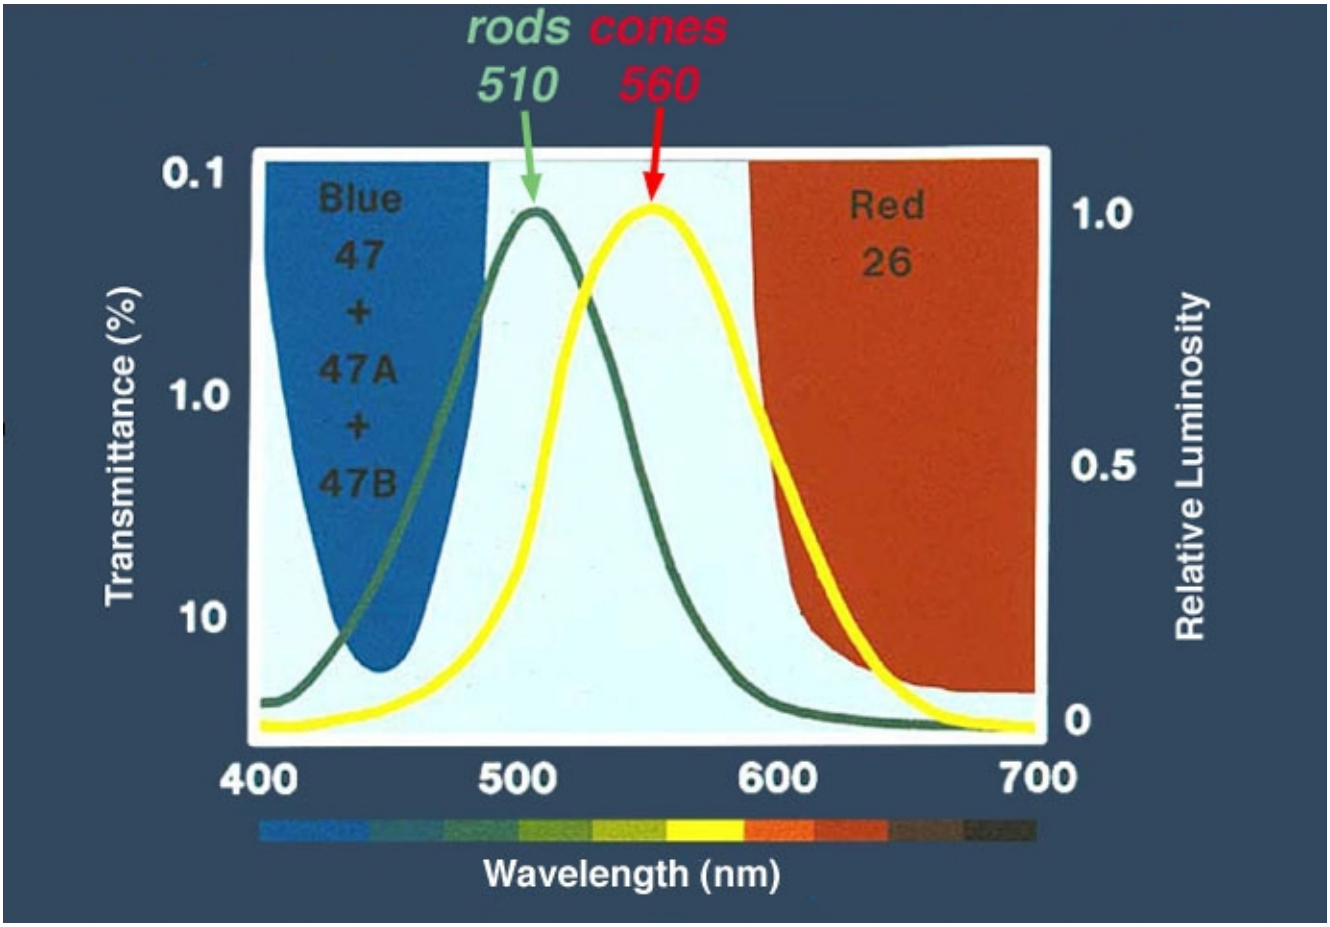

Figure 9a. Filter conditions used to isolate rod and cone components of the ERG using dim scotopic flashes.

ERGs in Retinitis pigmentosa-like Diseases

In all forms of retinal pathology, there is considerable variability. There are no absolute rules. Genetic variation in penetrance and expression, in combination with individual differences, affects retinal electrophysiology.

ERGs recorded from a representative normal subject (Fig. 12a) and from a patient with retinitis pigmentosa (RP) (Fig. 12b) using the above methodology are illustrated in Fig. 13. The scotopic blue and red ERG traces are 200 msec, and the other traces are 100 msec. The vertical calibration is 100 microvolts. The low bandpass limit was 0.1 Hz, and the upper bandpass limit was 1 KHz. When dim stimuli are used, such as an intensity series starting with low intensity white or dim scotopic red and blue flashes, it is important that the low bandpass be less than 1 Hz. The slow b-wave initiated by dim stimuli will be attenuated if a low bandpass is not used.

The first two responses are scotopically matched blue and red ERGs. The blue flash was dim enough that no a-wave can be discerned in a normal patient, leaving only the rod-dominated slower b-wave. The red flash is bright enough that oscillations can be observed just after the a-wave. Bright white flash in the dark produces the largest amplitude ERG. The 30-Hz flicker illustrates the response of the rapidly recovering cones, and the photopic response is representative of a normal response, with the more sensitive rods bleached by background illumination. Oscillatory potentials on the ascending b-wave are seen in responses to moderately high intensity white flashes and in response to red, yellow, and green flashes (Fig. 13).

This particular case of RP was selected because the individual was tested early in the onset of RP, as a young adult when she still had remnants of a cone ERG. As in most cases of RP, the rods are affected most severely, as

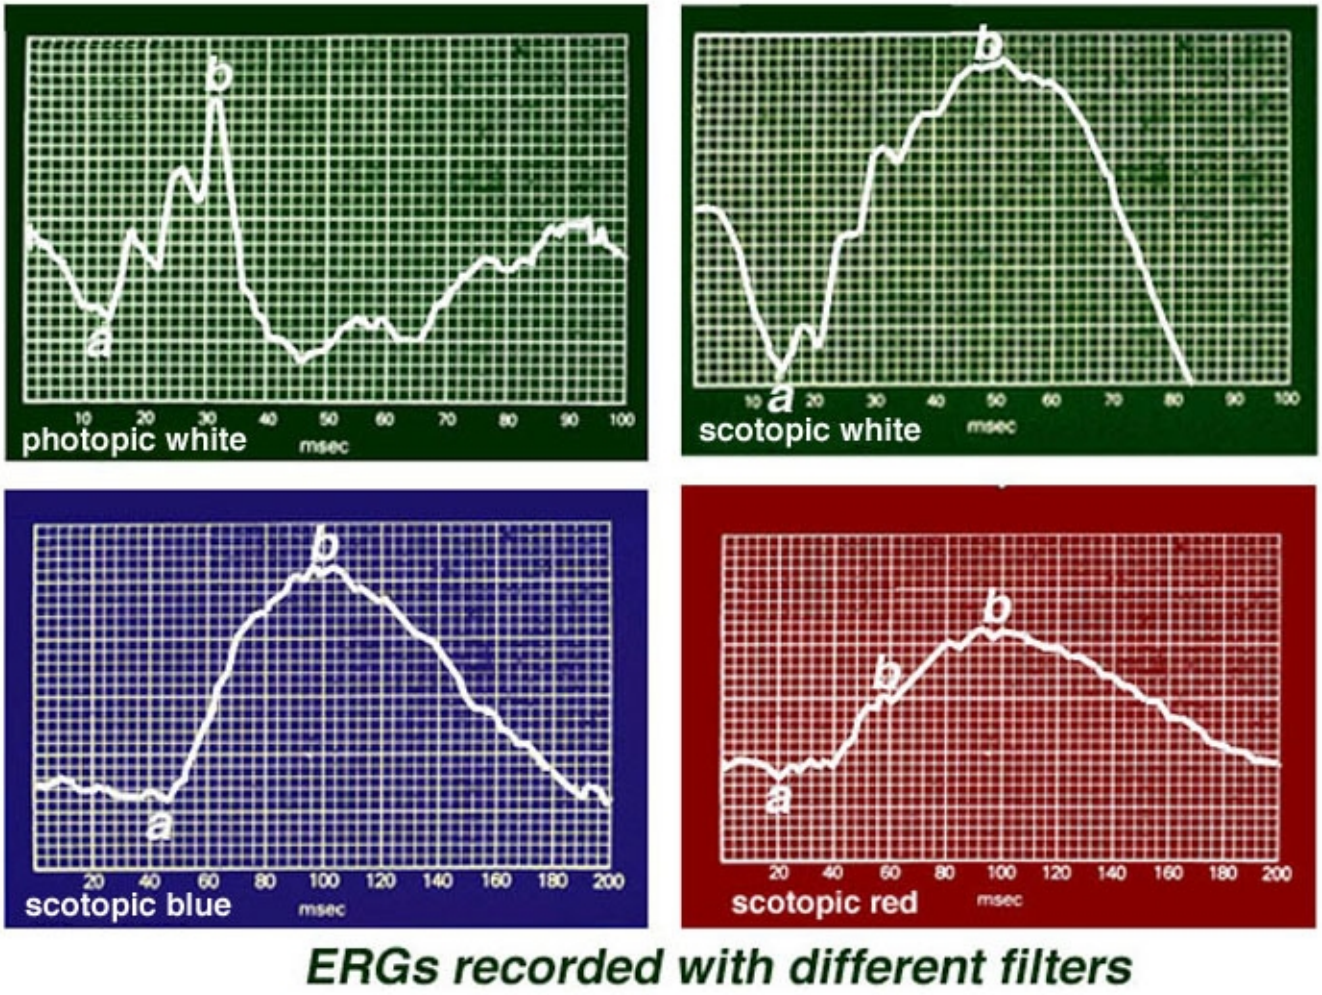

Figure 9b. Typical testing parameters used in our ERG recording set up.

evidenced by the extinguished response to the blue flash. Although it may take some imagination, some of those "squiggles" in the first half of the response to red flashes are remnants of photopic cone physiology. There are also remnants of cone physiology in the responses to bright white flash in the dark, 30-Hz flicker, and photopic white flash. In many individuals with RP, the electrophysiological progression is more severe with all ERGs extinguished, similar in appearance to the response to scotopic dim blue flash. Both scotopic and photopic b-wave peak implicit times are usually prolonged. Almost always, it is impossible to record OPs.

Early in the clinical onset of RP, with the exception of severe expressions such as Leber's congenital amaurosis or X-linked RP (Fig. 14), there are recordable ERGs, at least to bright photopic stimuli. Some individuals with dominantly inherited RP maintain recordable ERGs throughout most of their lives. I have tested over 100 members of one extended family with dominantly inherited RP. Some of the affected members showed no ERG changes until their mid-teens. Expression of RP in all forms of inheritance varies considerably, even between siblings. Female carriers of the X-linked form can show fundus changes and somewhat abnormal ERGs.

Atypical cases of RP are common. There are occasional cases of RP without the usual pigment changes in the fundus (retinitis pigmentosa sine pigmento). Often these cases represent early stages of the disease. Sector RP usually results in a subnormal ERG proportional to the area of retina involved. Paravenous RP (Fig. 15) is associated with a poor ERG most of the time, but again, similar to sector RP, the ERG may be attenuated proportional to the extent of retinal involvement.

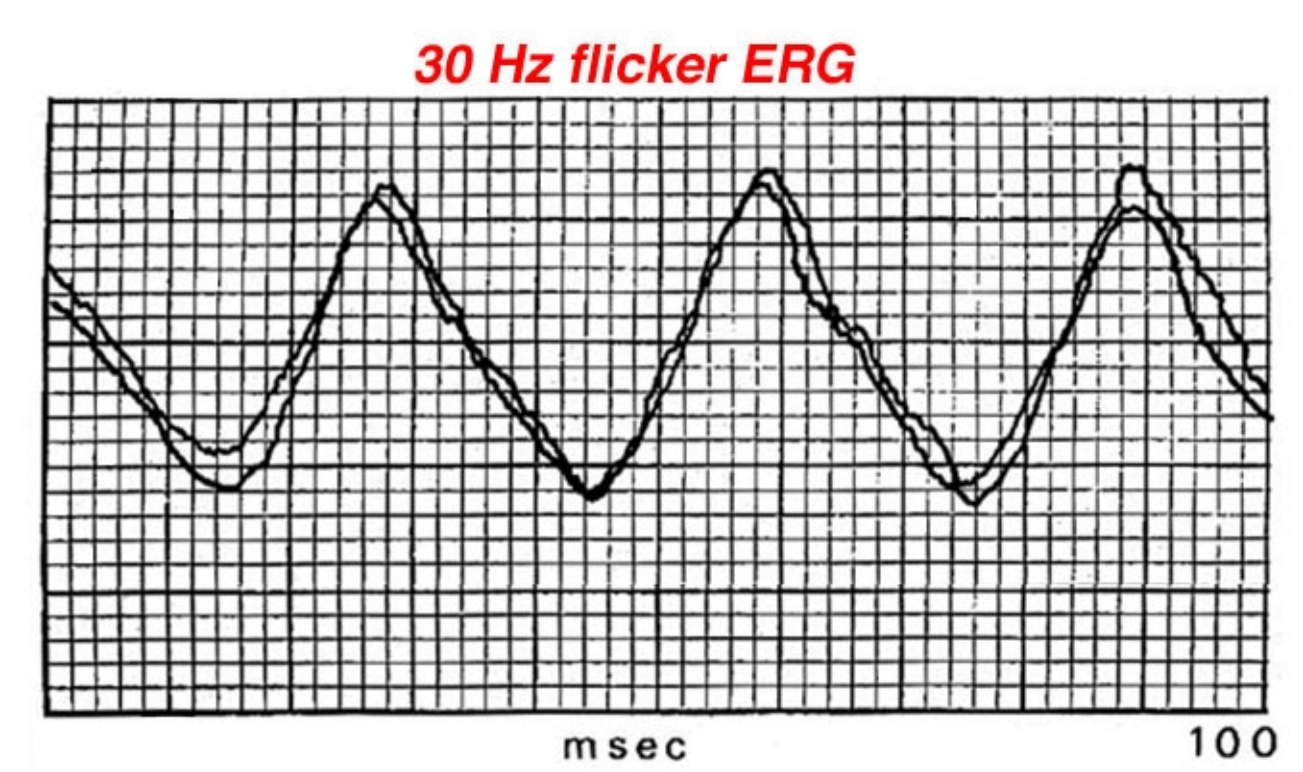

Figure 9c. Typical 30-Hz flicker ERG recorded in our clinic.

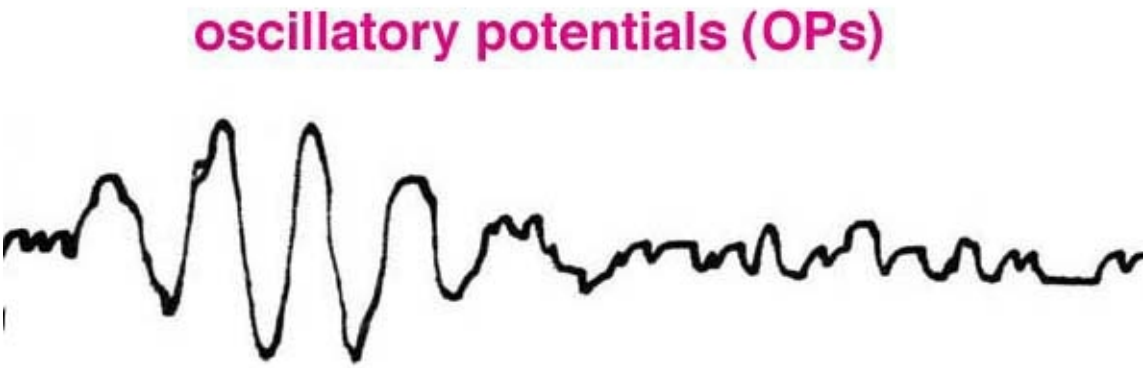

Figure 10. Oscillatory potentials.

RP is seen as a component of a number of syndromes with variability in expression. A common syndrome is Usher's. Usher's syndrome is congenital deafness plus RP. Usher's syndrome may comprise over 20% of RP cases not associated with other syndromes (16).

Myotonic dystrophy (MD) can show ocular changes similar to RP (Fig. 16). Even without fundus changes, the ERG in MD patients is usually moderately affected like that seen in early dominantly inherited RP (17). It is interesting to note that minimally affected individuals without neurological symptoms usually have significant attenuation of their dim flash scotopic ERG b-wave amplitudes. Thus, the ERG can be used to identify the minimally affected parent with MD (Fig. 16, the mother) in cases where neither parent of a child with MD exhibits neurological symptoms.

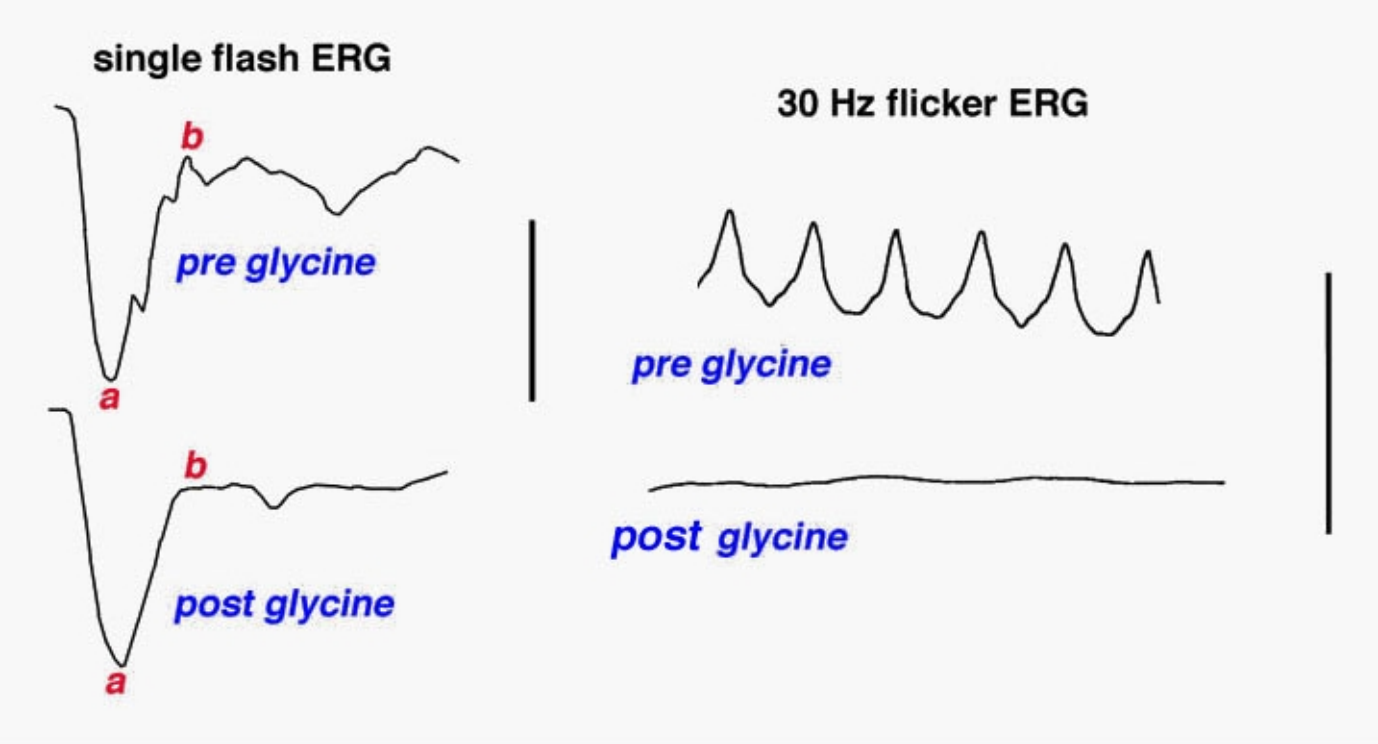

Figure 11. Patient with glycine overload.

There are a number of central nervous system syndromes with RP-like ocular involvement. Prominent among these are the mucopolysaccharidoses, such as the Hurler, Scheie, and Hunter syndromes, which often have abnormal ERGs early in the disease. Another group is the neuronal ceroid lipofuscinoses, such as Batten's disease, which have abnormal ERGs, usually attenuated b-waves.

There are syndromes that may include RP. The following list summarizes many of these syndromes:

- Alagille syndrome: ERG normal or subnormal
- Albers-Schonberg syndrome (osteopetrosis): ERG often abnormal
- Alport's syndrome: ERG normal or subnormal
- Alstrom's syndrome: ERG abnormal
- Ataxia with isolated vitamin E deficiency (AVED) and RP: ERG abnormal
- Bassen-Kornzweig syndrome (a-beta-lipoproteinemia): ERG abnormal
- Cockayne's syndrome: ERG often abnormal
- Cystinosis: ERG abnormal in older children
- Flynn-Ard syndrome: ERG sometimes abnormal
- Friedreich's ataxia: ERG sometimes abnormal
- Hallervorden-Spatz syndrome: ERG often abnormal
- Infantile phytanic acid storage disease: ERG usually abnormal
- Jeune's syndrome: ERG usually abnormal
- Joubert's syndrome: ERG abnormal
- Kearn's-Sayres syndrome: ERG some abnormal
- Laurence-Moon-Bardet-Biedl syndrome: ERG usually abnormal
- Methylmalonic aciduria with homocystinuria: ERG some abnormal
- Mucopolysaccharidoses (Hurler, Scheie, Hunter): ERG often has b-wave attenuation
- Myotonic dystrophy: ERG abnormal, dim scotopic ERGs

- Neuronal ceroid lipofuscinosis: (Haltia-Sanavouri, Jansky-Bielschowsky, Batten's): ERG often has b-wave attenuation
- Neuropathy ataxia and retinitis pigmentosa (NARP): ERG abnormal
- Refsum's disease: ERG often abnormal
- Saldino-Merzbacher syndrome: ERG usually abnormal
- Senior-Loken syndrome: ERG usually abnormal
- Spinocerebellar atrophy Type 7 (SPA7): ERG abnormal
- Usher's syndrome: ERG abnormal
- Zellweger's syndrome: ERG usually abnormal

In the differential diagnosis of RP, there are a number of disorders in which the ERG can be used to distinguish the correct diagnosis. Pigment in the retina is prominent in many infectious diseases and may not solely be an indication of RP. Syphilis, particularly the congenital form, can mimic the fundus appearance of RP (Fig. 17), but the ERG is usually normal or only slightly subnormal.

Rubella and viral infections, such as mumps, measles, and herpes, can produce pigment changes in the retina (Fig. 18). These ERGs are usually normal.

Stationary Rod Dystrophies

Congenital stationary night blindness (CSNB) is found in several forms. Although rare, CSNB is more often seen in the form with a normal-appearing retina and may be inherited in any fashion. Within this form are two types. Type 1 has an abnormal dim scotopic ERGs, but the bright-flash ERG maintains OPs on the ascending limb of the b-wave. Type 2 (Fig. 19) has a very abnormal, dim scotopic ERG, and the bright-flash scotopic ERG has a large a-wave and no b-wave (Fig. 20). OPs are also missing.

CSNB with retinal lesions is quite rare. Oguchi's disease is CSNB with an unusual golden-to-rust coloration of the fundus that is reversed with long dark adaptation. This is called Mizuo's sign and requires 2-3 hours of dark adaptation. The ERG resembles CSNB type 2 with no b-wave, although cases have been reported that the ERG returns to normal after hours of dark adaptation. Another rare form of night blindness is stationary albipunctate degeneration, also referred to as fundus albipunctata. This disorder includes stationary night blindness with white dots scattered throughout the fundus. The ERG b-wave is attenuated but returns to normal after long dark adaptation. A third form is Kandori's syndrome, characterized by large, irregular, hyperfluorescent flecks in the peripheral and central retina. In nyctalopia, the ERG is similarly affected as in stationary albipunctate degeneration.

Other retinal atrophies

The bright flash ERG b-wave is selectively attenuated in:

- Juvenile retinoschisis
- Coat's disease
- Central retinal vein occlusion and central retinal artery occlusion
- Myotonic dystrophy
- Congenital stationary night blindness type 2
- Oguchi's disease
- Lipopigment storage diseases (Batten's disease)

Choroideremia represents an X-linked, diffuse atrophy of the choroid and pigment epithelium. In its mature form, the fundus appearance is white to yellow-white with some small islands of choroid (Fig. 21). Carriers are asymptomatic except for more subtle peripheral fundus abnormalities (Fig. 22). ERGs are usually abnormal.

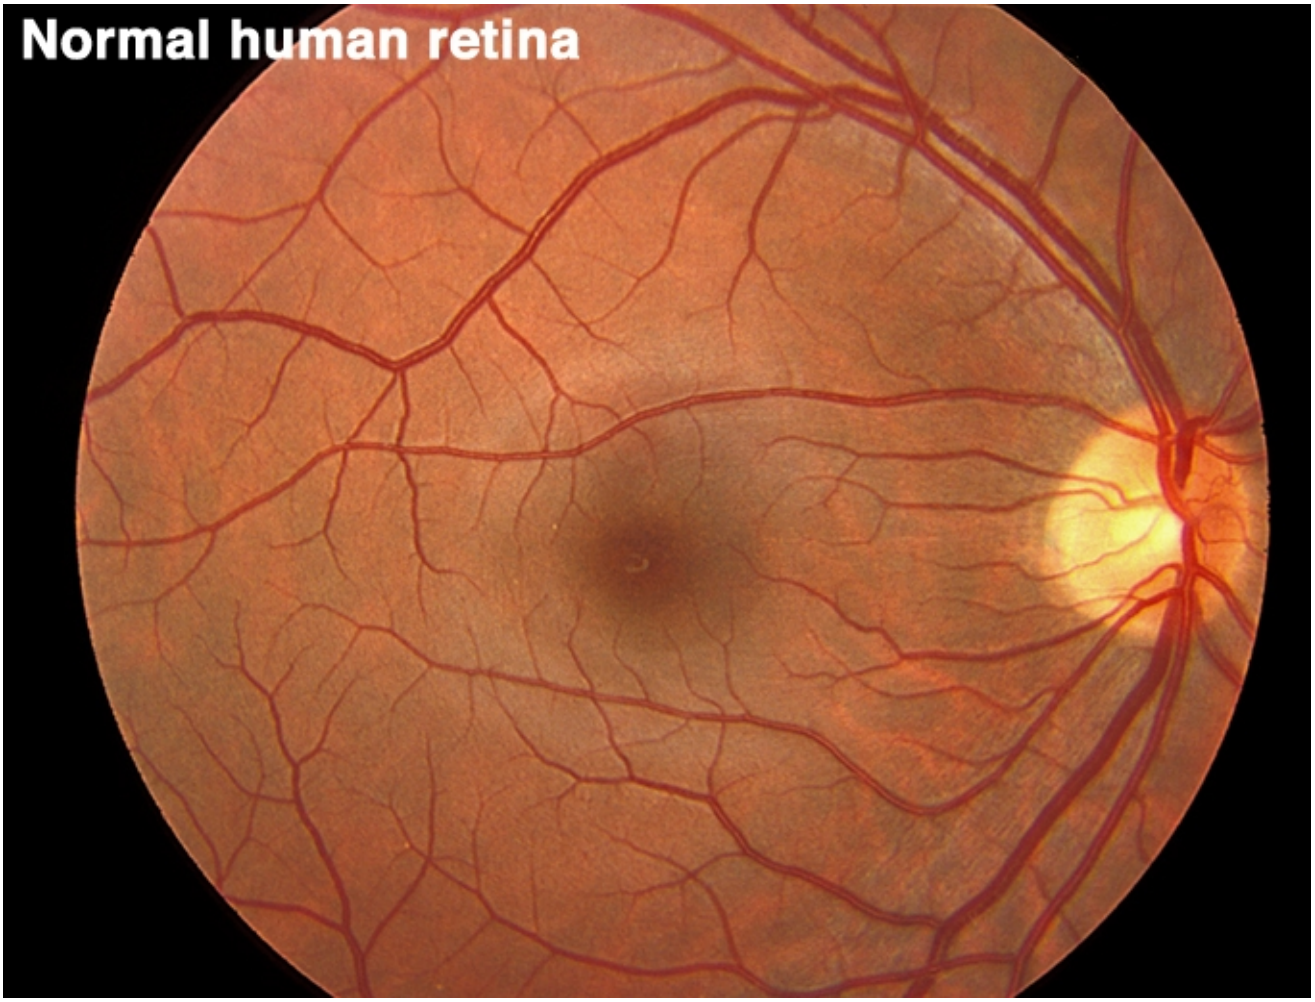

Figure 12a. Fundus photo of a normal human retina.

Gyrate atrophy (Fig. 23) is a recessively inherited atrophy of the pigment epithelium and choroid caused by a deficient mitochondrial enzyme ornithine aminotransferase (OAT).

Gyrate atrophy is less extensive than choroideremia, and the fundus usually shows scalloped borders to degenerative areas (Fig. 23). ERGs are abnormal and progressly deteriorate according to the extent of degeneration of retinal pigment.

X-linked juvenile retinoschisis is a splitting or schisis in the central retina with a characteristic fundus appearance (Fig. 24). These patients have poor acuity. The ERG has a specific abnormality showing a normal a-wave but no b-wave. It is a negative ERG (Fig. 24). The picture is similar to that recorded in central retinal artery occlusion and congenital stationary night blindness type 2.

Patients with Creutzfeldt-Jakob disease (CJD) can also show selective loss of the b-wave (18), even in early stages. We have followed several patients with CJD that have shown unusual ERG waveforms (Fig. 24, a). Similar in appearance to the ERGs of retinoschisis, the b-wave is greatly attenuated (Fig. 24, a). In later stages, the a-wave and OPs are also affected. This pattern is seen in very few disorders, principally X-linked retinoschisis and congenital stationary night blindness type 2.

Except for some retinal dystrophies such severe RP or Leber's congenital amaurosis, most retinal disorders produce reduced, "graded" amplitude attenuation of the ERG, as we have seen in the above cases. However, a few disorders result in a completely extinguished ERG. They include the following:

Figure 12b. Fundus photo of a patient with retinitis pigmentosa.

- Leber's congenital amaurosis
- Severe retinitis pigmentosa
- Retinal aplasia
- Total detachment of retina
- Ophthalmic artery occlusion

Leber's congenital amaurosis unfortunately presents with significant visual loss in the first year after birth. The fundus usually has a salt and pepper appearance. The ERGs are usually unrecordable.

The ERG in Cone Dystrophies

In contrast to RP, the ERGs of a patient with a cone dystrophy exhibit good rod b-waves that are just slower. However, the early "cone" portion (b_x) of the scotopic red flash ERG is missing. The scotopic bright-white ERG is fairly normal in appearance but with slow implicit times. The 30-Hz flicker and photopic white ERGs dependent upon cones are very poor. Cone dystrophies are inherited in all forms and include poor color vision and poor acuity. The most common fundus findings are a "bullseye" appearance or diffuse pigmentation in the macular area (Fig. 25). Many patients have nystagmus and photophobia. Cone-rod dystrophy appears to involve only cones early in the disease, but the ERGs usually show attenuated rod physiology after a while (Fig. 26).

Other dystrophies are the flecked retina disorders, such as fundus flavimaculatus (Fig. 27) and Stargardt's disease. The retinas display an abnormal accumulation of lipofuscin. The ERG in these disorders is normal except in very late stages, where it may become slightly subnormal.

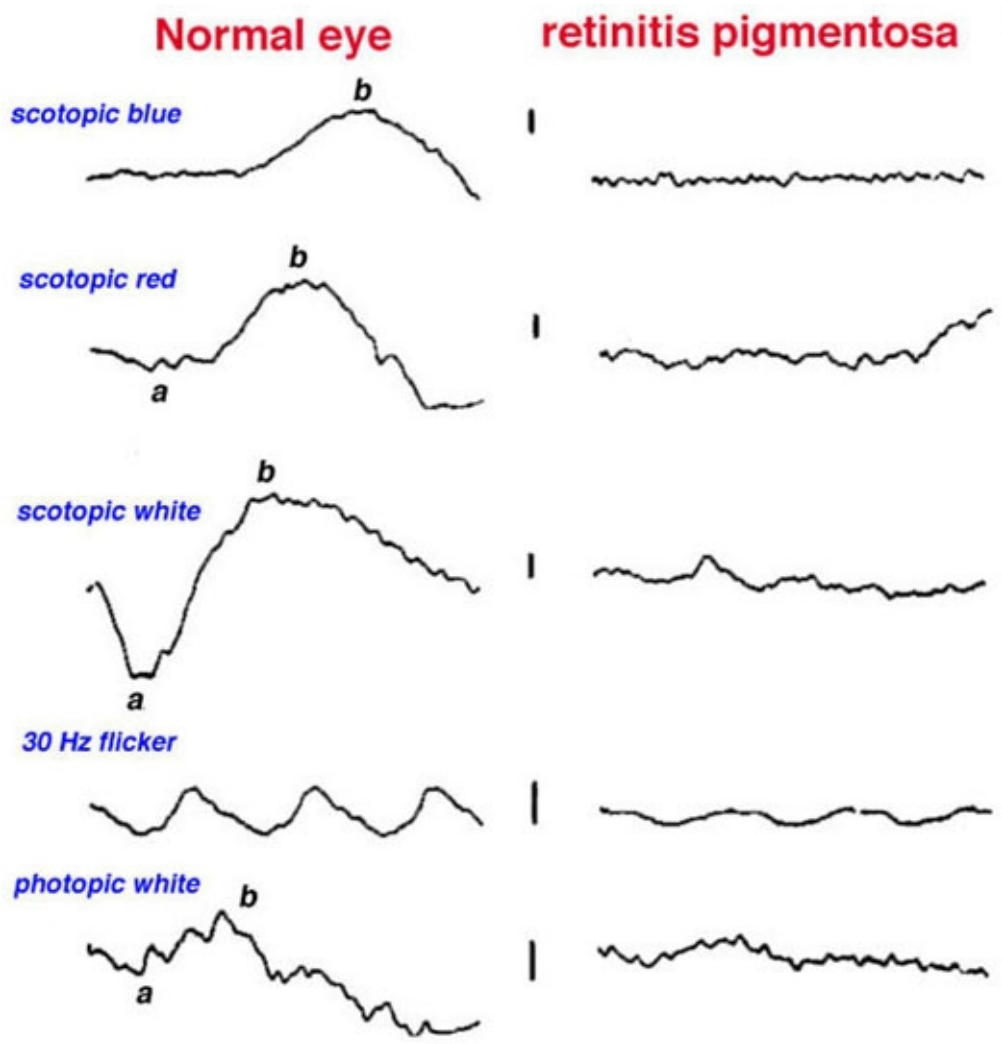

Figure 13. ERG recordings in a normal patient and one with retinitis pigmentosa.

ERGs in Retinal Vascular Disease

Vascular occlusions, such as central retinal artery thrombosis, produce a characteristic avascular appearance to select areas of the fundus (Fig. 28a) and an ERG with no b-wave (Fig. 28b). Ophthalmic artery occlusions usually result in unrecordable ERGs.

Foreign Bodies and Trauma

The ERG is useful to assess cases of retinal foreign bodies and trauma to estimate the extent of retinal dysfunction. Foreign bodies affect retinal function, depending on the extent of tearing of the retina, and the location and composition of the object. A small piece of stainless steel or plastic outside the macula may have a minor effect on the retina. However, a piece of copper or iron (Fig. 29) would likely have deleterious affects within a few weeks (Fig. 30a and Fig. 30b). In general, if b-wave amplitudes are reduced 50% or greater compared with the fellow eye, it is unlikely that the retinal physiology will recover unless the foreign body is removed.

The ERG can be used to estimate the extent of functional retina in cases of retinal detachment. An interesting case is shown in Fig. 31a and Fig. 31b. The patient had a small retinal detachment of the macular area in one eye (Fig. 31a, arrows point to circle of detachment). With the new techniques of optical coherence tomography

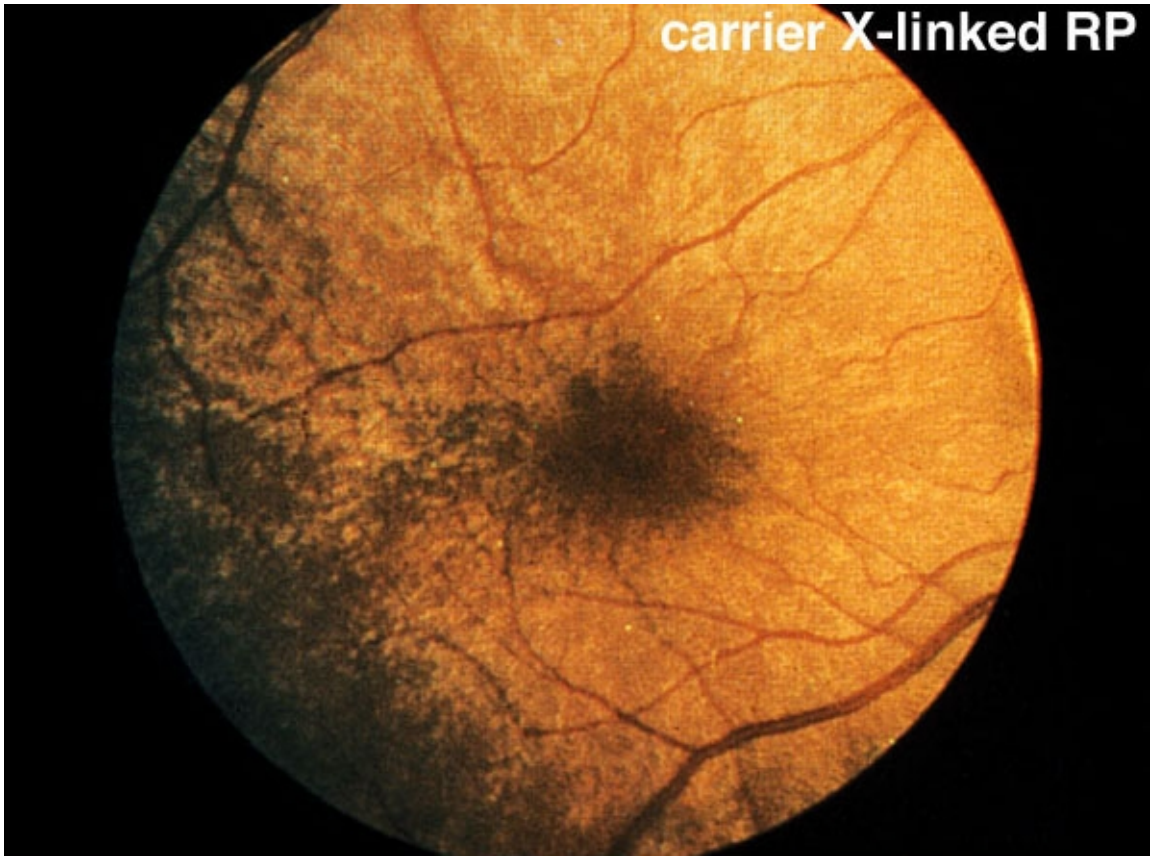

Figure 14. Fundus photo of patient with carrier X-linked retinitis pigmentosa.

(OCT), which gives an optical image like a vertical section plane, the detached portion of the retina in the foveal and macular area can be clearly seen, in comparison with the normal attached macular area in the fellow eye. In general, ERG b-wave amplitudes correspond to the amount of attached healthy retina, although the detached retina may function for some time.

Drug Toxicities

A number of drugs given in high doses or for long periods of time can produce retinal degeneration with pigmentary changes. Traditional culprits are thioridazine (Mellaril), chlorpromazine (Thorazine), and the antimalarial chloroquine. These are drugs usually taken at high dosages for many years and can end up damaging the retina and producing a retinopathy. Chloroquine retinopathy shows as a characteristic "bullseye" appearance of the macula (Fig. 32). The ERGs become abnormal in these cases (Fig. 33).

Hydroxychloroquine (Plaquenil) is usually less disruptive to the retina than chloroquine, but ERG changes can still occur. Other drugs can end up being accidentally toxic to the retina. Cisplatinum, used to treat brain tumors, sometimes reaches ophthalmic vascularization (Fig. 34) and causes a reduction in ERG waveform in the affected eye (OD in this case) (Fig. 35).

An interesting case was seen in our clinic, where an intranasal steroid injection affected the retina of the patient's right eye (OD) only. The fundus photo shows a cherry red spot in the macula (Fig. 36). The ERG response was diminished in size, particularly following dim scotopic flashes (Fig. 37).

Talc retinopathy is also seen occasionally (Fig. 38). Again, the global ERG is attenuated in such cases (Fig. 39).

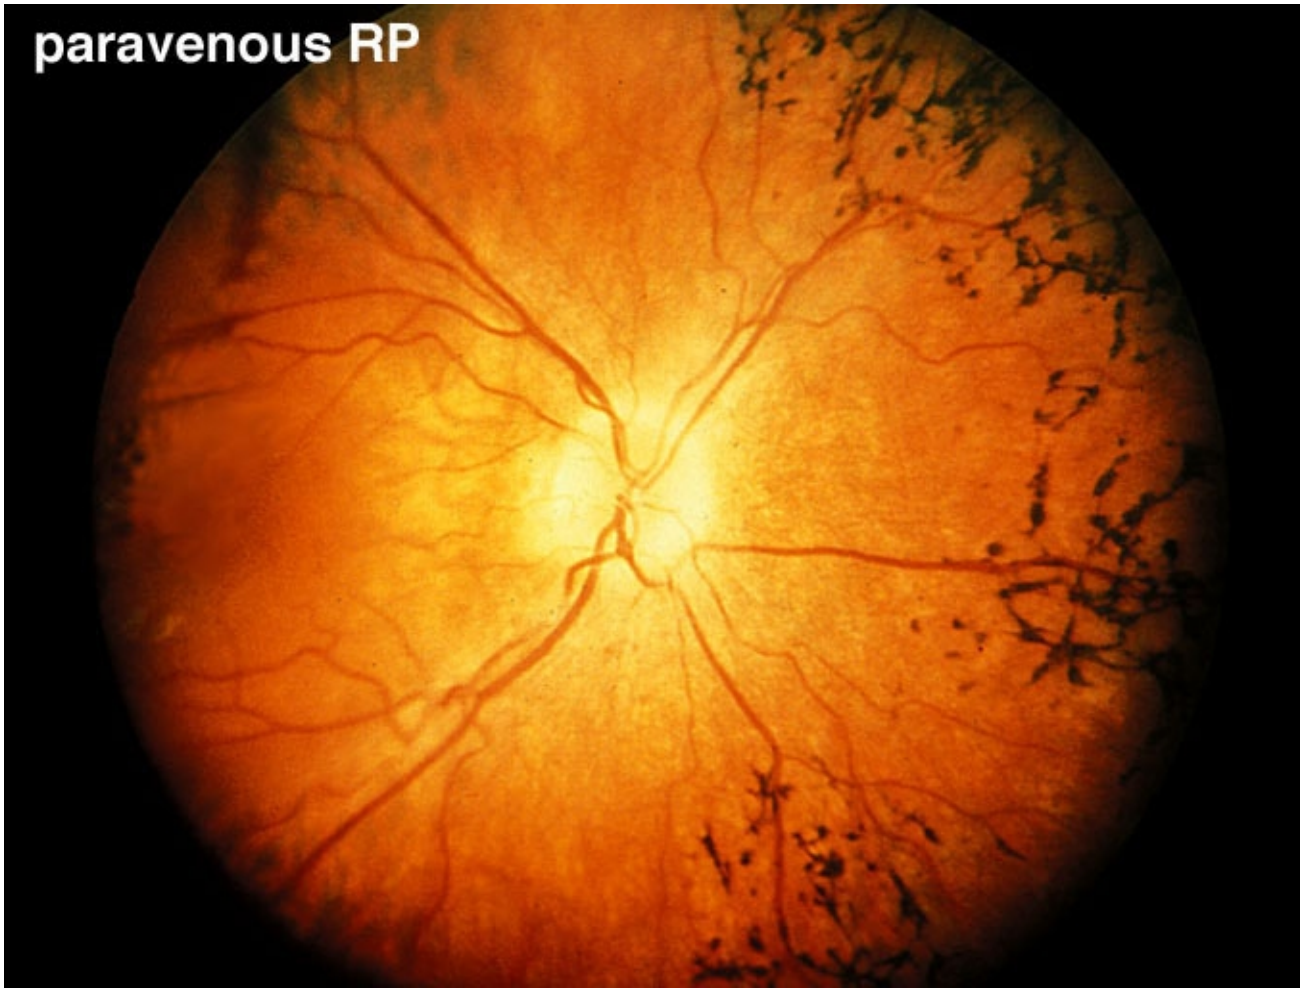

Figure 15. Fundus photo of a patient with paravenous retinitis pigmentosa.

Systemic Disorders and the ERG

Systemic metabolic disorders are reflected in retinal physiology. Liver and kidney disease and drugs that affect those organ systems, usually reduce ERG b-wave amplitudes, particularly in scotopic dim flash ERGs. For example, deferoxamine, an iron-chelating drug used to reduce iron overload, can be toxic to the retina. This is reflected in reduced a- and b-waves of the ERG (Fig. 40).

The Multifocal ERG (mfERG)

A limitation of the traditional global or full-field ERG is that the recording is a massed potential from the whole retina. Unless 20% or more of the retina is affected with a diseased state, the ERGs are usually normal. In other words, a legally blind person with macular degeneration, enlarged blind spot, or other central scotomas will have normal global ERGs.

The most important development in the ERG field in recent years is the multifocal ERG (mfERG) recording system (19). This system allows assessment of ERG activity in small areas of retinal dysfunction. With this method, one can record mfERGs from hundreds of small retinal areas (100 μm) simultaneously in less than 10 minutes per eye (20). A bipolar Burian speculum contact is usually used to record ERGs from the cornea from a dilated eye. Scotomas of only a couple of millimeters in diameter can be mapped, and the extent of retinal dysfunction can be quantified very accurately.

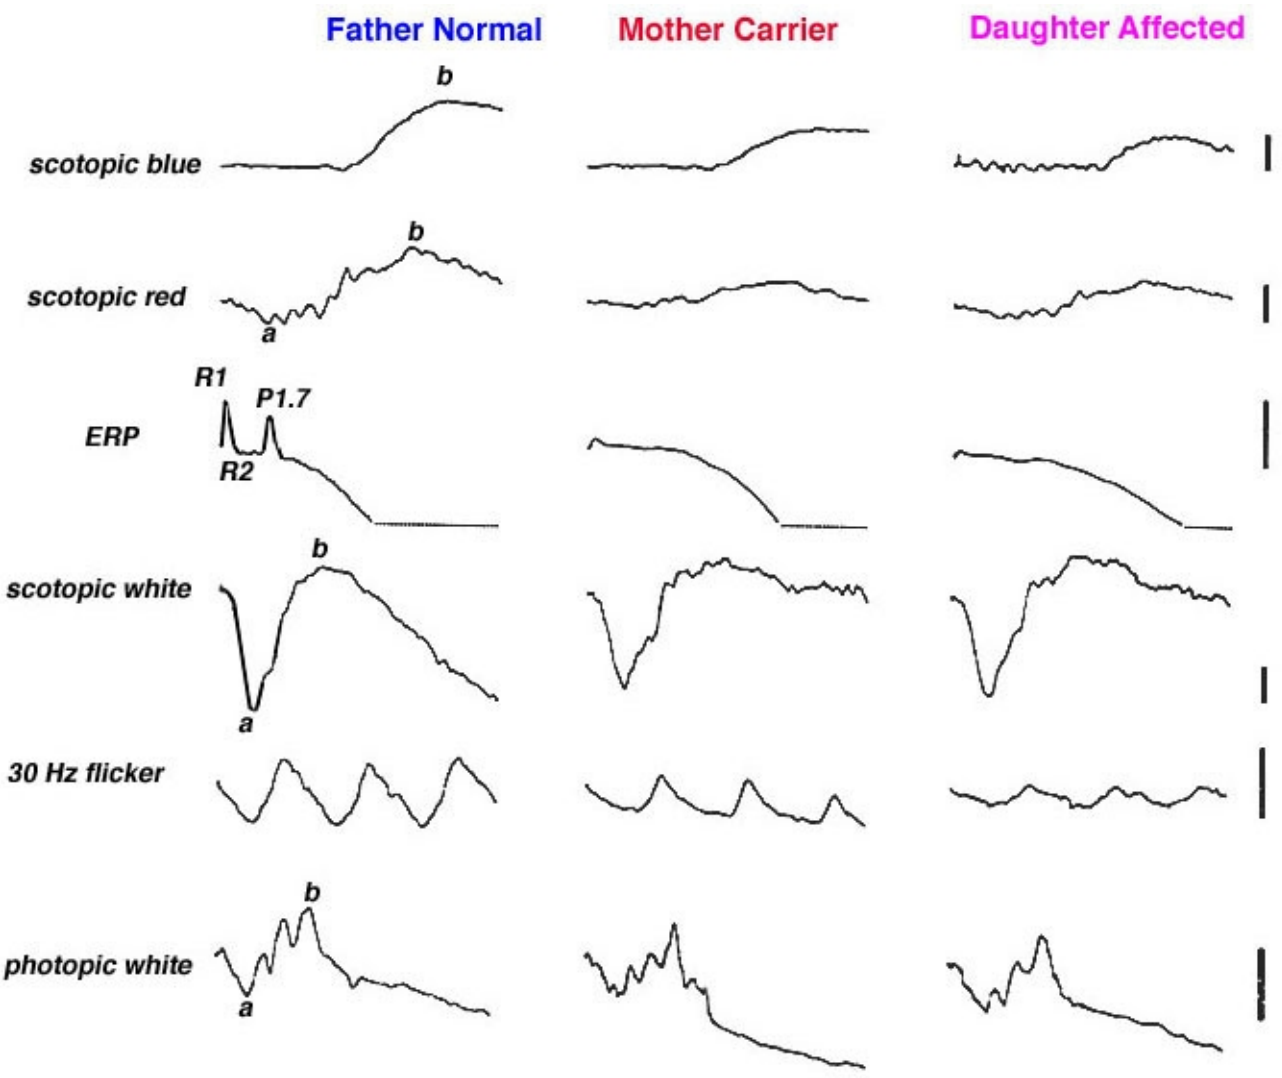

Figure 16. ERG of a family with a child with myotonic dystrophy.

Below are the mfERGs of a patient tested at the Moran Eye Center (Fig. 41b and Fig. 42). The patient is an elderly woman with macular degeneration. The fundus photograph of another patient with age-related macular degeneration (AMD) is seen in Fig. 41a. In Fig. 41b are 103 multifocal ERGs from approximately the central 50 degrees of retinal field. In Fig. 42 are the b-wave voltages from these 103 locations transformed into a 3-D color plot. The lower far right (Fig. 42) shows a plot of a normal patient for comparison. The top color transformation is the difference between the patient's multifocal ERGs and a normal group, which points out the worst areas of retinal function. Colors reflect standard deviations (S.D.) from average ERG amplitudes. These plots can be rotated from 3-D to 2-D so that they resemble visual field plots.

One of the best uses of mfERGs is for distinguishing between retinal and central etiology of visual problems in patients with no apparent abnormalities in the ocular fundus. These types of patients can include MEWDS (Multiple Evanescent White Dot Syndrome) and AZOOR (acute zonal occult outer retinopathy). Figure 43 is example of 17-year-old male diagnosed with AZOOR associated with a viral prodrome. The mfERGs are clearly showing the retinal abnormalities coincident with the visual field losses (Fig. 43). In contrast, the only visible fundus abnormalities were small, easily overlooked pinpoint hyperfluorescent lesions in Indocyanine Green Chorioangiography (ICG).

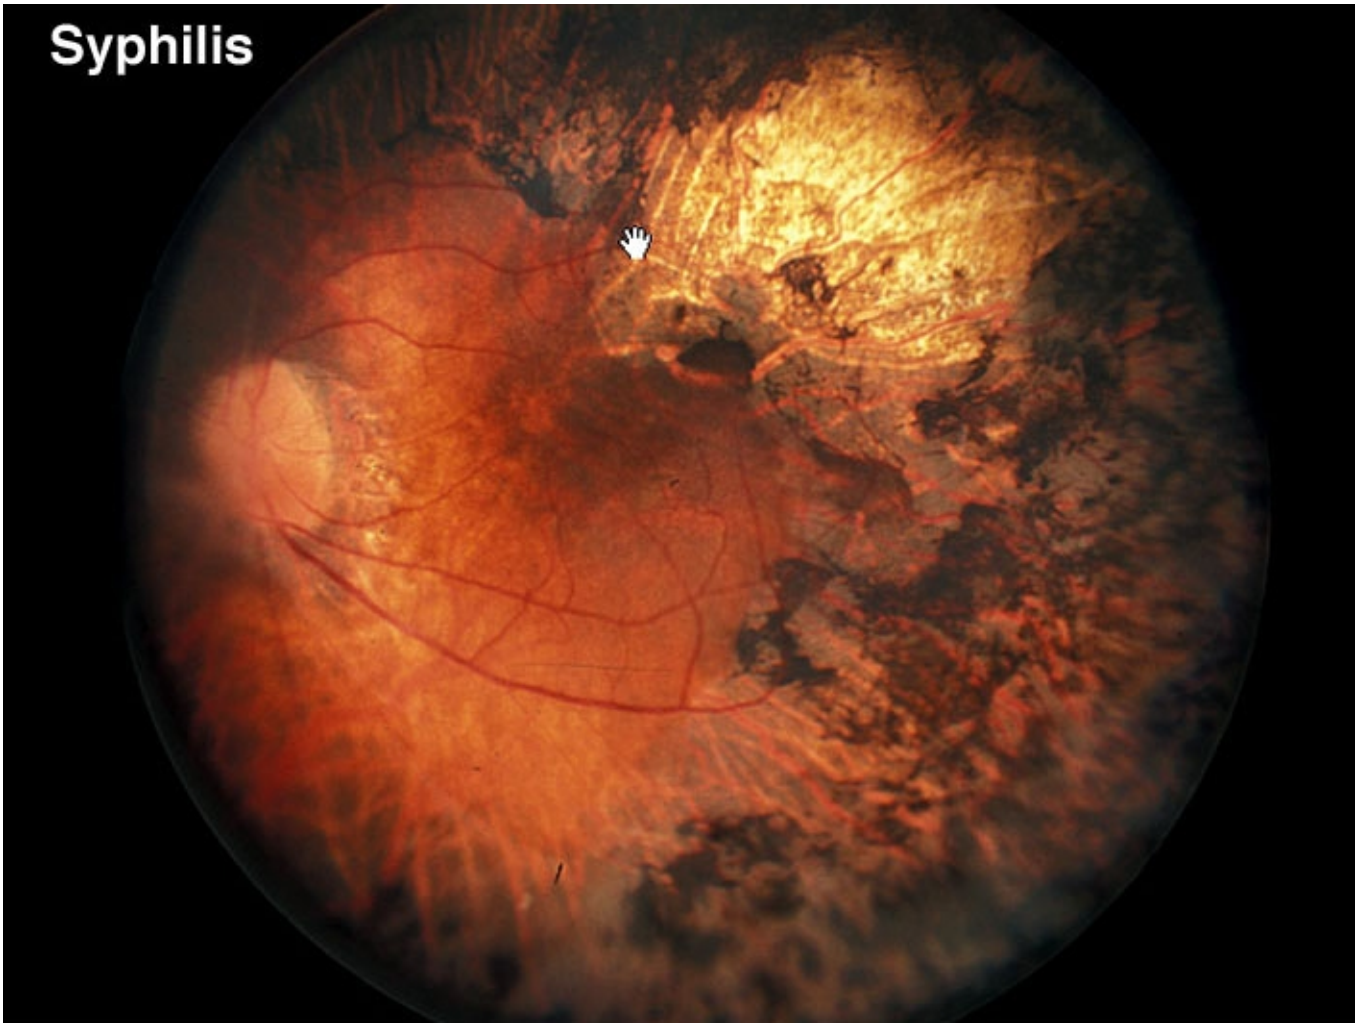

Figure 17. Fundus photo of patient with syphilis.

The mfERG method is a very reliable test and really helps in following the progression of a macular (or other limited retinal area) disorders.

The Electrooculogram (EOG)

The electrooculogram (EOG) measures the potential that exists between the cornea and Bruch's membrane at the back of the eye. The potential produces a dipole field with the cornea approximately 5 millivolts positive compared with the back of the eye, in a normally illuminated room. Although the origin of the EOG is the pigment epithelium of the retina, the light rise of the potential requires both a normal pigment epithelium and normal mid-retinal function. Elwin Marg named the electrooculogram in 1951 (21), and Geoffrey Arden (3) developed the first clinical application. With the cornea constantly positive, movement of the eye produces a shift of this electrical potential. By attaching skin electrodes on both sides of an an eye (Fig. 44), the potential can be measured by having the subject move his or her eyes horizontally a set distance (Fig. 45). The eyes are usually dilated. Skin electrodes are attached near the lateral and medial canthus of each eye (Fig. 44). A ground electrode is attached usually to either the forehead or earlobe. It is helpful, but not necessary, that the patient have a chin rest to reduce head movement. Either inside a Ganzfeld, or on a screen in front of the patient, small red fixation lights are place 30 degrees apart (Fig. 46). The distance the lights are separated is not critical for routine testing. Any set distance subtending from 20 to 40 degrees of visual angle is satisfactory.

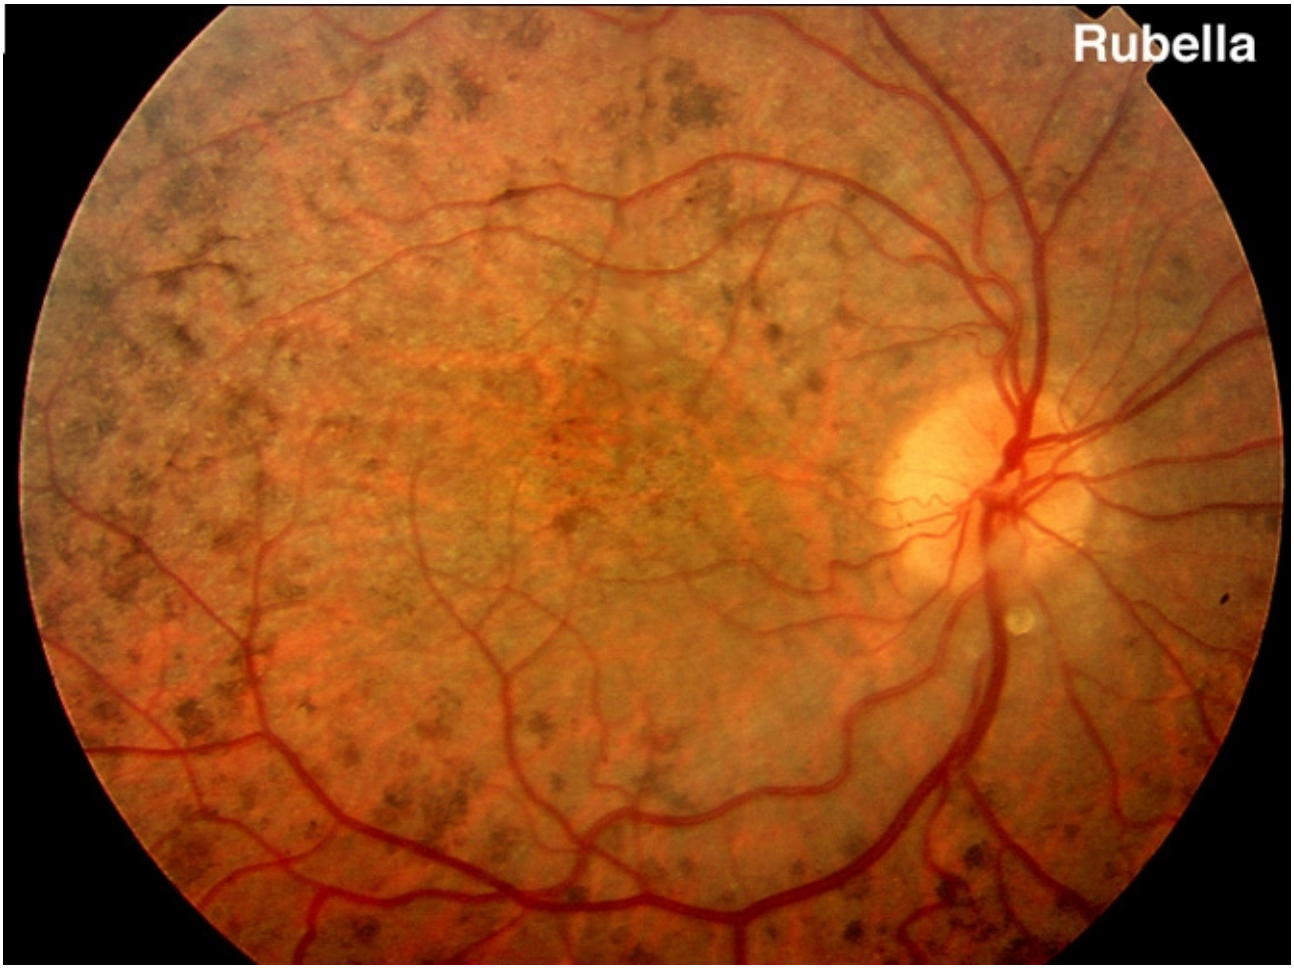

Figure 18. Fundus photo of patient with rubella.

The patient should be light adapted such as in an well-illuminated room, and their eyes dilated. After the electrodes are attached, the procedure is explained and the patient is asked to practice several times while baseline data are recorded. The procedure is simply that the patient keeps his or her head still while moving the eyes back and forth, alternating between the two red lights. The movement of the eyes produces a voltage swing of approximately 5 millivolts between the electrodes on each side of the eye, which is charted on graph paper or stored in the memory of a computer. In Fig. 47 are 10-sec periods of eye movement back and forth between two red LED lights placed 30 degrees apart inside a Ganzfeld.

After training the patient in the eye movements, the lights are turned off. About every minute, a sample of eye movement is taken as the patient is asked to look back and forth between the two lights (Fig. 47). Some laboratories have the patients move their eyes the entire testing period. After 15 minutes, the lights are turned on, and the patient is again asked about once a minute to move his or her eyes back and forth for about 10 sec. The top of Fig. 48 shows segments of eye movement that have been cut from 10-sec samples from a normal person. The chart (Fig. 48) graphs the change in voltage in the eye through 15 minutes of dark adaptation and 15 minutes of bright light. Typically, the voltage becomes a little smaller in the dark, reaching its lowest potential after about 8-12 minutes, the so-called "dark trough." When the lights are turned on, the potentials rise, and the light rise reaches its peak in about 10 minutes. When the size of the "light peak" is compared with the "dark trough", the relative size should be about 2:1 or greater (Fig. 48). A light:dark ratio of less than about 1.7 is considered abnormal. Fig. 49 shows an abnormal response recorded from a patient with Best's disease.

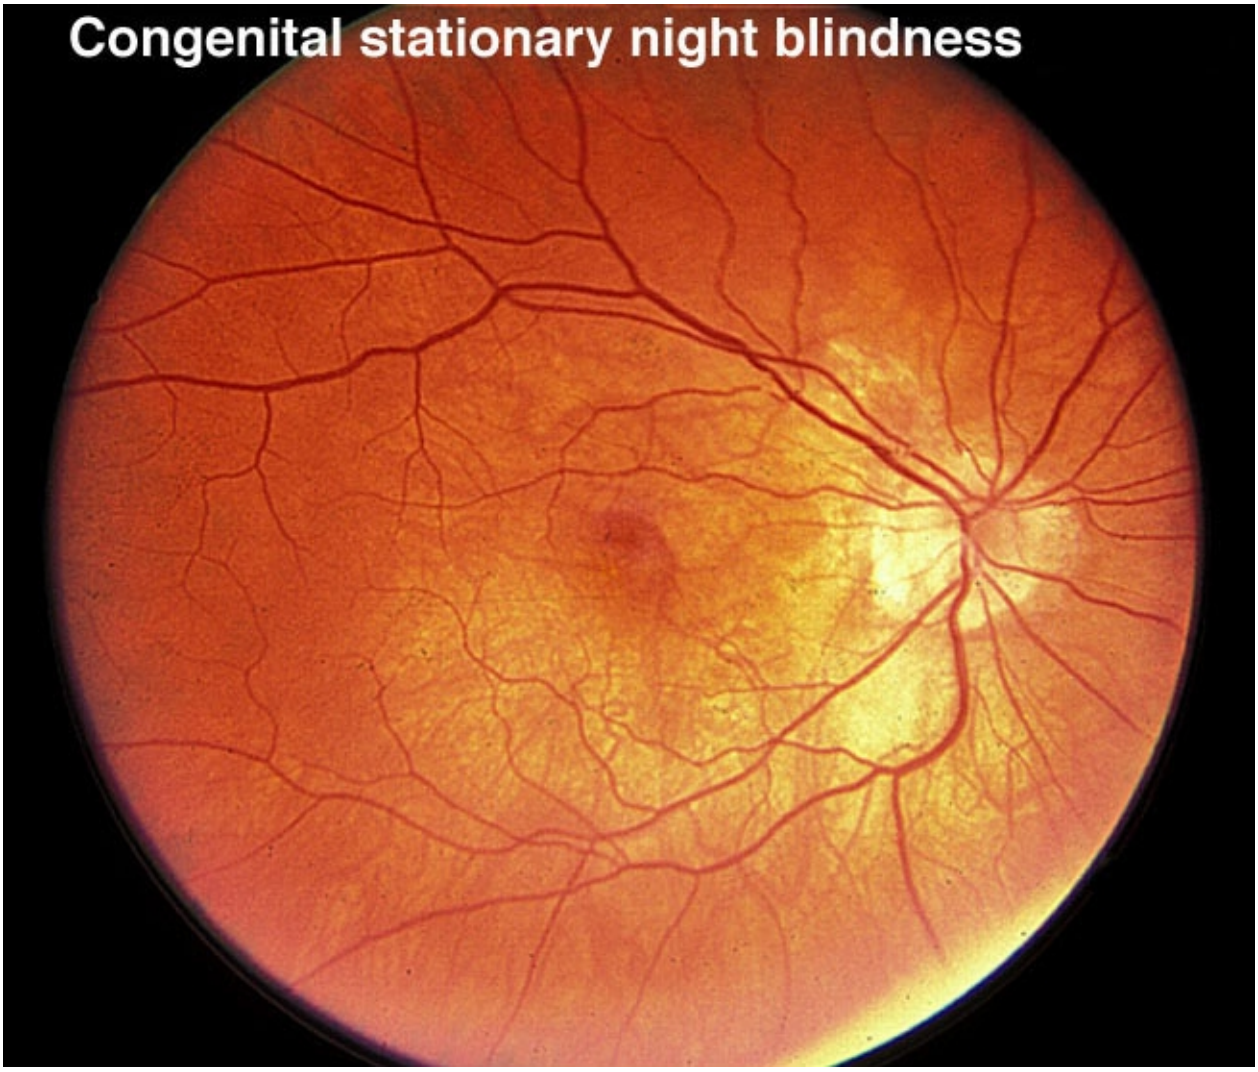

Figure 19. Fundus photo of patient with CSNB type 2.

The EOG is redundant with the ERG in most retinal disorders. Retinal diseases producing an abnormal EOG will usually have an abnormal ERG, which is the better test for analysis of scotopic and photopic measures. The most common use of the EOG is to confirm Best's disease. Best's vitelliform macular dystrophy and variants of this disease are usually identified by the appearance of a retinal lesion resembling an egg yolk early in the disease (Fig. 50). In vitelliform macular dystrophy (Fig. 51), the ERG will be normal but the EOG will be abnormal.

About the Author

Dr. Donnell Creel was born in Kansas City, Missouri. He attended the University of Hawaii and received his B.A and M.A. from the University of Missouri at Kansas City. His Ph.D. was in Neuropsychology from the University of Utah in 1969. Don's doctoral thesis and post-doctoral research centered on abnormal decussation of retinal ganglion cell fibers at the optic chiasm in albino mammals. In the early 1970s, he created a visual evoked potential test that detects this misrouting in human albinos. Later research demonstrated that melanin pigment in the inner ear is necessary for normal auditory function and that lack of pigment in albinos has consequences affecting normal cell development in the brainstem. Don has been in the Department of Ophthalmology, University of Utah Medical Center since 1980, and Director of Clinical Electrophysiology at the Moran Eye Center since its inception in 1993. Clinical research interests center around the application of visual and auditory evoked potentials and electroretinography.

Visual and Auditory Anomalies Associated with Albinism

Donnell J. Creel, PhD[1]

Created: June 18, 2015.

1. Introduction

One of the evolutionary characteristics of the mammalian visual system is the increase of binocular overlap of vision as eyes progress from being located on side of the head such as the guinea pig to the frontal position in Haplorrhine primates. Concomitantly as the proportion of temporal retina increases the number of uncrossed optic neurons at the optic chiasm expands from as little as 1% in guinea pigs to approximately 45% in primates including human beings (1, 2). Figure 1 illustrates the approximate distribution of crossed and uncrossed retinal ganglion cells (RGCs) in the visual pathways of normally pigmented human beings.

C. L. Sheridan (3) compared the interocular visual pathways in "split brain" ocularly pigmented (hooded) rats and albino rats. Sheridan concluded “Perhaps the paucity of uncrossed fibers that characterized rodents in general is even further reduced in the albino". That year Lund (4) verified Sheridan's hypothesis anatomically. Lund stated albino rats display no organized uncrossed optic fibers. Lund agreed with previous estimates that pigmented rats possess up to 10% uncrossed optic fibers. Figure 2 is a diagram of crossed and uncrossed optic projections in wild-type rodents.

Mammals with few uncrossed retinal ganglion cell fibers (RGCs) such as rodents and lagomorphs do not exhibit the laminated dorsal lateral geniculate nucleus (dLGN) seen in carnivores and primates including human beings. Carnivores and Haplorrhine primate dLGN contain up to six monocular layers with point-to-point representation of visual space organized in columns through these layers. The 90%+ crossed RGCs at the optic chiasm in rodents and lagomorphs fill the contralateral dLGN, with only a pocket of the ipsilateral dLGN devoted to the fewer uncrossed fibers. Figure 3 illustrates RGC fiber terminations in horizontal sections through the dLGN comparing black and albino rats. The fewer uncrossed fibers in albino rodents are also projected to the dLGN in a fragmented fashion as opposed to a close organization in pigmented rodents.

2. Visual learning studies

A retrospective review of visual learning experiments, which isolated uncrossed optic pathways in rats, published 1924 to 1966 indicated that ocularly pigmented rats can learn visual discriminations using uncrossed optic fibers, whereas albino rats cannot (5-9). This correlation was not noticed until 1965. These studies were all designed similar to depicted in Figure 4 of rat visual pathways. A combination of limiting visual input to one eye with ablation of visual cortex restricted visual information in rats to either crossed 90-95% of RGCs or 5-10% of uncrossed RGCs. Studies reported pigmented rats can learn visual pattern discriminations using uncrossed pathways. The uncrossed terminations in albino rats are minimal. Albino rats do not learn visual pattern discriminations when limited to uncrossed visual pathways.

3. Siamese cats

For several years the anatomical anomaly of few uncrossed RGCs at the optic chiasm in albinos appeared to be limited to rats and rabbits (10). Guillery (11) described aberrant retinogeniculate organization in Siamese cats, but the connection to albinism was not recognized.

Author Affiliation: 1 Department of Ophthalmology, University of Utah Medical Center.; Email: Donnell.creel@hsc.utah.edu.

Corresponding author.

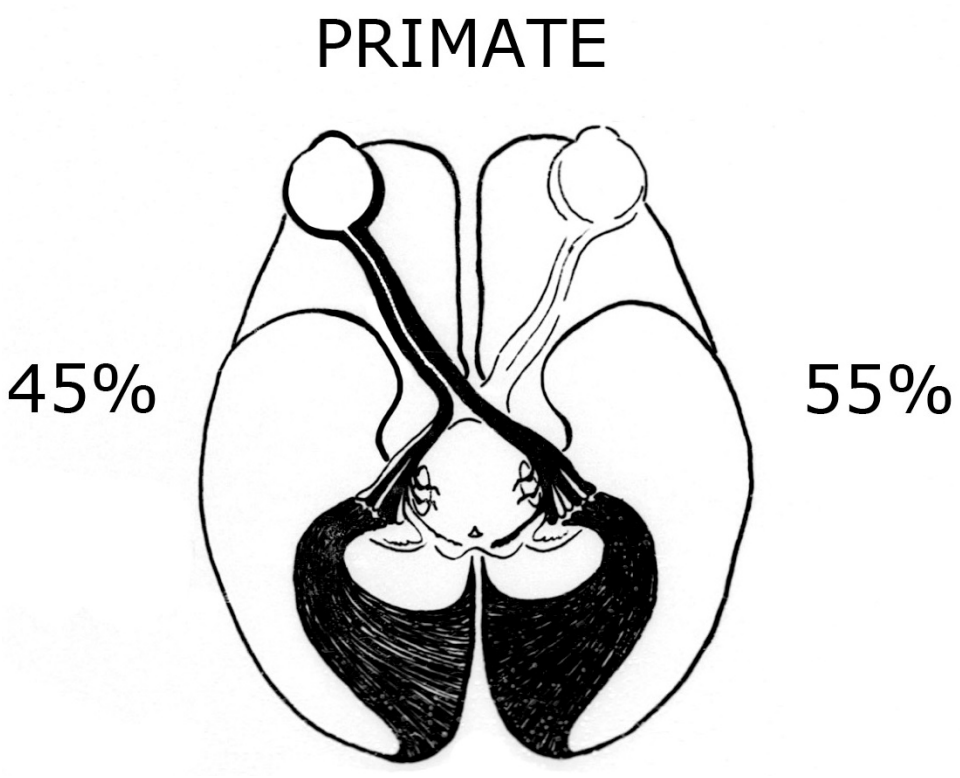

Figure 1. Schematic of approximate distribution of crossed and uncrossed retinal ganglion cells at the optic chiasm in primates including humans.

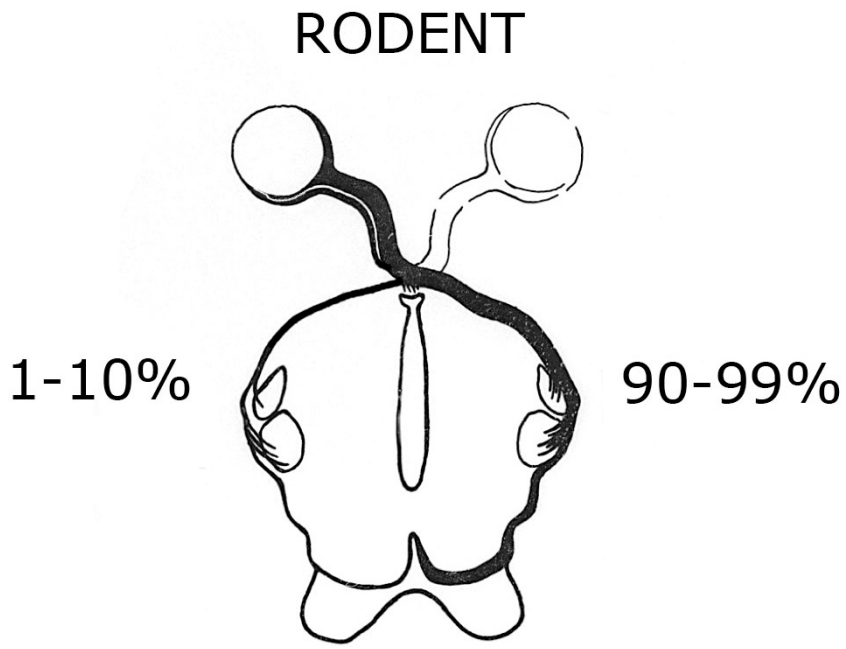

Figure 2. Schematic of range of crossed and uncrossed retinal ganglion cell fibers at optic chiasm in rodents.

The first link between Siamese cats and albinism, and suggestion that reduced uncrossed optic fibers likely is a "highly general trans-species phenomenon in albinic mammals" was in 1971 (12, 13). Siamese cats possess a tyrosinase-locus mutation that is a temperature sensitive pigmentation defect, i.e. pigment forms only on the cold parts of the body similar to Himalayan mice, rats and rabbits. This mutation is sometimes referred to as the

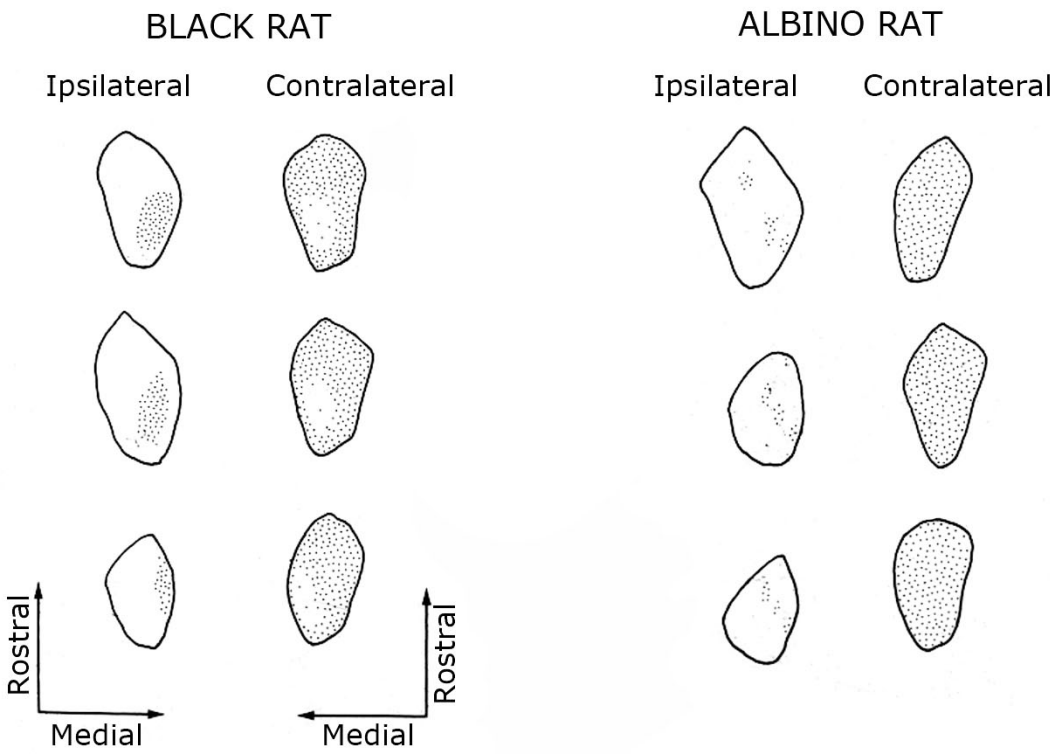

Figure 3. The distribution of pericellular optic fiber degeneration in the dorsal lateral geniculate nucleus (dLGN) of BLACK and ALBINO rats in serial horizontal section at three levels of dLGN.

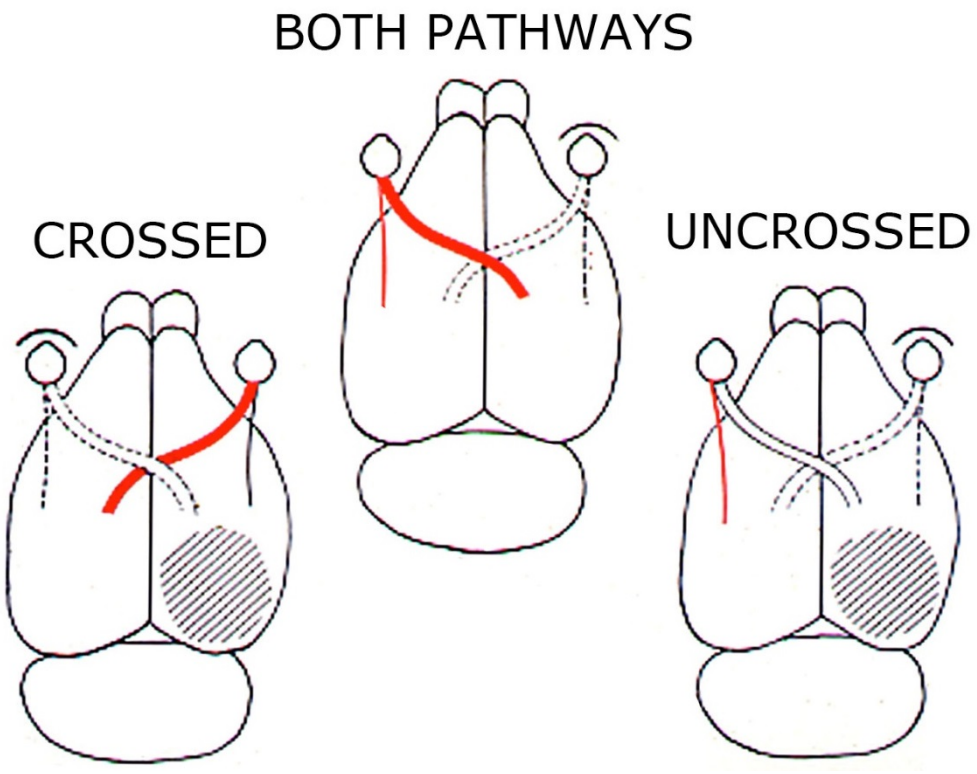

Figure 4. Illustration depicting functioning optic pathways combining occlusion and visual striate cortex ablation (cross hatched areas).

Siamese - Himalayan temperature effect. Cortical mapping of visual projection areas in normally pigmented and Siamese cats demonstrated significant differences in their uncrossed optic pathways. Figure 5 depicts monocular visual evoked potentials recorded from a Siamese cat's cortical visual area showing preponderance of contralateral innervation.

These cat studies discovered that a single recording site over each visual cortical projection area could reflect differences between pigmented and albino cats (Figure 6). This observation was the basis for testing human albinos using scalp-recorded visually evoked potentials (14).

4. Albino animal studies

Many animal studies in the 1970s reported that all albino mammals with oculocutaneous, or only ocular albinism, demonstrate reduced uncrossed optic projections (15-17). A review with figures characterizing types of visual organization in the Siamese cat is R. W. Guillery's 1974 publication in Scientific American (18). One human albino brain (19, 20) and an albino monkey brain were studied verifying similar anomalies in albino primates (21, 22). Defects identified in albino mammals encompass a decreased number of photoreceptors, foveal/area centralis hypoplasia, misrouting of the temporal retinal ganglion cell axons across the chiasm, variation of central RGC terminations, vascular intrusion into area centralis, anomalous cortical organization, and fewer cones and RGCs in macular area (23-27).

The organization of the visual system varies considerably among mammals. Haplorrhine primates display well-defined foveae, foveal avascular zone, and large numbers of uncrossed optic fibers, whereas rodents and even carnivores exhibit only a central fixation area in the retina. In the domestic cat there is a trend towards an avascular zone with only capillary vessels found in the area centralis. Mammals vary not only in numbers of optic nerve fibers that decussate but further in embryonic development and proportion of optic projections terminating in various levels of the optic system from suprachiasmatic nuclei, to midbrain, to geniculate nuclei, to cortex.

An animal model manifesting dramatic effects of misrouting is the albino cat. Figure 7 is a photograph of a litter of albino cats homologous to Type 1 tyrosinase-locus oculocutaneous human albinism (OCA1) with no ability to make pigment. All these cats had observable nystagmus and many strabismus. Figure 8 pictures the optic chiasm of an OCA1 albino cat showing almost all RGCs cross at the chiasm.

Figure 9 depicts the geniculate nuclei of a Type 1 albino cat compared to a normally pigmented cat. The dLGN of albino cats containing only one small pocket of ipsilateral projections is almost as primitive as a rodent dLGN. Four patterns of geniculocortical organization are described in albino mammals (18, 22, 28-30). All forms likely exist in human albinos. Abnormal proportions of ipsilateral and contralateral RGCs continue to mid-brain nuclei probably providing the basis for atypical optokinetic nystagmus in albino mammals.

Few of the rare forms albinism have been investigated anatomically in carnivores or primates. One rare form that has is the Chediak-Higashi syndrome (CHS), which occurs in mammals including human beings and cats. Decreased oculocutaneous pigmentation, enlarged cytoplasmic granules, increased susceptibility to infections, and hemorrhagic tendencies characterize CHS. Ocular anomalies include pale irides and albinotic fundi. Cats with CHS exhibit photophobia and prolonged post-rotatory nystagmus. Figure 10 depicts littermate cats of a Blue Smoke Persian strain. The hypopigmented cat on the left is affected with CHS. Visual projections of CHS cats misroute at the optic chiasm fragmenting layer A1 of the dLGN into several islands (Figure 11), similar to the disruption of A1 outlined in the Siamese cat (31). Visual and auditory anomalies resembling those in albinos were described in human beings with CHS using evoked potentials (32).

Phylogenetically older connections are less abnormal in albino mammals. Retinohypothalamic projections predate vertebrates, existing in early chordates that possess retinal pigment matching vertebrates (33). Melanopsin-sensitive retinal ganglion cells are completely crossed or bilaterally projecting to suprachiasmatic

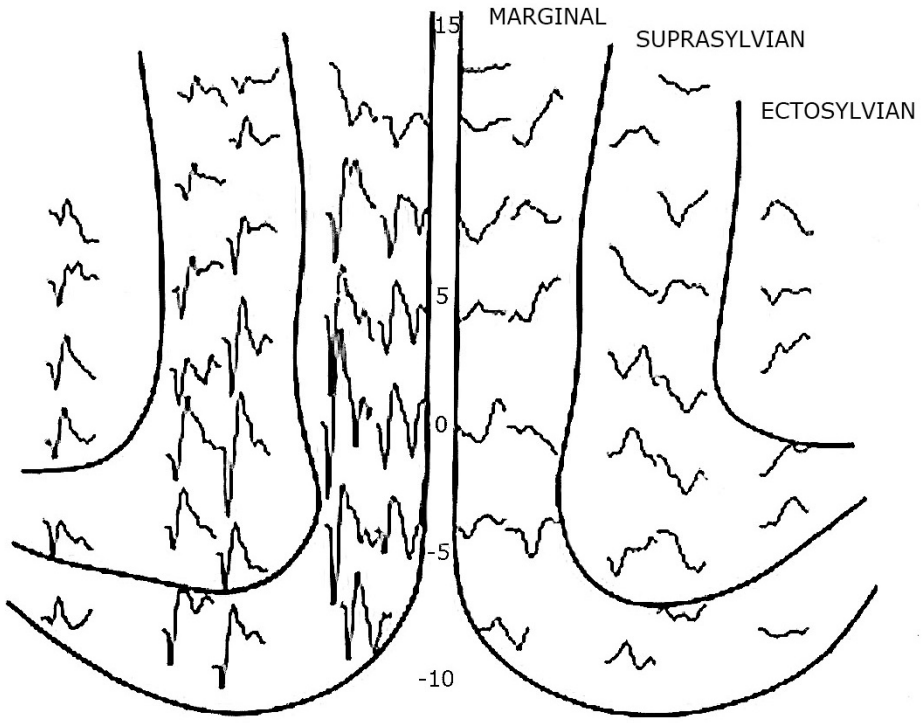

Figure 5. Map of dorsal surface of Siamese cat visual cortex chowing monocular visual evoked potentials via crossed (left) and uncrossed (right) optic projections. From Creel, 1971 (12).

nuclei, and not affected (34, 35). The phylogenetically older bilateral projections to suprachiasmatic nuclei in albino cat (Figure 8) appear to be unaffected (36). The crossed/uncrossed ratio of approximately 1.4:1 of retinal ganglion fibers to the suprachiasmatic nuclei in albino cats corresponds to the ratio reported for normally pigmented cats (37).The later-evolving vertebrate rod-cone-RPE-ganglion cell system is vulnerable to alteration in albino mammals whereas the phylogenetically older melanopsin pathway is generally not.

5. Genetic mechanisms

Sprinkled through publications since the 1970s are suggestions that genetic effects are paramount. Sanderson et al. (38) and Sanderson (15) in the mink and rabbit, and Creel & Giolli (16, 39) in guinea pigs and rats early addressed genetic factors modifying expression of anomalies in ocularly hypopigmented models. In the cat model there are indications of genetic control including reports of heterozygote effects in pigmented cats (29, 40). Carriers of the genes for human albinism do not show detectable visual anomalies (41). Up to 90% of obligate carriers of X-linked ocular albinism exhibit pigmentary mosaicism in their ocular fundus, a lyonization effect, but with no further visual anomalies yet discovered (42).

Many candidate agents, including signaling and transcription factors have been suggested that plausibly control targeting of retinal ganglion cells coursing through the chiasm and other visual features associated with albinism. Likely many of these conclusions are correct within the model studied, but not a general solution within mammals. Each species appear to vary. For example, significant differences between mouse and human embryogenesis specific to chiasm formation are described (43). These differences include that the nodal point of neurogenesis in the human/primate retina is the fovea, while in rodents it is the optic nerve head. In rodents uncrossed cells are born early for their retinal location. This is not the case in primates. Consequently temporal patterning of axon arrival at the optic chiasm and their course through the chiasm are different between man and mouse. In addition there are no absolutes. The expression of these genetically determined traits has a statistical probability of occurrence (16).

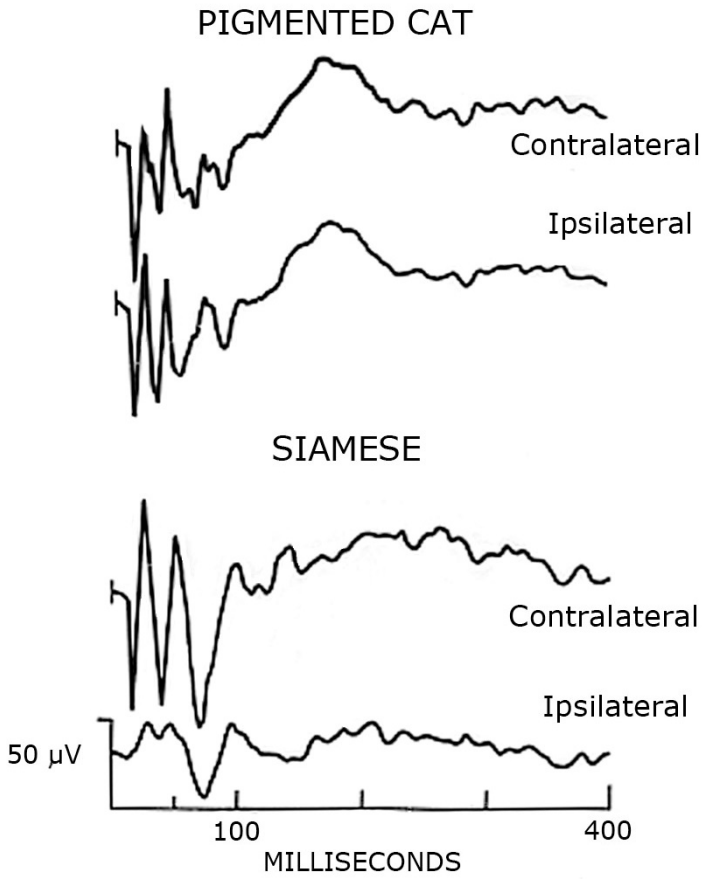

Figure 6. Visually evoked potentials recorded by single dural electrode from normally pigmented and Siamese cat showing dramatic difference in proportion of ipsilateral optic projections. From Creel, 1971 (13).

Figure 7. Litter of Type 1 oculocutaneous albino kittens. All displayed nystagmus and some strabismus.

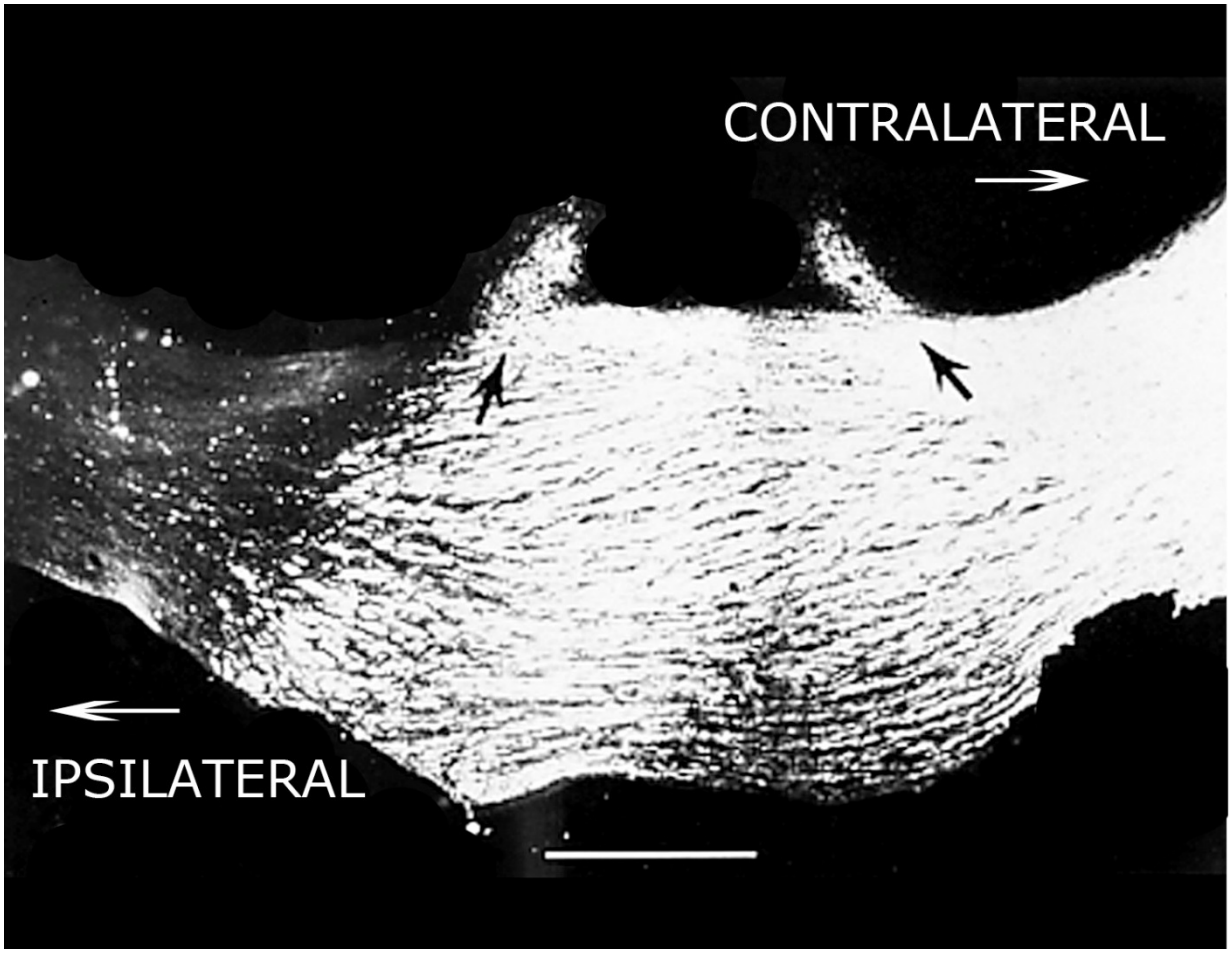

Figure 8. Dark-field autoradiograph of coronal section through the optic chiasm of a Type 1 albino cat after injection of tritiated leucine into right eye showing difference between contralateral and ipsilateral RGC projections. Almost all RGCs cross at the optic chiasm. Arrows point to projections to suprachiasmatic nuclei. Scale bar 1 mm. From Creel et al, 1982 (211).

Variation can also be seen in the drift of retinal evolution even in Haplorrhine primates. Old World and New World monkeys evolved different retinal color vision receptors (44) and different cortical visual organization (45). Another example of variability concerning pigment chemistry is that human tyrosinase-related sequence locus on chromosome 11pll.2 is described in gorilla, but not chimpanzee (46). Even minor differences in pigment metabolism alter metabolic proteins, which possibly could initiate a cascade of effects on visual embryogenesis.

Due to millions of years of divergent evolution the micro mechanisms of axon guidance underlying optic neuron decussation and target fate are likely idiosyncratic for each species. Pax2, Pax6, SOX2 appear to be necessary for ocular development. Only the most fundamental, ancient, conserved loci such as SOX, ROBO 3 and 4, homeobox (VSX2), Sonic hedgehog (Shh) and PAX2/PAX 6 interaction are likely perpetual and contributing to guidance and angiogenesis decisions in most mammals (47-51). The conservation of some genes spans hundreds of millions of years. SOX21, active in developing retina and inner ear, occupies the same human loci (13q31-32) as DCT (L-dopachrome tautomerase), active in melanogenesis and tyrosine metabolism, has maintained 90-100% identity across species for hundreds of millions of years of divergent evolution (52, 53). Worth noting is mutations of ROBO 3 and 4 are associated with non-decussation of the pyramidal motor pathways (54). ROBO 3 and 4 may affect visual pathway decussation by interacting with tyrosinase loci on the same arm of chromosome 11q. Tyrosinase loci 11q13-22 are millions of base pairs from loci 11q23-24.2, but possibly communicate by interacting with noncoding RNA target sites close in three-dimensional space such as by

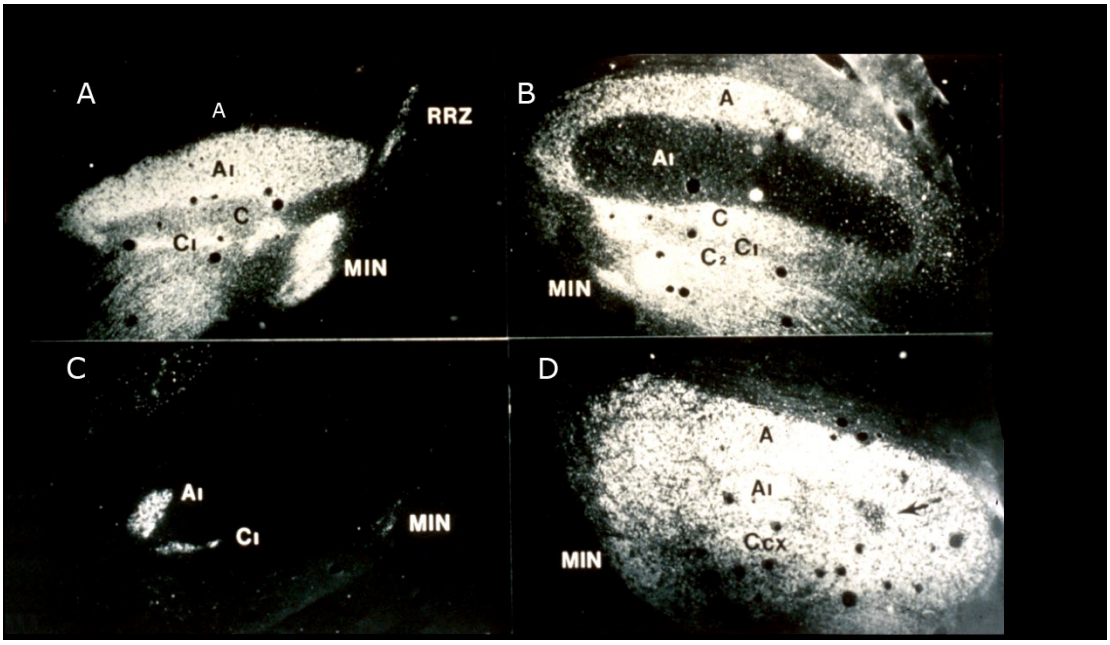

Figure 9. Dark-field autoradiographs of coronal sections through the ipsilateral (A) and contralateral (B) dLGN of a pigmented cat and the ipsilateral (C) and contralateral (D) dLGN of a Type 1 albino cat. The arrow in (D) points to small ipsilateral A1 input. From Creel et al, 1982 (211).

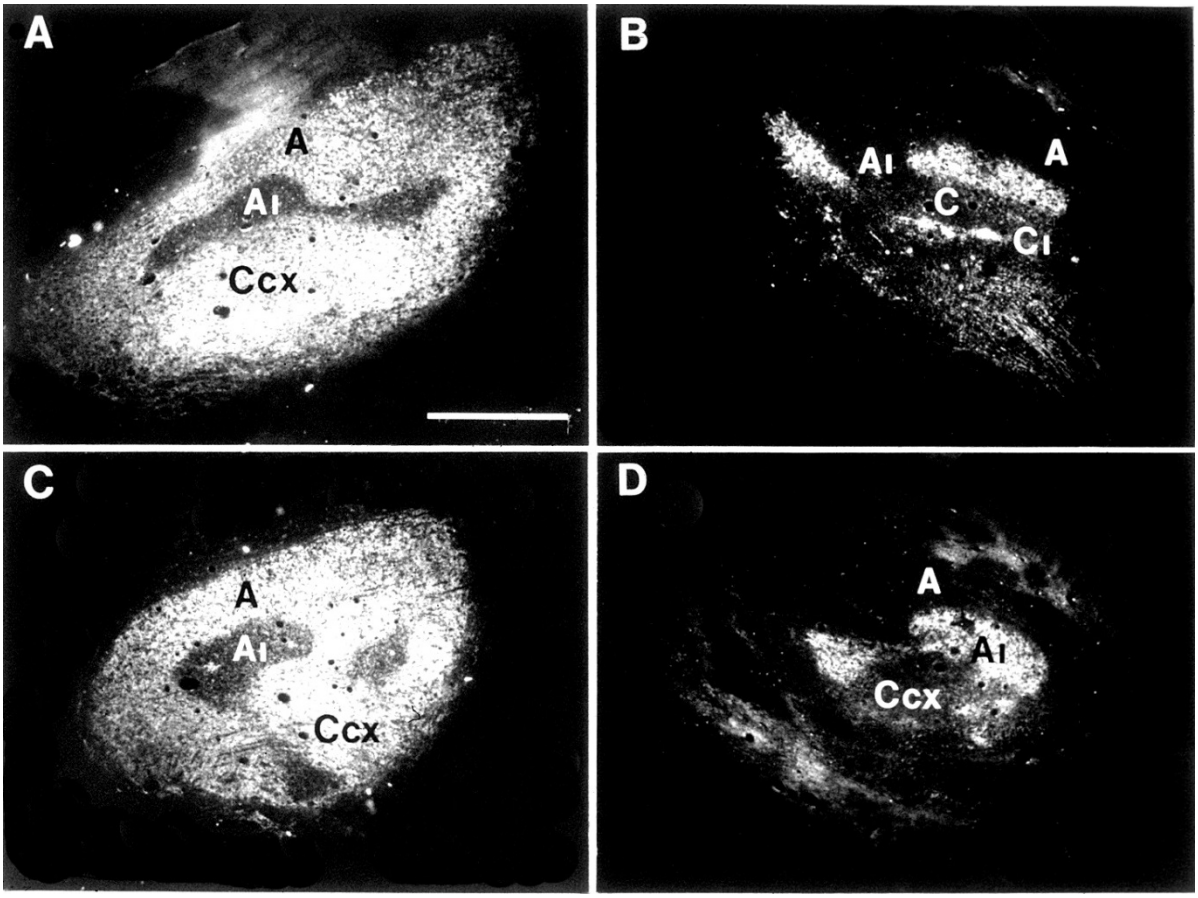

Figure 11. Dark-field autoradiographs of sections through the dLGN of a cat with Chediak-Higashi syndrome (HS). Contralateral (A) and ipsilateral (B) sections about two-thirds through the dLGN, and contralateral (C) and ipsilateral (D) sections about one-third through the dLGN are shown. These sections show fragmented laminae A1 and nearly complete filling of laminae C. From Creel et al., 1982 (31).

chromosomal looping rather than linear sequence such as suggested for the X chromosome (55, 56). Chromosome 11q possibly contains a domain coordinating tyrosine metabolism and coding for decussation (57).

More intra-genome communication is probably taking place than currently credited. In addition to control of visual embryogenesis by protein coding, embryogenesis is plausibly affected by contributions from noncoding DNA or conserved noncoding portions of the genome. Noncoding DNA sequences are located near or within developmental gene loci that likely contribute to modulation or expression, and provide communication to bridge the gap between loci (52, 53, 58). Species-specific differences appear to originate more in noncoding space (59). Species likely evolve unique noncoding sequences contributing to variation in embryogenesis between species, and presumably are responsible for singular features in human CNS development (60).

The chromosomal proximity of tyrosinase loci and ROBO 3 and 4 is not replicated in most mammalian genomes, but primate vision is the most complicated of mammals, and interactive gene control likely is more centralized in human beings. In other mammals loci on different chromosomes plausibly communicate to coordinate their expression (61). The "ROBO code" is likely a code of gene expression not an environmental interaction during embryogenesis (62).

6. Melanin pigment

Melanin pigment is a phylogenetically and genetically consistent metabolic vertebrate pathway dating back to at least the evolution of early chordates. The presence of melanin pigment is as fundamental as any characteristic of vertebrates. During mammalian embryonic development melanin pigment is pervasive as is its interaction with neural crest cell migration, along with ocular and auditory system development. Additionally the chemical pathways of melanin pigment, brain catecholamines, liver, thyroid and adrenal gland metabolism maintain a delicate balance anchored by tyrosine metabolism (63). Even in phenotypically pigment-less cavefish that mutated to not express pigment the ability to produce pigment is preserved in neural crest derived melanoblasts (64).

Melanin's role in visual function can be traced back to the hydra and jellyfish 600 million years ago (65). Melanin pigment's roles in the eye are different than other parts of the body. Melanin pigment is conspicuously present and melanocytes are most active early in vertebrate embryogenesis. Ocular melanocytes are relatively dormant after embryogenesis and unlike extra-ocular melanocytes do not secrete melanin. The genetic basis of pigment cell development and differentiation is conserved from teleosts to mammals. The melanin pigment chemical pathway initiated with tyrosine is expressed similarly from drosophila to primates. The common ancestor of drosophila and primate eye was likely an organism similar to a rag worm 500 million years ago (66). The molecular sequence leading to eye formation in the fly is recapitulated in the developing human eye (67, 68). In general, phylogeny is recapitulated in the embryonic development of the visual system.

7. Human albinos

The features associated with hypopigmented retinae vary between species and individuals. Readily observable in most human albinos is anomalous foveal development and lack of vascular sparing of central foveal area of retina (24, 69). Less obvious is the predominance of crossed optic fibers at the optic chiasm quantified by visually evoked potential, functional magnetic resonance imaging (fMRI) (27), cortical thickening (26) and aforementioned anatomical studies. Retinal ganglion cells (RGCs) in pigmented retinae that originate from the nasal side of fovea cross at the optic chiasm. RGCs originating temporal side of fovea in pigmented human beings do not cross at the optic chiasm. Figure 12 is a schematic approximation of differences between the optic chiasm of ocularly pigmented and albino human beings.

In mammalian hypopigmented retinae optic nerve ganglion cells that originate from retinae nasal side of fovea, and nearly all RGC neurons originating from up to 15 degrees in temporal retina also cross at the optic chiasm (Figure 12). The proportion is not known in human beings and likely varies considerably. In many albino animals essentially all optic neurons from nasal and temporal retina cross at the optic chiasm. In Figure 12 the 80% crossed and 15 degree shift of vertical meridian in human albinos was estimated based on animal anatomical studies and multifocal visually evoked potential studies (29, 41).

The routing of RGCs through the chiasm of human and other Haplorrhine primates is organized similar to schematic Figure 13 in that uncrossed RGCs originate and remain lateral at the chiasm (70), whereas in rodents and carnivores the nasal and temporal RGCs mix within the chiasm before routing ipsilateral or contralateral (2, 71). In marsupials, insectivores and primates the RGCs projecting to either hemisphere remain largely segregated with uncrossed fibers located laterally in the chiasm. In rodents and carnivores RGCs mix in the caudal nerve.

Figure 14 depicts comparison of optical coherence tomography (OCT) through the foveal area of an ocularly pigmented human being (A) and a human albino's (B) foveal areas. In (A) note the foveal depression and that the nerve fiber layer, i.e. red layer on top, is not present across the foveal area. In most human albino retinae the nerve fiber layer (B) continues over the potential foveal area. Figure 15 pictures OCTs of four albinos examined at the Moran Eye Center. To view more human albino OCTs see Gargiulo et al. (72) and McAllister et al. (69).

Foveal under development and considerable variability among albino foveae is likely due to amount of ocular pigment and genetic background (73). Albino human beings manifest a reduction in cone density in the central retina of infants (74) and adults (25). Multifocal ERG studies provide evidence of arrested postnatal development of foveae in albino infants (75). Primates are the only mammals with foveae, but in almost all mammals with albinism the central retina is underdeveloped (76, 77).

An exception is the albino squirrel (78). Squirrel retinae contain a very large cone population. Rods are disrupted in albino development probably because they develop slightly later in retinal development and that cell cycle events get out of control when rod production is taking place. Cell cycle control is relatively normal early in retinal development when cones are being generated.

Retinal vascularization in human pigmented retinae spares the foveal area, whereas in albino human retinae small vessels and capillaries intrude into foveal area. Figure 16 compares the central vascular organization in ocularly pigmented and albino human retinae. Retinae of ocularly pigmented human beings exhibit an avascular zone surrounding the fovea, albinos do not. There are likely many modifying factors such as extent of hypopigmentation specific to the loci tempering phenotypic expression.

The neural retina and retinal pigment epithelium (RPE) demonstrate an intimate embryonic relationship to the extent that each can differentiate into the other (79). An interaction exists between melanin pigment in the RPE and the development of the fovea and choriocapillaris, the blood supply to the retina, and RGC axon guidance (80). The RPE-derived vascular endothelial growth factor (VEGF) is essential for choriocapillaris development (81, 82). Additionally, pigment epithelium derived factor (PEDF) was isolated in the developing fovea suggesting axon guidance genes presumably accompany early mechanisms determining vascular patterning in macular area (83). The PEDF has a major function in development of the foveal avascular area (84).

8. Scalp-recorded VEPs in human beings

In 1974 using scalp-recorded visually evoked potentials (VEPs) four genetic forms of human oculocutaneous albinism exhibited electrophysiological evidence of reduced uncrossed optic fibers (14). Similar results were published for human ocular albinos (85) and replicated in early studies by Taylor (86) and Coleman et al. (87). Reviews of research in this area: Guillery (88), Hoffman et al. (41), Neveu & Jeffery (2) and Bridge et al. (26).

The best visual stimulus to use recording VEPs from most albinos is a pattern onset/offset with individual checks subtending about 1 degree of arc. For individuals with very poor vision and infants, flash stimuli are preferred. In some albinos comparing evoked potentials using the International 10-20 System locations O1 and O2 (89) demonstrate the misrouting. In most albinos more lateral locations along the same plane about halfway to T5 and T6 (H3 and H4), marked in Figure 17 as blue area, better demonstrate misrouting. An early finding was that with monocular stimulation the “difference” potential comparing 10-20 International System scalp locations O1-O2, or H3-H4 across the midline is an efficient way to exhibit chiasmic misrouting in albinos (90). The worst stimulus is pattern reversal, which exacerbates nystagmus in albinos blurring the image.

To detect misrouting at the chiasm a minimum of two recording sites is required, one positive electrode and one negative location in each hemisphere about 3 cm above the inion in an adult and 4 cm or more off the midline. This bipolar montage records a "difference" potential, requiring no additional reference electrode. The ground electrode can be attached anywhere on the person. In ocularly pigmented human beings innervation of visual cortex from nasal and temporal retinae is comparable so the "difference" potential recorded between hemispheres would be similar in form whether stimulating the left or right eye (Figure 18). In contrast, most central visual field retinal ganglion fibers (RGCs) cross to the contralateral hemisphere in albinos so the "difference" potential recorded between occipital hemispheres will change polarity across the occipital area when VEPs following monocular stimulation are compared (Figure 19).

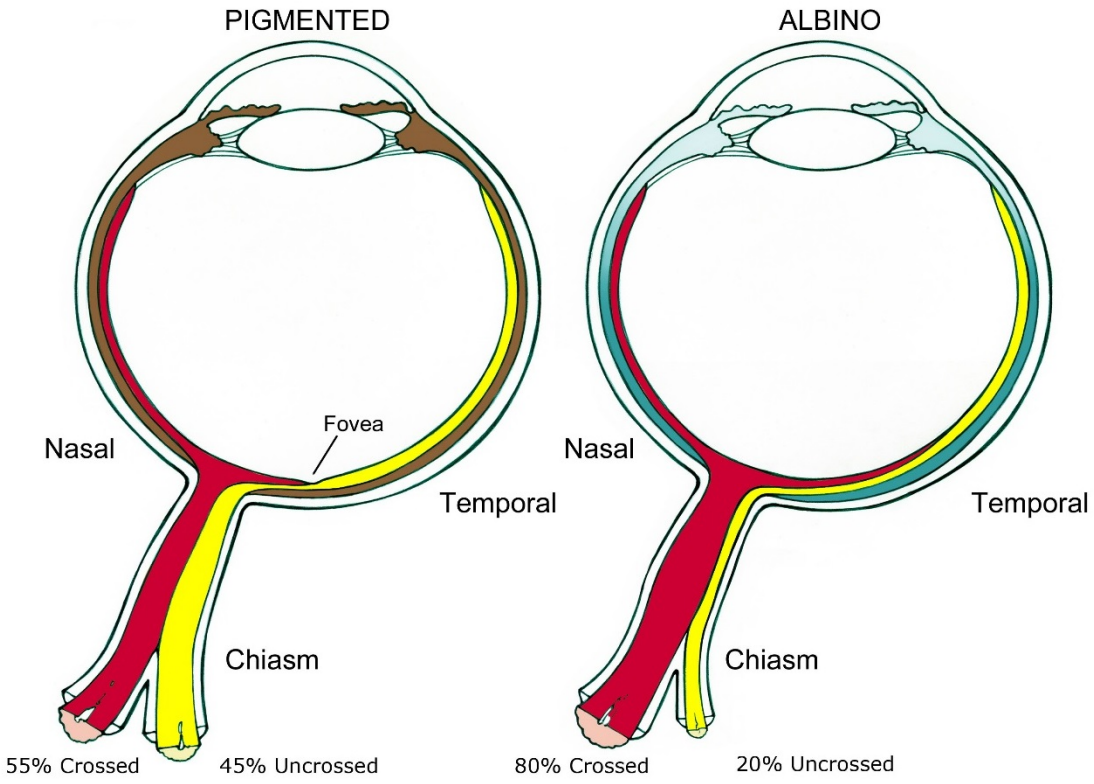

Figure 12. Schematic of approximate distribution of crossed and uncrossed RGCs at the optic chiasm in albino human beings.

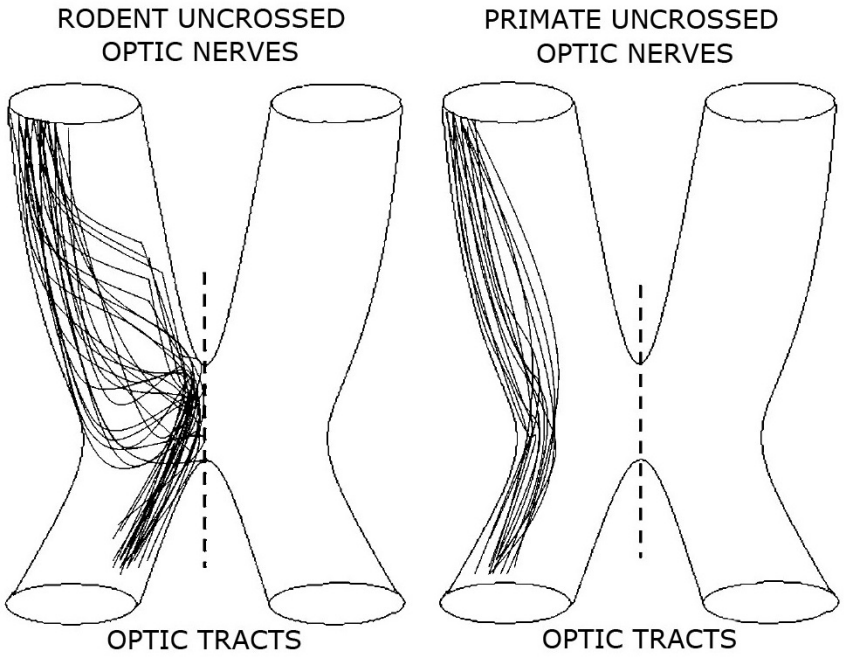

Figure 13. Schematic drawings of two forms of RGC axon projection through the optic chiasm to the ipsilateral optic tract. Ipsilateral RGCs of the rodent mix with RGCs from the other eye. Primate and marsupial RGCs maintain a lateral course through the chiasm. From Neveu and Jeffery, 2007 (2).

An important addition to VEP methodology was the development of multifocal visually evoked potential (mfVEP) technology by Erich Sutter (91). The first publication of mfVEPs in human albinos was by Michael

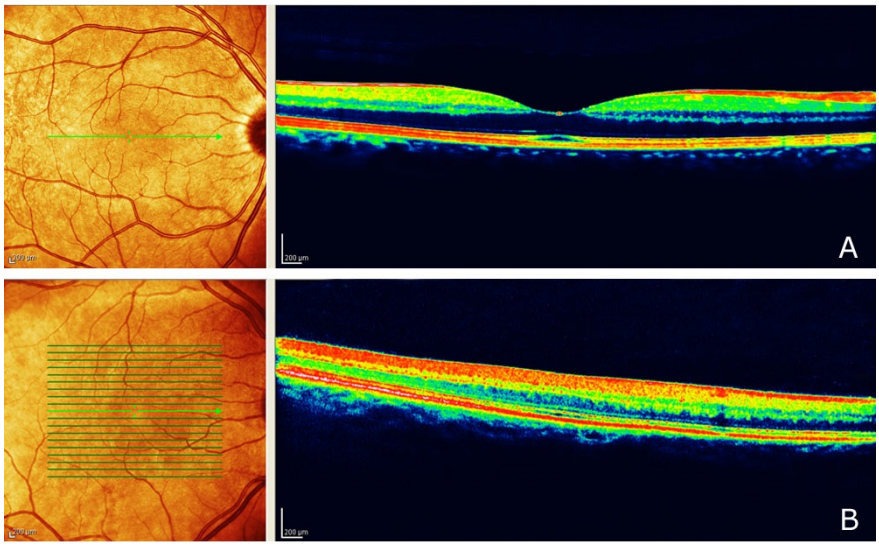

Figure 14. Ocular coherence tomography (OCT) through the fovea of a normally pigmented (A) and albino (B) human being. Note the absence of foveal pit and the nerve fiber layer (red) coursing over foveal area in albino compared to pigmented (A) nerve fiber layer (red) ending before fovea.

Hoffmann and colleagues (41). This group has continued to publish advances in dissecting the human albino visual system using mfVEPs and fMRI studies (26, 92-95).

VEPs are of profound value in detecting the misrouting of the optic nerves in human albinism and revealed that an on average a central ±8 degree wide vertical strip in the central is affected by the resulting representation abnormality (96). The extent of the misrouting varies, depending on pigmentation deficit, between 2 and 15 degrees. This indicates that RGCs originating up to 15 degrees into temporal retina erroneously cross at the optic chiasm. The most important addition of mfVEPs is allowing for a spatially resolved characterization of VEP responses. This approach can be combined with the misrouting VEP paradigm (90, 97) to yield visual field

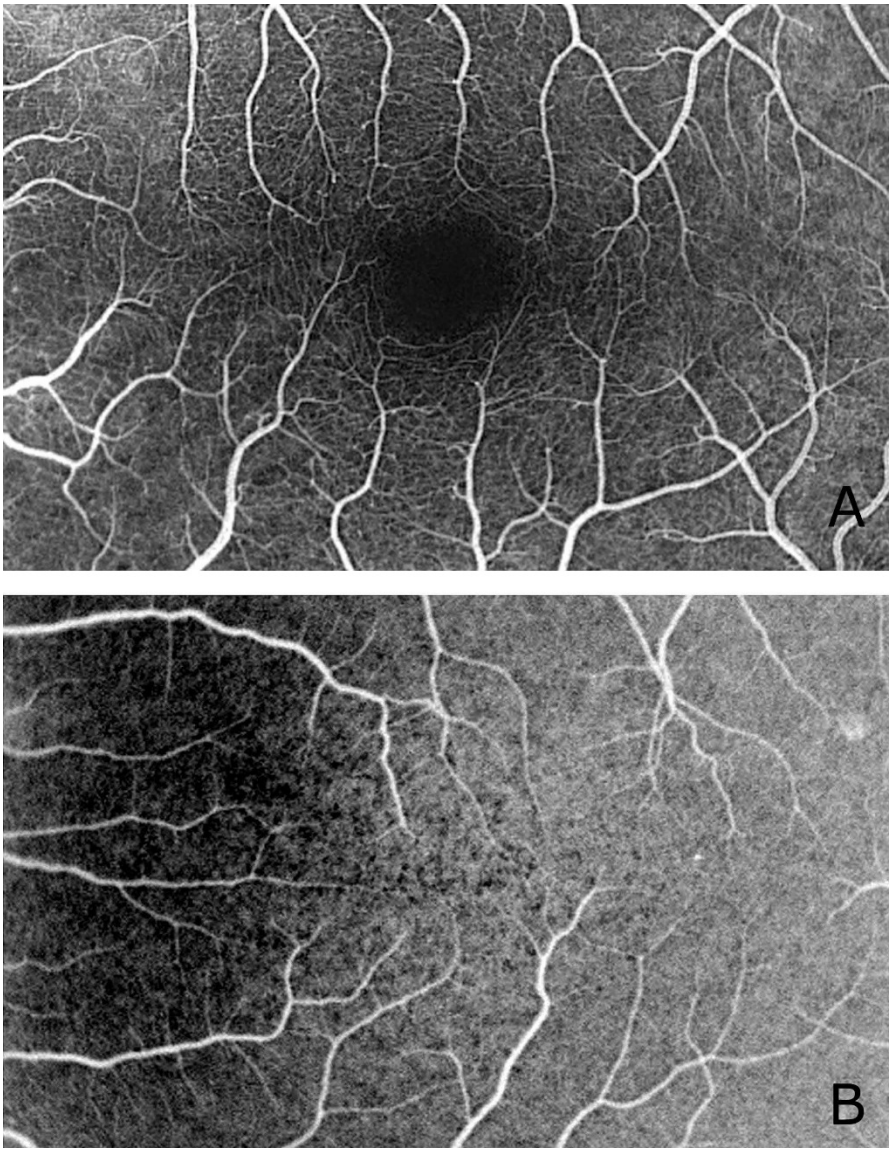

Figure 16. Angiogram of choriocapillaris of normally pigmented human ocular fundus (A) showing vascular sparing of the foveal area, compared to negative of red-free photograph of human albino ocular fundus (B) showing vascular intrusion into foveal area.

topography of the abnormal visual field representations typical for albinism as pioneered by Michael Hoffmann et al. (41). Figure 20 is a print of mfVEPs recorded from a Type 1 oculocutaneous albino (OCA1). This person has nystagmus and exotropia, but exceptional acuity for a Type 1 oculocutaneous albino. His acuity meets requirements of visual acuity required for a driver's license. The central visual field stimulated for these mfVEPs extended over 35 degrees horizontally and 30 degrees vertically, similar to the perceptual field of a Humphrey 24-2 visual field perimeter test. Potentials that reverse in polarity indicate temporal retinal field areas projecting RGCs that cross the optic chiasm. MfVEPs require reasonably stable fixation (41, 96, 98), but they are a useful extension of the classical misrouting VEP paradigm as they permit the detection of locally confined, i.e. only small misrepresentations. Their prime use is to explore the specificity of misrouting for albinism. MfVEP studies confirmed the absence of evidence of misrouting in carriers of OA (41).

While fMRI was used to validate the misrouting VEP (27, 92), it further assists in uncovering the organization of the human visual cortex in albinism, and higher cortical function (30, 99). These studies indicate that the unrepresentative visual input to each hemisphere is propagated to higher processing stages (95) and is made available for perceptual (94, 100) and visuo-motor integration (101). Further, structural

MRI investigations underscore that the anatomy of the visual cortex in human albinism appears to be affected more strongly by the foveal hypoplasia than by the misrouting of the optic nerves (26, 102).

Maturation and aging of the visual system produce measurable changes reflected in visually evoked potentials. Neveu et al. (103) described dramatic differences in a population of albino human beings ranging from 8 months to 60 years. Visual acuity usually improves until adolescence due to physiological maturation, dampening of nystagmus, finding a favorable head position, and learning how to manage poor acuity, including perceptual cues (104-106).

Acuity is significantly diminished in most human albinos averaging from 20/80 to 20/200 with a wide range of 20/40 to 20/400. Nystagmus, usually horizontal, pendular or jerky in character is almost always present. A high incidence of strabismus is also seen in albinism including both horizontal and vertical misalignment (86, 107).

Contributing to differences in optic tract development are possible differences in axon sizes and myelination in the albino mammal's optic tract (108). When RGC axons go to the wrong side of the brain they may not myelinate properly. Myelination changes with age add weight to Neveu et al.'s (103) finding of age-related changes in VEP development.

9. Visual perception

Studies demonstrate that albino human beings do not fuse binocular stimuli (104, 109, 110). Few binocular cells are located in areas 17, 18 and 19 in Siamese cats and cats with complete albinism, disturbing the underlying anatomical connections for stereovision (111-113). Some individuals with albinism manifest coarse binocular fusion with some stereovision (114). In addition, while areas 17/18 of the Siamese cat do not contain binocular cells, the postero-medial lateral suprasylvian area (PMLS) includes binocular cells (115). The superior colliculus (SC) also possesses binocular cells (116). The corpus callosum possibly is an anatomical connection enabling some binocular vision (117-120). Stereovision may be accomplished through these cortico-cortical connections. Although stereovision is dramatically affected in albinos, spatial perception remains (94).

Adjustments improving perception appear to be made at each level as the anomalous visual information in albino visual pathways progress towards the cortex. In the albino cat the disaster at the level of the dLGN where only 46% of cells responded normally improves to 84% in cortical area 17, and to 70% of cells in cortical area 18 (121). The competence of the albino visual system improves greatly at the cortical level of cats and human beings (100) resulting in near-normal visual perceptual abilities within the limits of an individual's acuity.

In general the level of pigmentation of an albino correlates negatively with severity of expression of visual anomalies (73) (122). It is likely that the more pigment present in the retina, the more normally routed RGC fibers.

10. Genetic classifications of forms of human albinism

Current classification of forms of albinism is based on genetic locus. Figure 21 is a photograph of an individual with Type 1 oculocutaneous albinism. Chromosomal location has been identified for twenty forms of human albinism on twelve different chromosomes: oculocutaneous albinism (*OCA1-7)*, ocular albinism (*OA1*), nine forms of Hermansky Pudlak syndrome (*HPS1-9*), Chediak Higashi syndrome (*CHS*) and Griscelli syndrome (*GS*) (123, 124). An additional syndromic form of albinism to be added is the rare Vici syndrome (*VICIS*) (125-127). Phenotypic expression varies considerably within genetic forms of albinism, and even between siblings (128, 129). Many genes modify expression of albinism (130). For tyrosinase enzymes alone more than 100 mutations are involved in coding (see Albinism Database (http://www.ifpcs.org/albinism/index.html).

Visual abnormalities reported in albinism do not include disorders of hypopigmentation due to embryonic migration defects of neurons and pigment cells from the neural crest such as in Waardenburg syndrome and

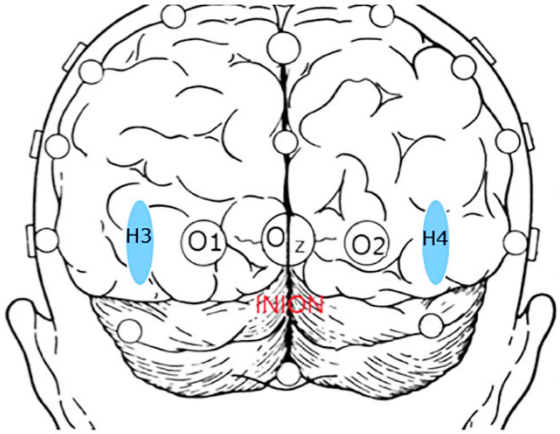

Figure 17. Schematic of occipital area indicating 10-20 International System scalp electrode locations highlighting locations H3 and H4.

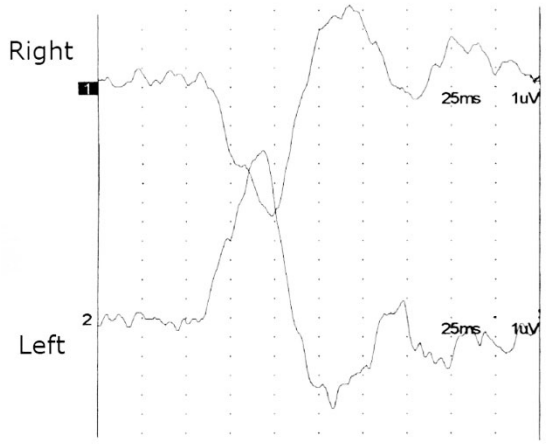

Figure 19. Pattern onset/offset visually evoked potentials recorded across occipital scalp from an albino showing the significant difference between Right and Left monocular simulation.

deaf white cat (*W* gene), vitiligo or piebald spotting, nor other forms of hypopigmentation such as phenylketonuria. These conditions do not exhibit the visual anomalies.

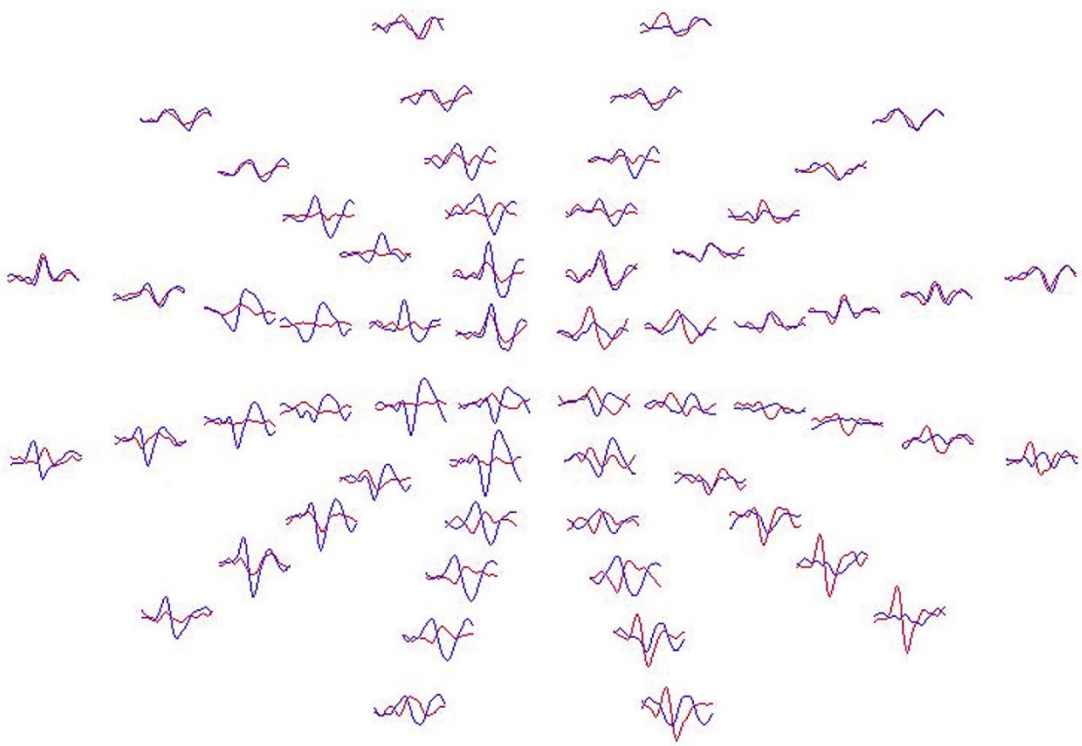

Figure 20. Multifocal visually evoked potentials recorded from a Type 1 human albino reflecting the central 35 degrees of visual field. Potentials that reverse in polarity indicate locations in temporal retina that retinal ganglion cells (RGCs) cross at the optic chiasm.

11. Exceptions to direct association with albinism

Recently a novel gene mutation on human chromosome 16 was described that is associated with foveal hypoplasia, optic-nerve-decussation defects, and anterior segment dysgenesis (FHONDA) in the absence of pigment deficits (131, 132). Current research addresses whether in this condition optic nerve misrouting is initiated by a mechanism that is independent of the one that is associated with the pigment deficit in albinism. While enhanced crossing of the optic nerves at the optic chiasm was previously viewed to be specific for albinism or related only to ocular pigment deficits there may be exceptions. FHONDA may be an important exception. A possible site of common determination of visual abnormalities in FHONDA and albinism could be the similar influences affecting optic anomalies in both such as genetic control by Sonic hedgehog (Shh), VSX2, PAX 2 and PAX 6.

There are reports of optic misrouting in human non-albinos such as some with Kartagener syndrome (133), and selected hypopigmented patients with Prader-Willi syndrome (134), with microdeletion at tyrosinase locus 15q11-13 superimposed on the most prominent albino sequence. The Kartagener syndrome loci, 15q24-25, are on same arm of chromosome 15q as the most prominent human albino sequence. Few individuals with the Kartagener syndrome show optic misrouting (135). Other exceptions are some individuals with congenital stationary night blindness (CSNB) reported to express optic misrouting (136, 137). Genetic loci for forms of CSNB range from chromosome Xp11 to Xp22 (138). These mutations are located on the same arm of X chromosome located Xp22. Some of these exceptions are possibly due to interaction with albino loci or a common feature to both of dysregulation within these sequences. Communication may be enhanced by noncoding DNA bridging the gap between nearby loci.

Figure 21. Type 1 oculocutaneous albino (OCA1).

12. Underlying mechanisms

Many studies were published pursuing a causal relationship between retinal pigmentation and determination of neuronal routing at the optic chiasm. No mechanism has been described that can be generalized across species and genetic loci. Prominent theories include the role of tyrosinase or its precursor DOPA as critical in the synthesis of melanin such as reporting addition of DOPA to albino eyes in vitro normalizes patterns of cell production (139). Ocular albinism (OA1) associated with a mutation of the GPR143 (G-protein-coupled receptor) gene on the X chromosome (Xp22.3) provides evidence of another possible function of DOPA. The GPR143 gene regulates melanin biosynthesis (140). The OA1 GPCR protein encoded by GPR143 gene was found to be a selective DOPA receptor, where both Dopamine and DOPA compete to bind at its site (141). DOPA function in the melanin pathway may also play a role in the downstream effects that affect the developing retina (142).

Other factors influencing ganglion cell targeting at the optic chiasm include, in different species, growth cone action, molecules, and regulatory genes including laminin, NCAM, L1 and cadherins (143). Evidence that Netrin-1 (144), Slit ligand molecules that are expressed at the optic pathway and their associated axon guidance receptors from the Roundabout (Robo) family (145), Sema5A (146), Sonic Hedgehog (Shh) (147), transcription factor 2 (Zic-2) regulated by Islet 2 in mice (148, 149), and EphrinB2 (EphB2) (150) are also suggested as impacting cell fate. The transcription factor visual system homeobox 2 (VSX2) probably also affects the retinal anomalies (151, 152). Many signals likely vary between species.

13. Vision and hearing

Vision and hearing have an ancient history of evolving in parallel traced back to the PaxB gene, which functions as a single gene controlling eye and hearing (mechanoreceptors) genesis in box jellyfish predating the later-appearing separate Pax 2 and Pax 6 genes (153). The continuity of SOX 21 was mentioned earlier (53). There are evolutionary connections between eyes and mechanoreceptors of the inner ear to the extent that during evolution, "sensory cells can shift their sensory modalities" (154).

There is a history of both functional integration and anomalous syndromes involving the visual and auditory systems such as Usher's Syndrome, which includes retinitis pigmentosa and congenital deafness. In spite of their differences in embryogenesis further similarities were recently described in retinal and inner ear hair cell physiology. The same Usher protein functions in retinal rod physiology and inner ear hair cell physiology (155, 156) and ribbon synapses are similar in structure and function in both photoreceptors and hair cells (157). Further metabolic roles of melanin in the inner ear, and the similarities of retinal and inner ear physiology are yet to be elucidated. Melanin pigment is located in the stria vascularis of the inner ear (158, 159). Figure 22 depicts a decalcified cochlea of pigmented guinea pig (A) displaying a band of melanin pigment (P) in the stria vascularis, and a section through a pigmented guinea pig cochlea (B) showing melanin pigment. Figure 23 is an enlargement of an area in a different guinea pig similar to that boxed in Figure 22B illustrating detail of pigment deposition. Melanocytes are adjacent to and wrap around capillaries in the stria vascularis.

In most mammals auditory cues mainly tell vision where to look (160, 161). Within each species spatial vision and auditory localization evolve in a coordinated manner. Analogous evolutionary and functional relationships exist in vision and audition. The second level termination of visual neurons is cortical including synapses with binocular cells, the substrate for binocular, stereo, and spatial vision. The second level neuron terminations in the auditory system are in the superior olivary complex where binaural cells receive input from each ear giving similar spatial information. The auditory space map in the brainstem is strongly related to the cortical visual space map (162). Visual and auditory spaces are connected to the extent that in human beings fMRIs depict more recruitment of visual cortex than auditory cortex when blind individuals perform auditory echo localization (163).

Albino mammals are not hearing impaired, per se. The auditory and visual deficits in albino mammals are connected in that similar anomalies are present in processing the highest-level integration of spatial localization.

Auditory anomalies are reported in albino mammals. The absence of melanin pigment in the inner ear of albinos is associated with susceptibility to noise damage (164, 165). In human beings and animal models prolonged sensitivity to noise measured as a longer temporary threshold shift (TTS) following exposure to loud sounds is documented (166-168). Cell size and dendritic length in the medial superior olivary nucleus is reduced in albinos (167, 169). Functionally the reduced cell size in brainstem olivary nuclei was associated with reduced binaural cell responses in medial superior olive of albino cats (170). One study demonstrated reduced ipsilateral projections from the cochlear nuclei in hypopigmented ferrets (171).

The auditory brainstem response (ABR) is an auditory version of a visually evoked potential except the generators measured end at the level of the superior colliculus. Auditory brainstem responses are recorded by placing a positive electrode on top of the head at 10-20 International System position Cz. A negative pole electrode is placed on ipsilateral earlobe or mastoid. Often the contralateral earlobe or mastoid is used for ground location. Click stimuli at one or more intensity approximately 70 dB above hearing level threshold (HL) are presented to one ear at click rates of 10 or more per second. Potentials appearing in the first 10 milliseconds evoked by about 2,000 clicks are averaged. Audiologists record a more complicated sequence using several click intensities, tones bursts, and bone conduction testing to evaluate hearing.

A feature of the ABR is that in addition to anomalies in the auditory brainstem pathways, alterations in adjacent brainstem structures such as cranial nerve nuclei IV to VII are often detected. The ABR is of use locating etiology of ocular and facial movement disorders such as Duane's retraction syndrome, Marcus-Gunn ptosis, blepharospasm, facial cranial nerve palsies, and is a common site of demyelination in patients with multiple sclerosis. Another feature of the ABR is the first five peaks, I – V, are associated with the level of the brainstem generating each component.

A sample human ABR is depicted with generators labeled in Figure 24. ABRs of most mammals contain 5 or more components in the first 6 milliseconds following click stimuli. ABRs of some rodents include a double component III due to separate medial and lateral olivary nuclei generators. A variant in some human ABRs is coalesced components IV and V into one wave. In albino human beings and animal models component III of ABRs are attenuated. These are generated in region of the medial superior olivary nuclei reflecting the reduced neuronal size and dendritic length in albino mammals (32, 167, 169, 172). Figure 25 illustrates sample abnormal ABRs in a Type 1 oculocutaneous human albino with components III – IV attenuated in amplitude.

14. Eye Movement: Albinism, Dissociated Vertical Deviation, Latent Nystagmus

Adjacent to the brainstem auditory centers are the nuclei integrating sensory input including the superior colliculus and other nuclei involved in eye alignment and fixation. Abnormal proportions of ipsilateral RGCs in albino mammals include reduced RGCs to mid-brain nuclei that contribute to strabismus, nystagmus, and atypical optokinetic nystagmus in albino mammals. In albino guinea pigs, rabbits and ferrets there are no ipsilateral optic projections to the ventral lateral geniculate nucleus (LGNv), superior colliculus (SC), pretectum, nucleus of the optic tract (NOT) or accessory optic system (AOS) (173-175).

In the normally pigmented cat about 50% of RGCs project via the LGN to the ipsilateral cortex. 24% of RGCs originating in temporal retina project to the ipsilateral superior colliculus (176), and about 15% of RGCs project to the ipsilateral pretectum (177). The albino cat has very few ipsilateral projections to the pretectum and almost no ipsilateral projections to superior colliculus (31). All albino cats have nystagmus and many have strabismus.

Several types of aberrant optokinetic nystagmus (OKN) are described in human albinos (178-180). The nuclei responsible for the OKN are the terminal nuclei of the accessory optic system: the dorsal terminal nucleus (DTN), lateral terminal nucleus (LTN), medial terminal nucleus (MTN) and the Nucleus of the Optic Tract (NOT). Figure 26 depicts the rat and rabbit accessory optic system showing the connections of the medial terminal nucleus (MTN) (181). Figure 27 illustrates the accessory optic system (AOS) projections from the lateral terminal nucleus (LTN) of a primate, the Marmoset.

Albinism in mammals is associated with most RGCs crossing in the optic chiasm. Few RGCs project to the ipsilateral side ultimately projecting to the cortex and brainstem. The optic chiasm plays a pivotal role in human binocularity. Hemidecussation in the optic chiasm dictates the nasal retinal ganglion cells to cross to the other side of the brain, and temporal retinal ganglion cells to stay on the same side of the brain. Retinotopy directs ganglion cells, one nasal and one temporal from each eye, to pair up at the cortex. In this way each pair finally drives one binocular cell in the visual cortex. Besides hemidecussation in the optic chiasm, the corpus callosum and commissural connections in the brainstem are essential building blocks of mammalian binocularity. Identical binocular retinotopic loci on both sides of the cortex are connected through the corpus callosum. These connections facilitate fusion of the eyes, and the right and left visual hemifield (182, 183). Albinism, characterized by a substantial reduction in ipsilateral projections of RGCs in the optic chiasm, and poor binocularity, results in less coordination and loss of association between the eyes, and infantile strabismus occurs. Dissociated Vertical Deviation (DVD) and Latent Nystagmus (LN), both occurring in infantile

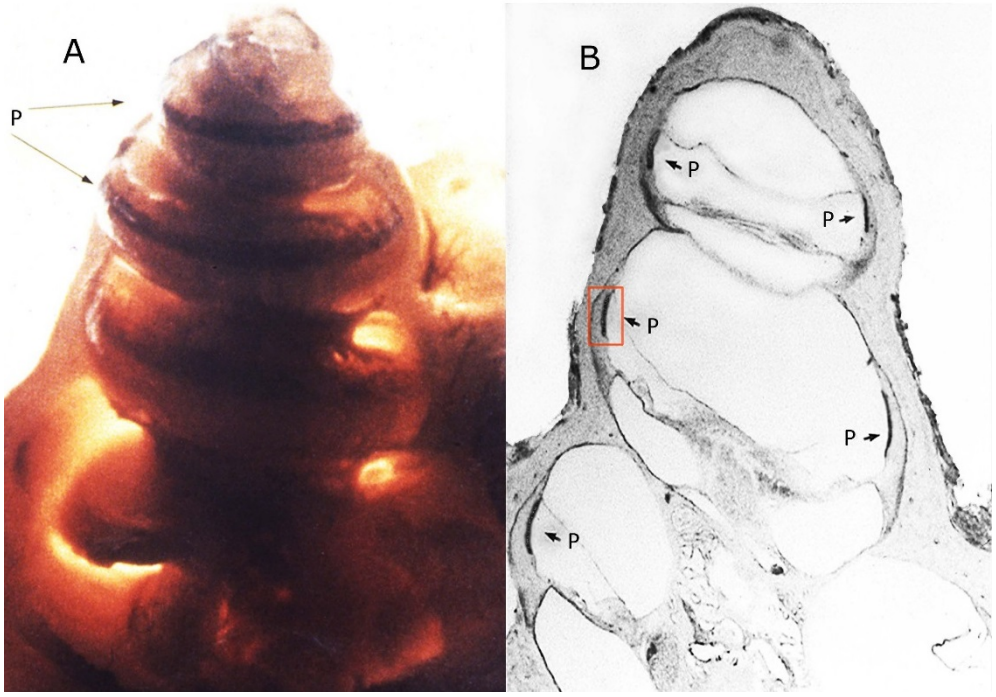

Figure 22. Decalcified guinea pig cochlea (A) and sagittal section (B) through a guinea pig cochlea show deposition of melanin pigment (P) in stria vascularis Red boxed area enlarged in Figure 23.

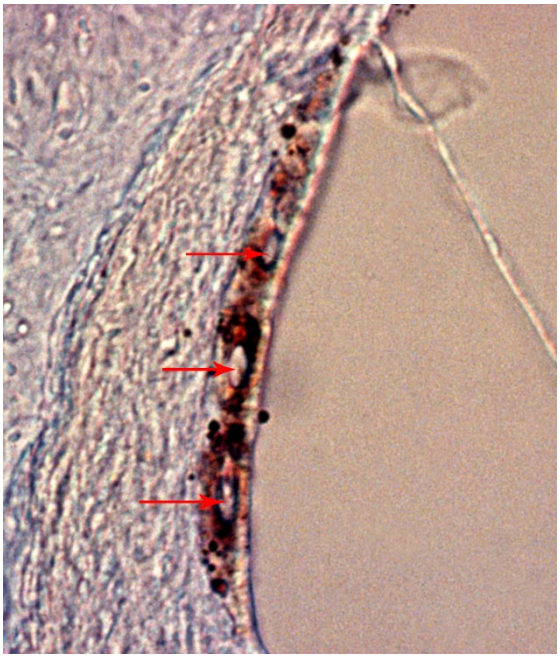

Figure 23. Red-boxed area in Figure 22 enlarged showing melanin deposition adjacent to capillaries indicated by red arrows. From Conlee et al., 1989 (158).

strabismus, are characterized by binocular motor dissociation. The co-occurrence of both DVD and LN in albinos suggests a common dissociative origin (182).

There are several theories rooted in the argument that older evolutionary connections dominate during the first several months of human infancy before cortical pathways have matured. Michael C. Brodsky and colleagues propose atavistic reflexes of the accessory optic system generate the dissociated eye movements associated with

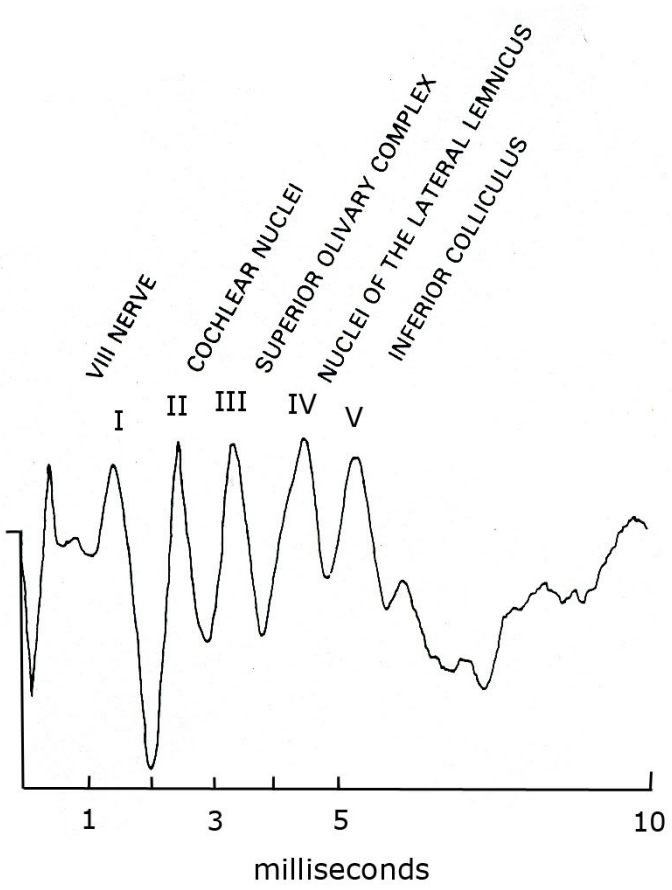

Figure 24. Auditory brainstem response (ABR) recorded from pigmented human being at click intensity of 70 dB HL and rate of 11.9 per second.

infantile strabismus (184-187). They argue that when foveal vision develops slowly in early infancy, the phylogenetically older optokinetic system prominent in lateral-eyed vertebrates that is expressed in first 2 months of infancy continues to be expressed. Monocular, subcortical, nasotemporal optokinetic asymmetry normal in lateral-eyed vertebrates is suppressed in human beings with cortical binocular vision. They suggest cases of possible infantile nystagmus may be due to genetically determined maturational delay in development of cortical binocular vision allowing phylogenetically older pathways to dominate; "[hypothesizing] that the oculomotor disturbances of infantile strabismus correspond to subcortical binocular visual reflexes that are operative in lateral-eyed animals."; and that the vestibulocerebellum actively contributes to generating infantile nystagmus (184).

Marcel ten Tusscher also proposes a fall back to older evolutionary connections including the corpus callosum, lateral geniculate nucleus, lack of normal binocularity at the cortex, and subsequent loss of binocular input to the subcortical centers including the superior colliculus (182, 188-191).

The evolution of the eye and the brain provides a possible explanation for both the anomalous eye movements in albino mammals, and the dissociation of infantile esotropia and its motor characteristics. In the course of evolution, the eyes moved from a lateral to a frontal position. In 300 million years, modern mammals, birds and reptiles evolved from a common ancestor, the captorhinidea (192, 193). Consequently, the monocular visual fields progressed forward on the head to overlap resulting in a binocular visual field. In lateral-eyed animals, the retinae project to the contralateral visual cortices only. These projections are also found in binocular mammals and birds with binocular visual fields. In binocular mammals there are also uncrossed projections from the

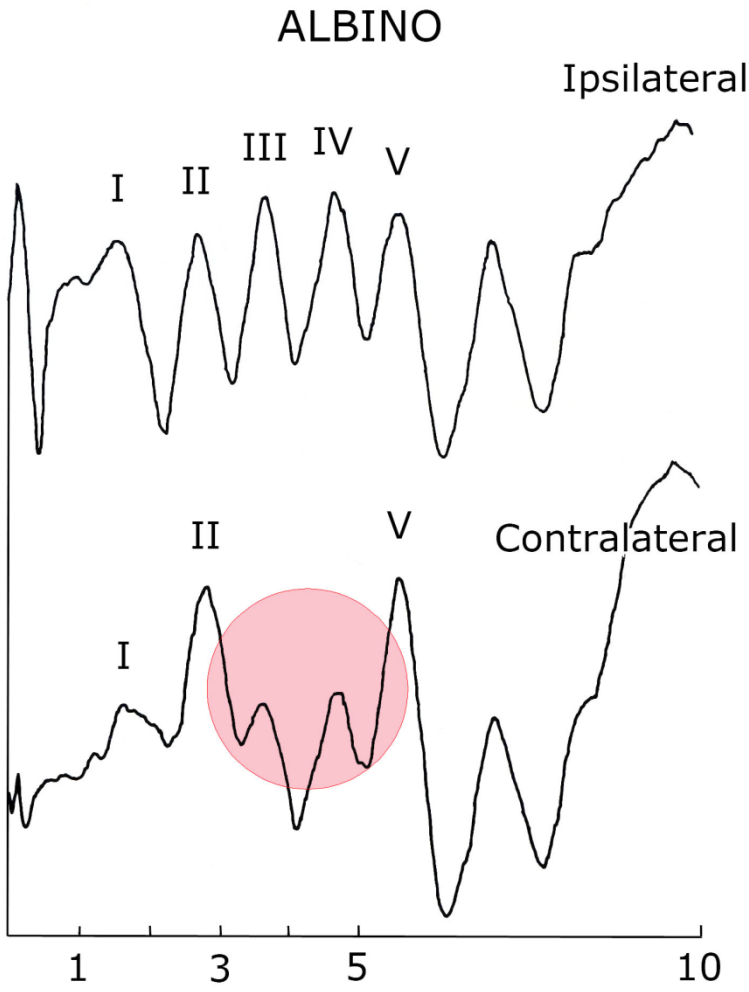

Figure 25. Auditory brainstem response (ABR) recorded from a Type 1 oculocutaneous human albino (OCA1) showing attenuated component III in contralateral ABR. From Creel et al., 1980 (172).

temporal retinae to the visual cortex. Partial chiasmal decussation and the corpus callosum provide the necessary connections for binocular vision to develop (194). Disruption of normal binocular development causes a loss of binocularity in the primary visual cortex and adjacent areas. Outside the primary visual cortex, the contralateral eye dominates while the temporal retinal signal appears to lose influence.

Complete motor dissociation between the eyes often results from sensory dissociation between the eyes. In human achiasma, where all retinal nerve fibers project to the ipsilateral cortex, saccades are executed monocularly. Dissociation with monocular saccades also occurs in animals with lateral eyes, e.g. reptiles. Retinal ganglion cells in these species show 100% crossing in the optic chiasm.

Eye movements in animals with laterally-located eyes are intended to stabilize the visual environment. The vestibular ocular reflex compensates for body movements and the optokinetic reflex compensates for optic flow. Motion sensitive neurons in the retina project to the contralateral brainstem, i.e. the terminal nuclei of the accessory optic system (Figure 27) that comprise the afferents of the optokinetic reflex. The nucleus of the optic tract (NOT) is one of these nuclei. The right NOT senses horizontal movement to the right, and the left NOT senses movement to the left. The major target of the optic tract in lateral-eyed animals, however, is the superior colliculus that is responsible for directing gaze movements and sensory integration. Similar neuroanatomical pathways and eye movements also exist in human beings. Human beings, in addition, demonstrate saccades,

pursuit and vergence, all of which are initiated by the visual cortex, not the brainstem. The retinal ganglion cells partially decussating in the optic chiasm are one of the evolutionary solutions for combining information from frontal eyes, enabling a correlated binocular signal in the visual cortex. The binocular human cortex ties the temporal retina of one eye together with the nasal retina of the fellow eye. Binocular visual experience overrules the brainstem through an ipsilateral signal directly from the retina, but even more so, via the visual cortex. The optokinetic reflex interacts with the pursuit system, while the superior colliculus (SC) interacts with the saccade and vergence systems (182).

Newborn children have smooth nasally directed monocular pursuit and impaired temporal-directed pursuit (195). At birth, the eye is controlled by the contralateral nucleus of the optic tract (NOT) (196). The right nucleus of the optic tract senses movement to the right, the left nucleus to the left. The newer pathways (ipsilateral from retina to nucleus of the optic tract (NOT), and the more abundant cortical projection to the NOT are activated through binocular visual experience. When the primary visual cortex does not receive realistic binocular input from both eyes the crossed older pathway dominates. The corticotectal pathway is dominated by the contralateral pathways (196, 197). Van Rijn et al. (198) showed that the same mechanism responsible for LN might be true for DVD (Figure 28). DVD combines vertical vergence with binocular torsional version. The elevating eye shows excyclotorsion while the fixating eye shows incyclotorsion. Van Rijn et al. (198) measured eye movements in DVD and showed that these movements are similar to the eye movements in disparity-induced vertical vergence. They suggested that, like LN that likely results from dissociation in the optokinetic /pursuit pathways, DVD might result from dissociation in the vergence pathways (190, 198). In LN the optokinetic pathway is driven by the signal that originates in the crossed retinal ganglion cells due to sensory dissociation, and less so the uncrossed cortical influence on the NOT in the brainstem. DVD likely is a supranuclear cortical problem of the pathways responsible for vergence originating in the crossed retinal ganglion cells due to sensory dissociation and less binocular cortical influence on the brainstem level (190).

DVD appears as a result of inhibition of the uncrossed temporal retinal signal. Beyond the primary visual cortex and the reciprocal connection of the callosum, a biased cortical activation leads to corticotectal stimulation dominated by the nasal retina. Figure 28 depicts the neuroanatomical summary of the pathways involved in DVD projection from nasal retina of the contralateral eye that dominate the superior colliculi in infantile strabismus. With occlusion of the left eye, the nasal bias in ocular dominance in the visual cortex in a patient with infantile strabismus gives rise to dominance of the left visual cortex and the left corticotectal pathway. The left superior colliculus (SC) projects to the left interstitial nucleus of Cajal (INC) and the right omnipause (OPN) neurons that results in elevation of the left eye and counterclockwise cycloversion. The pathway from the superior colliculi (SC) to the interstitial nuclei of Cajal (INC) links the two dimensional cortex and superior colliculus to the three dimensional brainstem. A monocular vertical signal leads to torsional vergence, DVD.

Partial decussation in the optic chiasm appears to be only one of the components important for binocularity. In rodents, e.g. the rat, with 95% crossing in the optic chiasm binocularity of the visual cortex depends on the combination of a signal from the contralateral eye through the geniculate pathway, and a signal from the ipsilateral eye to the contralateral geniculate and back through the corpus callosum. But even in cats that have substantial hemidecussation at the optic chiasm, transection of all crossing retinal ganglion cell axons in the optic chiasm appears not to affect most kinds of disparity (183). In mammals without partial decussation in the optic chiasm and without a corpus callosum, like marsupials, e.g., the wallaby, binocularity is still demonstrated in brainstem neurons (199). Binocularity appears to depend on commissural connections between both superior colliculi and between the nuclei of the optic tract. So, mammalian binocularity includes information provided by 1) partial decussation in the optic chiasm, 2) the corpus callosum and 3) commissural connections in the brainstem (182).

A high percentage of both infantile exotropia (67%) and esotropia (49%) patients were found to have a coexisting ocular or systemic abnormality (200). Agenesis of the corpus callosum underlines the importance of

the corpus callosum for normal binocular fusion. Strabismus is found in 46% of patients with partial agenesis of the corpus callosum (201). Moreover, hemispherectomy early in life often causes strabismus (202). Hemidecussation in the optic chiasm allows retinotopic matching between the nasal and the temporal retina. In albinism, many RGCs originating in temporal retina project to the contralateral LGN then to contralateral visual cortex. The border between crossed and uncrossed ganglion cell fibers in most human albinos appears to vary from point of fixation to 6–14 degrees into the temporal retina. Besides prominent misrouting in the chiasm, as in albinism, or agenesis of the corpus callosum, more subtle misrouting may cause a mismatch between temporal and nasal signals or between the direct thalamic and the indirect corpus callosum signal. Also the vertical meridian of one retina may not coincide with the overlapping zone of the other eye. In a primate study, the retinal vertical meridian in one of three monkeys was found not to coincide with the fovea (203).

Both esotropia induced by prisms or surgery in the sensitive postnatal period, and infantile esotropia change the binocular response of neurons in the primary visual cortex dramatically. After early surgically induced strabismus, neurons in the primary visual cortex, area 17, of kittens were found to be responsive to one eye only. An approximately equal representation of both eyes was found in both hemispheres. These results have often been confirmed, although a small bias of the non-operated eye in the ocular dominance columns sometimes occurred. Also most cortical neurons distal to area 17, the extrastriate cortex, could exclusively be triggered by one eye. An equal representation of both eyes is not found in the extrastriate cortex. The large majority of neurons in, for example, area 18, respond to the contralateral eye exclusively. In contrast to this huge contralateral dominance, only a slight dominance of the non-operated eye was found. In electrophysiological studies cortical neurons representing the temporal retina were found to be unresponsive to a stimulus from the squinting eye. In the early postnatal period, crossing nasal retinal afferents were found to be far less vulnerable than temporal uncrossed retinal afferents (204).

Crossed retinal dominance beyond the primary visual cortex appears to explain Dissociated Vertical Deviation and Latent Nystagmus, however, the cause of DVD is often explained differently. In a 2014 overview of a symposium on dissociated vertical divergence (DVD), Christoff et al. (185) discussed two popular theories on the origin of DVD: a hypothesis that suggests that DVD results from damping of latent nystagmus (LN), and another theory that postulates an atavistic origin: a righting reflex in fish.

Ten Tusscher argues the co-occurrence of both DVD and LN in infantile strabismus may well suggest a common dissociative origin, or perhaps one of these phenomena may be the result of the other. It is postulated to be the latter because damping of latent nystagmus occurs after the start of vertical divergence in DVD. However, DVD is more frequent than latent nystagmus. Moreover, DVD is a unique binocular cyclovertical eye movement. It is suggested to occur in order to suppress a horizontal eye movement and only if this movement is latent. Why does it not occur in manifest latent nystagmus and why not in congenital nystagmus? ten Tusscher argues the righting reflex observed in fish as the origin of DVD is less likely (190, 191). They argue the righting reflex is a postural reflex, not an ocular one and is orchestrated by the torus longitudinalis and the valvula cerebelli, and that both of these have no analogue in the human brain. Moreover, during a righting reflex the eye that is illuminated most, will move downward and the other upward. In DVD, however, blinding an eye by light will cause an upward movement of the blinded eye (the Bielschowsky phenomenon). Also, in contrast with the righting reflex, DVD is influenced by blur and by fixation. DVD combines vertical vergence with binocular torsional version. The elevating eye shows excyclotorsion while the fixating eye shows incyclotorsion. Early research measured eye movements in DVD. DVD characteristics appeared similar to the eye movements in disparity-induced vertical vergence (198).

Albinism is an example that sensory dissociation may be the result of a change in chiasmal decussation. Dissociated Vertical Deviation (DVD) and Latent Nystagmus (LN), are characterized by binocular motor dissociation with a common dissociative origin. Brain pathology may cause sensory dissociation, which may subsequently lead to motor dissociation. The binocular link between the cortex and the brainstem nuclei like the

NOT and the superior colliculus, is a key element in the origin of motor dissociation in infantile strabismus. In primates with infantile strabismus, the visual cortex beyond V1 is dominated by the crossed retinal signal. The equilibrium between the crossed and the uncrossed signal is not established. The brainstem is deprived of normal binocular input. This causes the NOT and superior colliculus to be driven mostly by the contralateral eye (Figure 28). If an eye is connected mostly to the contralateral NOT it will be more sensitive to motion directed towards the nose. This asymmetry causes latent nystagmus during monocular viewing. Fixation, saccades and vergence rely on the information from visual cortex to the superior colliculus. Loss of uncrossed retinal signal to the superior colliculus causes the upward movement of the eye. Cortical deactivation of this system causes Bell's phenomenon and the upward movement of the eyes during the early stages of general anesthesia that is related to the loss of cortical influence. The two dimensional cortex and superior colliculus are connected to a three dimensional brainstem. Vertical eye movements are associated with torsional movements by way of a pathway from the superior colliculus to the contralateral interstitial nucleus of Cajal (191, 205). If the contralateral eye dominates the cortical information to the superior colliculus, vertical vergence and torsional version (DVD) result.

If all features of infantile strabismus can be explained with a general principle based on proven changes in primate neuroanatomy, ten Tusscher suggests Occam's razor applies; and there is no reason to explain one of its features with a body reflex with characteristics different from DVD originating from the fish brain that phylogenetically bears little relationship to the primate brain, or assume it arises to facilitate viewing during occlusion of one eye. It follows that sensory dissociation beyond V1, most likely due to active suppression by the older evolutionary crossed pathway (crossed retinal dominance) leads to the eye movement dissociation that is typically seen in the infantile strabismus syndrome.

15. Creel theory

The Creel theory proposes that the lack of melanin pigment initiates atavistic expression of visual and auditory embryogenesis. In albino mammals' embryogenesis vision and hearing take an analogous step back. Visual anomalies in albino mammals, including human beings, represent a developmental field defect that occurs as a normal developmental state in closely related species (206). As pointed out by Meckel (207), primary malformations, in this case complete optic decussation, are not aberrant. Complete decussation of retinal ganglion cells at the optic chiasm is a conventional ancestral state in non-mammalian vertebrates, and reduced non-decussated optic fibers are the norm in ancestral mammals.

In an embryonic environment, neural stem cells, lacking positive signals to progress, transition into more primitive neural precursor cells (208). Melanin pigment in the nascent retina, or likely genetic coding for melanin pigment, is the positive inductive signal launching normal retinal development and retinal ganglion cell targeting. When retinal melanin is reduced, retinal embryogenesis defaults to the conserved genetic package existing when the species first evolved with a cascade of consequences.

The vertebrate genome includes coding of genetic past. Charles Darwin (209) popularized atavism as the term for reappearance of ancestral characteristics in future generations. Most atavistic expression is probably not random, but due to an error in early embryonic environment triggering expression of genes conserved across evolution. Actuating atavistic optic misrouting likely includes several possible events.

Mammals retain the evolutionary base instruction package for complete crossing of the retinal ganglion cells in ancestral vertebrates, and little genetic information re area centralis development, foveal, or vascular sparing of the foveal area. As each mammalian species or subspecies branched off and went their own way the genetic control of visual and auditory system development evolved to fit the environment of the species, revising embryogenesis that existed at the time the species became independent.

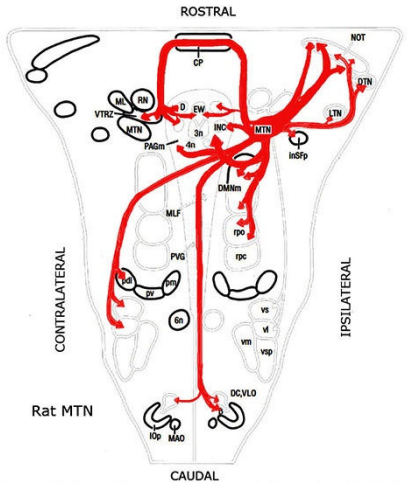

Figure 26. The efferent projections in the rat and rabbit of the medial terminal nucleus (MTN) are depicted. The plane of this figure is horizontal. Arrows depict projections of the MTN. (Re-labeled with permission from Giolli et al., 2006 (181).

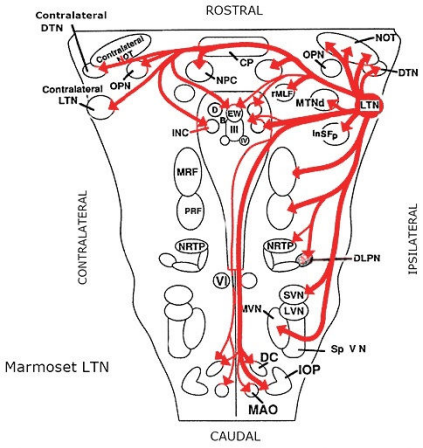

Figure 27. Diagram of the projections from the lateral terminal nucleus (LTN) in the marmoset. The illustration depicts a horizontal plane. (Re-labeled with permission from Giolli et al., 2006 (181).

The essence of this theory is that retinal melanin pigment is so fundamental to retinal, vascular, and early retinal ganglion cell targeting that insufficient retinal melanin triggers a switch resulting in the conventional genetic instructions not to be completed. Mammals with nondecussating retinal ganglion cells are genetically unstable. In albinos genetic instruction defaults to the simpler, more entrenched, platform. An atavistic expression of the conserved, more stable, genetic platform skewed toward complete crossing of retinal ganglion cells at the chiasm, and commensurate visual and auditory anomalies, develops consistent with genetics of each species' evolutionary origin.

A genome is not comprised of independently functioning loci on chromosomes, but an interactive compilation of coded instructions that reacts to alterations in the genome. The inductive signals for entirely crossed optic fibers are conserved in mammals. The atavistic fallback to this morphology is an easy misstep because of the phylogenetically recent development of the temporal retina, vascular sparing in macula, and foveal development in primates. As suggested by Gehring (210) regarding early evolution of eyes, morphogenetic pathways are progressively being modified by intercalation of novel genes. Phylogenetically late genetic addendums to conserved instructions are vulnerable to not being expressed if genetic cues, such as sufficient retinal melanin

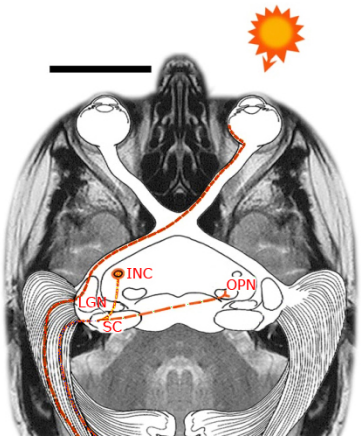

Figure 28. Neuroanatomical summary of the pathways involved in dissociated vertical deviation (DVD). (Redrawn with permission from ten Tusscher, 2014 (182).

pigmentation, are not present to support variation from highly conserved coding. Coding for reduced pigment in the retina also possibly disrupts silencing of ancestral genes, which dictate complete decussation of optic neurons and more primitive vascular and retinal development.

Diseases of the Eye and Retina

Retinal Degeneration, Remodeling and Plasticity

Bryan William Jones, Ph. D.,[1,*] Robert E. Marc, Ph. D.,[2,†] and Rebecca L. Pfeiffer, B.A./B.S.[3,‡]

Created: October 28, 2016.

1. Introduction

Retinal degeneration and remodeling encompasses a group of pathologies at the molecular, cellular and tissue levels that are initiated by inherited retinal diseases like retinitis pigmentosa (RP), genetic and environmental diseases like age-related macular degeneration (AMD) and other insults to the eye/retina including trauma and retinal detachment. These retinal changes and apparent plasticity result in neuronal rewiring and reprogramming events that include alterations in gene expression, de novo neuritogenesis as well as formation of novel synapses, creating corruptive circuitry in bipolar cells through alterations in the dendritic tree and supernumerary axonal growth. In addition, neuronal migration occurs throughout the vertical axis of the retina along Müller cell columns showing altered metabolic signals, and retinal pigment epithelium (RPE) invades the retina forming the pigmented bone spicules that have been classic clinical observations of RP diseases.

Retinal photoreceptors drive signal processing networks in the neural retina comprising bipolar, horizontal, amacrine and ganglion cells. It has been historically thought that retinal degenerative diseases such as RP affect the sensory retina, leaving the neural retina relatively unscathed. This is incorrect as the resulting loss of rod and cone input to the neural retina constitutes deafferentation and remodeling at the cellular and molecular level becomes unavoidable (1-22) .

Retinal degenerative diseases have a number of potential initiating events that result from naturally occurring disease processes (23), trauma like retinal detachment (24, 25) or any of the forms of retinitis pigmentosa (5, 23, 26, 27), but regardless of cause, if photoreceptors are lost, particularly cones, a sequence of progressive events is initiated that induces negative plastic remodeling of the neural retina (9-11, 14, 15, 21, 22, 28, 29). Essentially every disease process that results in photoreceptor loss triggers retinal remodeling as the final common pathway culminating with cell death and topological restructuring of the retina. The progression of retinal remodeling is like the negative plasticity that occurs in CNS pathologies like trauma and epilepsy and constitutes substantial impediments to rescue strategies of all types.

2. Phases of retinal remodeling.

Retinal remodeling occurs in phases: In *Phase 1*, photoreceptor stress initiates early remodeling & reprogramming events. In *Phase 2*, microglia, Müller glia and RPE cells become involved. Outer nuclear layer (ONL) thinning/ablation occurs and cell stress pathways are engaged, while Müller cells begin sealing the retina off from the choroid. In *Phase 3*, de novo neurite formation, rewiring and neuronal death start a process that continues to progress with neuronal translocation and massive topological restructuring of the retina. We will

show in this chapter that all retinal degenerative diseases examined to date including natural, crafted and induced models demonstrate remodeling to some extent and the severity of the negative plasticity depends upon coherency of insult and whether cones survive. Additionally, the early retinal remodeling is often clinically occult and occurs prior to any notable clinical fundoscopic imaging.

3. Age-related macular degeneration (AMD).

In contrast to normal retina (Figure 1), AMD presents with another set of clinical findings including fundoscopic drusen or yellow spots as well as areas of chorioretinal atrophy seen in dry AMD also called geographic atrophy (GA) (Figure 2). The disease is progressive, as seen in Video 1.

Histological presentations of AMD show drusen development in dry AMD that appears to induce photoreceptor cell stress and loss (30). Wet AMD is another disease process entirely that results in death of photoreceptors due to blood vessel development and leakage of blood and serum into the neural retina. This sub retinal blood can also result in RPE detachment that can have its own retinal degenerative mechanisms as well as direct retinal death.

Clinically, patients with dry AMD will often complain of difficulty seeing at night or in dark environments, and of needing brighter lights to work with. They report problems with decreases in color saturation and increases in blurriness of printed words or images in the central part of their vision. Vision deficits progress until there are distortions in the central visual field and ultimately blindness as the degenerative process progresses.

While most of the discussion in this chapter will focus on Retinitis Pigmentosa (RP), it should be noted that the terminal phases of retinal remodeling discussed above and the plasticity and remodeling that will be elaborated on below also occur in AMD, particularly dry forms of AMD (30).

4. Retinitis pigmentosa (RP)

RP is a progressive, genetic, neuro-degenerative disease that typically begins in the periphery and progresses to the center of the retina. There are many different forms of RP with a variety of initiating etiologies including defects in the retinal pigment epithelium, defects in rhodopsin processing and trafficking, defects in rhodopsin stacking, defects in the cilia and many others. RP comes in 3 main categories that include rod-degenerative, mixed rod/cone degenerative and debris-associated forms like mertk defects, and models like the light damage models in albino mice/rats. Regardless of the initial insult, the outcome is the same: photoreceptors undergo stress and subsequent cell death, which effectively deafferents the neural retina, resulting in neural remodeling events that alter the topologies and circuitry of the neural retina.

The clinical sequelae depend upon the broad category of RP involved. Initially, the rod/cone dystrophies manifest with complaints about night blindness beginning in the teenage years or early 20's. Changes in the electroretinogram (ERG) can often be observed prior to fundoscopic findings, most notably in the X-linked form of RP as rods begin to undergo stress and cell death. This reveals a fundamental finding: Photoreceptor function is altered or impaired prior to photoreceptor cell death and gross alterations in the histology become evident. Glutamate channel permeation studies with 1-amino-4-guanidobutane or agmatine (AGB) in early degenerate retina also support this finding by documenting alterations in subpopulations of bipolar cells and glutamate channel expression before loss of bipolar cell populations (22, 31).

By the time the classic fundoscopic image (Figure 3) appears, retinal degeneration is advanced, many cell populations have been dramatically altered or lost, and Müller cells have become hypertrophic, acting as highways for neuronal translocation as well as pigment translocations into the inner retina from the RPE (22, 31).

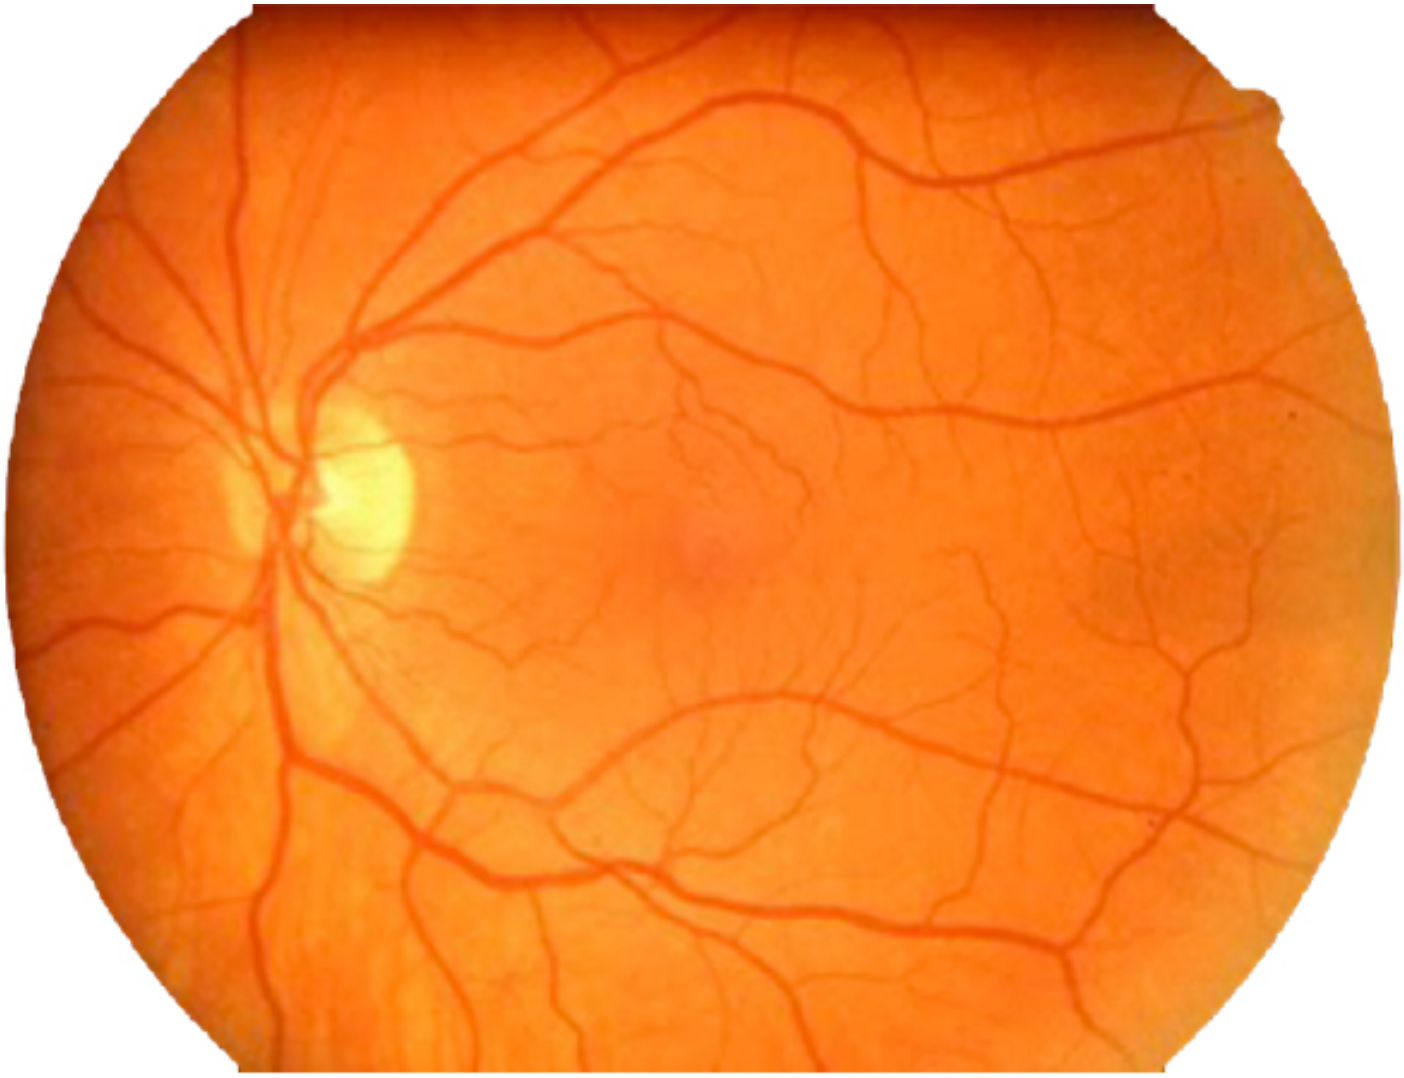

Figure 1. Normal funduscopic examination of a human eye. The clinical picture of retinal degeneration varies depending upon the insult. Above is a standard funduscopic image showing the optic cup, optic disc, fovea, macula, arteries and veins. We see normal color, pigment and vascular distribution.

Pigmented bone spicules in retinitis pigmentosa are accumulations of pigment granules from the RPE that have been coalesced into ribbons and clumps and pulled down into the neural retina. Figure 4 is a backlit and magnified image of a globe and intact retina that is focus stacked to illustrate the structure of pigmented bone spicules in an intact globe.

When you consider how the pigmented bone spicules form, the status of other classes of cells in the retina becomes a question. This is particularly true in advanced cases of RP that are being proposed for bionic and biological interventions that we'll discuss at the end of this chapter. (See also the Webvision section on Visual Prosthesis). Visual science has been examining the histology of retinal degenerative diseases for some time and there have been lots of descriptions made, yet somehow important features have gone missing or were briefly discussed, then forgotten. In 2010 Jaissle et. al. (32) looked at how pigmented bone spicules form in the rhodopsin knockout mouse model rho-/- and concluded that RPE pigment granules migrate along blood vessels. However, we now know that Müller cells act as conduits of migration that are seen not only in the rho-/-, but in many other models as well.

Considering Figure 4 and the obvious changes to retinal topology that are demonstrated in late stage RP, the condition of individual cell classes in the retina as well as their connectivities comes into question. If you do an

Figure 2. Funduscopic image of classic drusen seen in AMD in human eye. AMD presents with another set of clinical findings including funduscopic drusen or yellow spots as well as areas of chorioretinal atrophy seen in dry AMD also called geographic atrophy (GA).

Download video

accounting of the types of cells that make up a retina, you find upwards of ~82-84 classes of cells that might each be affected in different ways in degenerate retina. Nominally, we have 1 transport epithelium class, the RPE cell, 3 photoreceptor cell classes composed of 2 cone photoreceptor classes and 1 rod photoreceptor class, 2 glial cell classes: Müller cells and Astrocytes, 2 horizontal cell classes (1 horizontal cell class in the mouse eye in Figure 5), 2 vascular cell classes, 35 amacrine or association cell classes, 10 bipolar cell classes, 1 immune cell class and 18-20 ganglion cell classes (19).

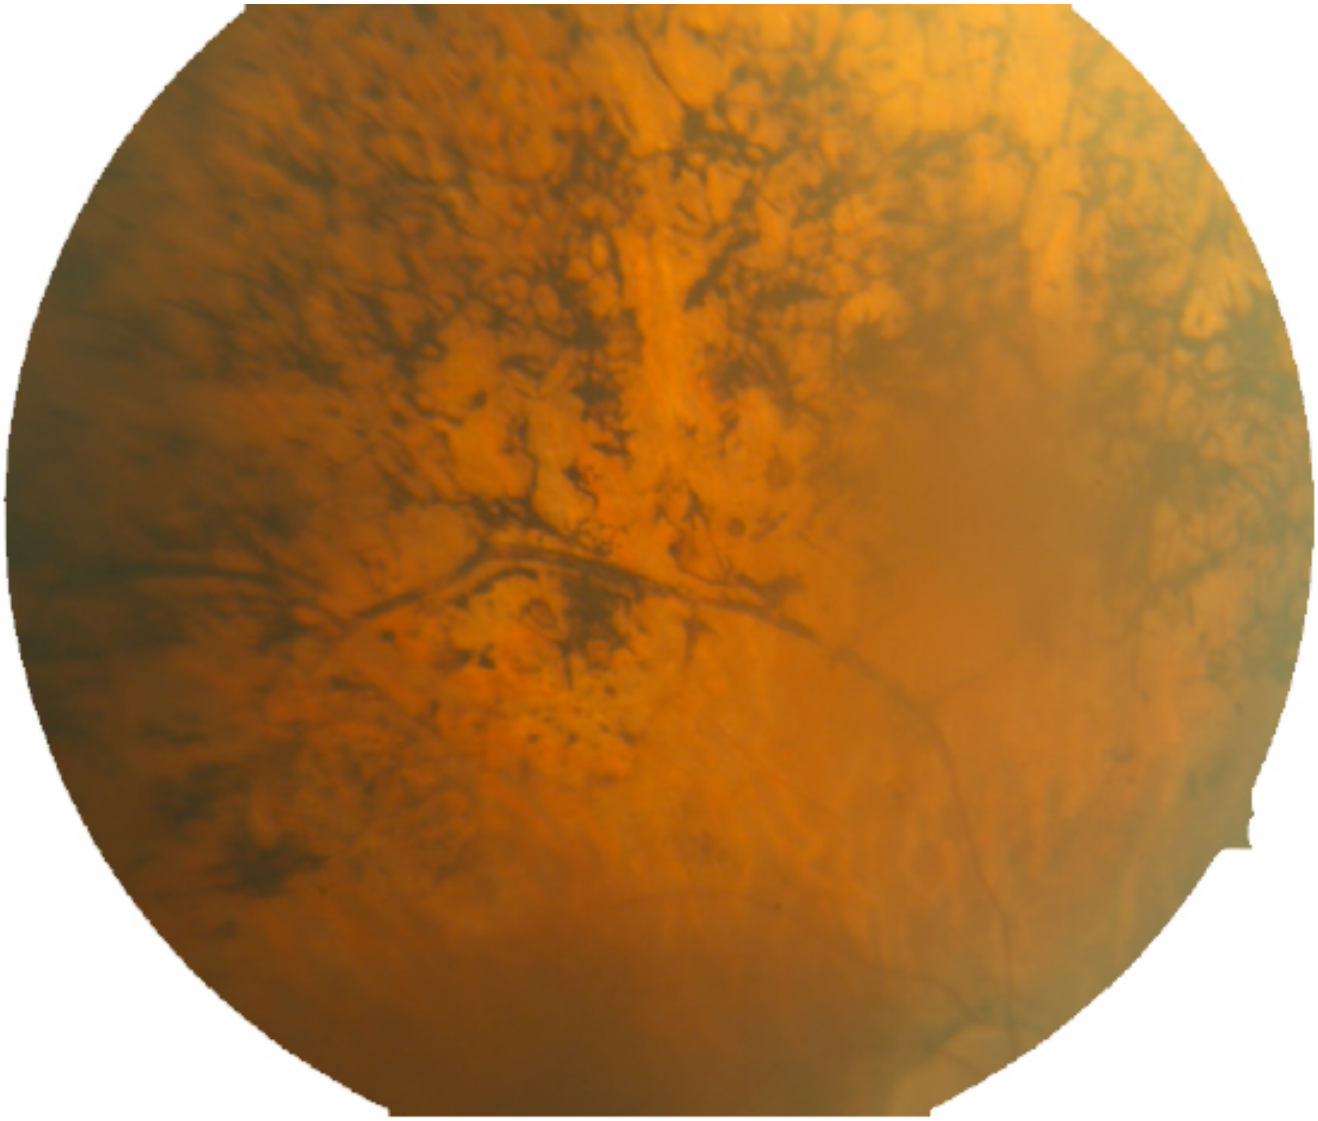

Figure 3. Funduscopic image of advanced RP seen in a human eye.

5. Historical histological methods.

Traditional histological preparations like toluidine blue in Figure 5 and Figure 6 are the common currency in much of the literature and they give us the ability to easily discriminate layers and count the numbers or layers of photoreceptor cell bodies, which has been a traditional measure of the level of integrity of the retina. These measures give us morphometric descriptors and provide some metric for degree of degeneration.

It turns out that this type of histology while incredibly informative, got us, the vision community, into a bit of trouble over the past few years. Examining Figure 6 seems to demonstrate a thinner outer nuclear layer that has been described as partial thickness, but the rest of the retina, at least here, looks OK, leading many to make assumptions on the level of intactness of the neural retina. When discussions of retinal rescue arose, along with subsequent strategies designed to intervene and cure blindness, they were based upon this assumed level of knowledge about retinal integrity, to rescue vision.

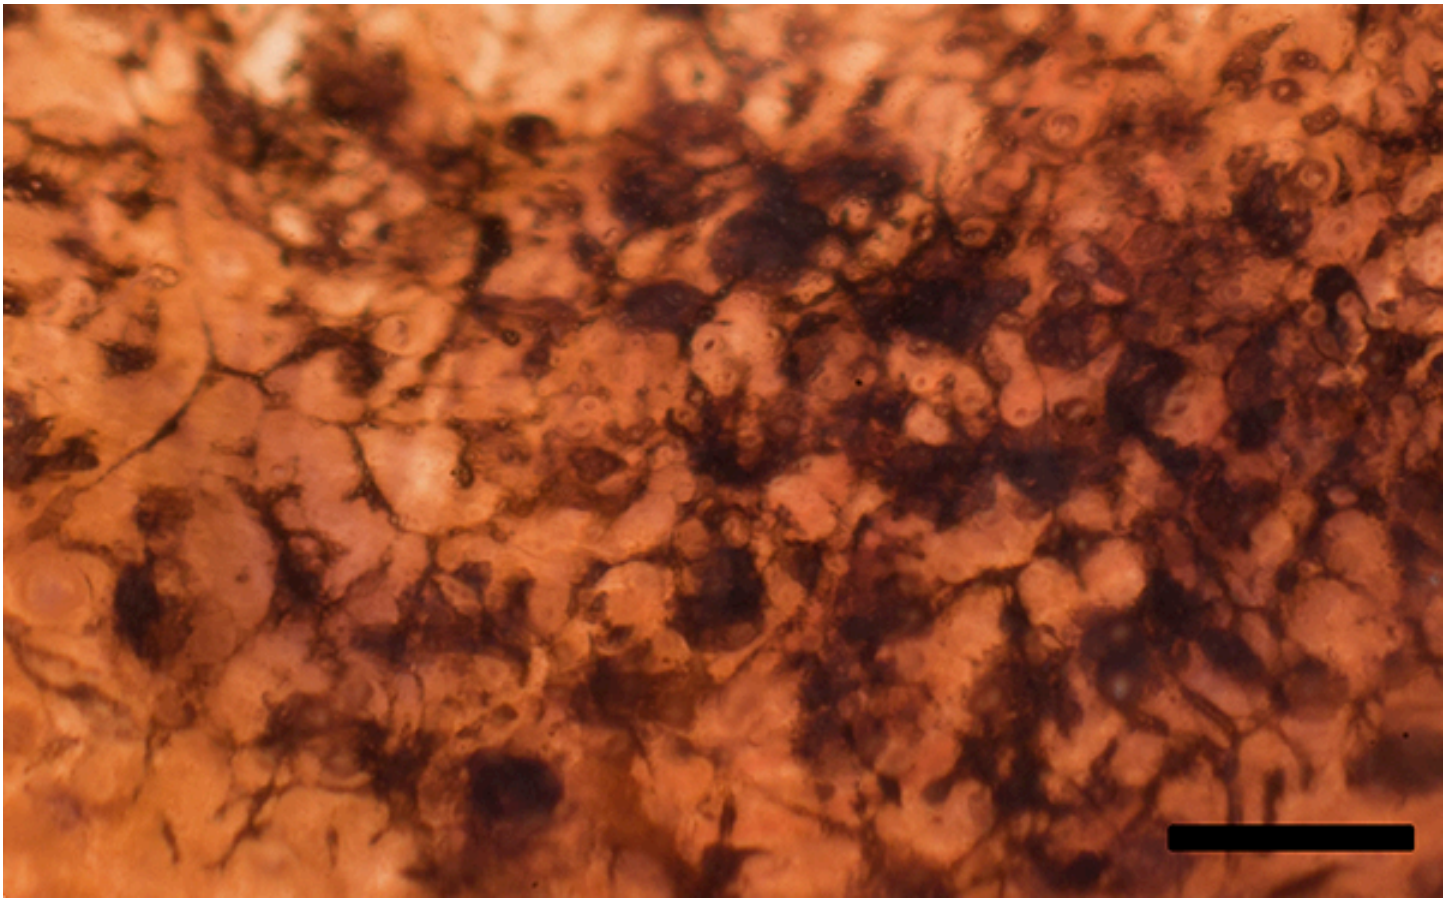

Figure 4. Retina from a human patient with advanced RP. The illustration shows pigmented bone spicules or accumulations of RPE pigment granules that derive from translocations of Müller cells, which alter the topology of the neural retina and cause the accumulation of pigment along clumps, lines and grooves in the vertical axis of the neural retina. Scale bar = 200 µm.

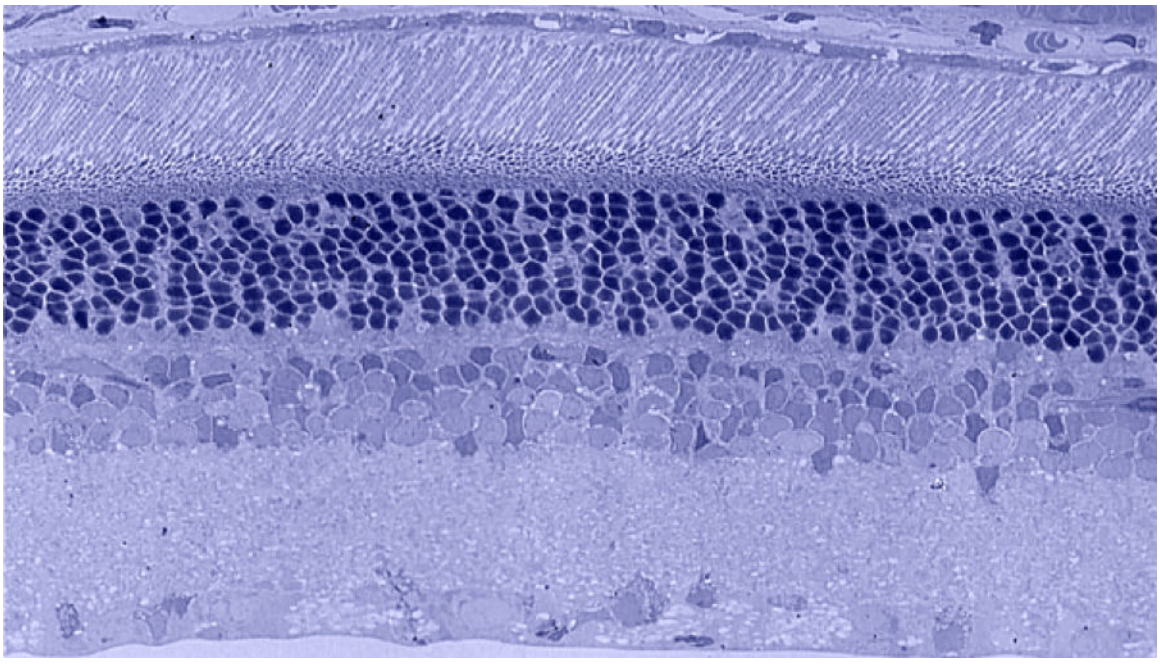

Figure 5. Toluidine blue stain of wild type mouse retina. The photoreceptor layer is at top with the ganglion cell layer on bottom.

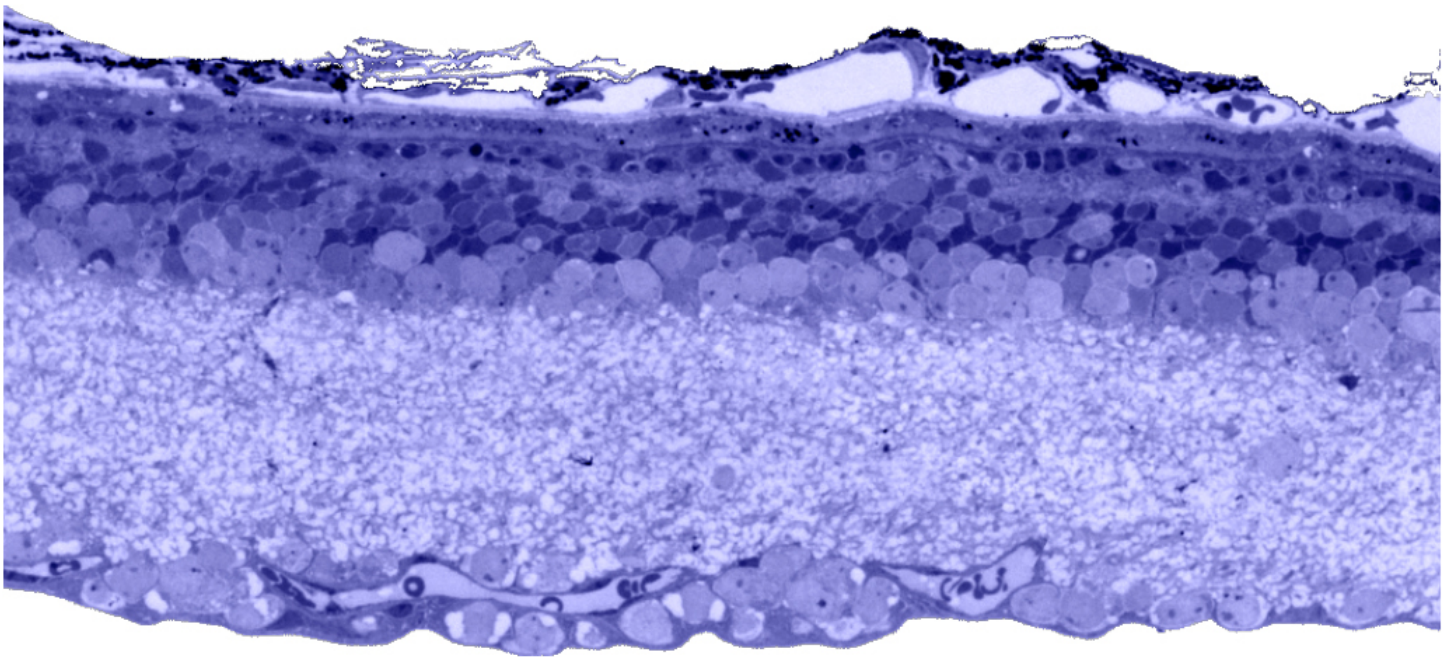

Figure 6. Toluidine blue stain of light damage albino mouse retina. The (now decimated) photoreceptor layer is at top with the ganglion cell layer at bottom.

6. Plasticity in the retina.

Of course, the retina is neural tissue, and plasticity in the central nervous system (CNS) or retina is not a new concept. We have also known for quite some time that the developing retina is highly plastic. This knowledge goes back to 1933 with Ramon Y Cajal in his elegant illustrations of Golgi stains from developing retina, shown in Figure 7. (33).

Another classic example of retinal plasticity in development was illustrated by Hinds and Hinds in 1978 (34) (Figure 8) with an elegant serial section study that showed amacrine cell neurite development from embryonic day 13 to 17. Hinds and Hinds also explored autoradiographic studies on the origin of cells prior to E15. Interestingly, Hinds and Hinds also confirmed the Cajal observations of bipolar shaped amacrine cells in the developing outer ventricular layer 45 years prior.

Over the last 40 years many studies of retinal development have shown how the different retinal cell types develop and go through various morphologies and migrations through the retina to finally reach their mature retinal positions and involvements in neural circuits. The interactions of cells with others and establishment of synaptic circuitry often with pharmacological as well as light and pattern stimulation leads to a mature retina. See chapters in Webvision by Ning Tian, Rachel Wong and Marla Feller concerning these developmental stages in retinal organization. These studies have shown conclusively that the developing retina is very plastic. However, it was assumed that the adult retina remained hard-wired, once established.

Some clues that this is not so came from studies in non-mammalian species. Fish are known to add rod photoreceptors and some secondary retinal interneurons in the retina throughout life (35-37). Moreover, amphibians can regenerate a complete retina and even connections between retina and brain when the eye is damaged (38). A subtler instance of plasticity in the sub-mammalian retina was shown, again in the fish, as a response to just the daily light and dark cycle. There are retinomotor movements of the retinal pigment epithelium in light and dark in fish retina for instance (39). Additionally, there is evidence of neural plasticity in the photoreceptor synapses with horizontal cells with the coming and going of spinules according to light conditions in the adult retina (see chapter on horizontal cells in Webvision). Furthermore, the bipolar synapses

in the inner plexiform layer show synaptic apparatus i.e. synaptic ribbons, appearing and disappearing with light and dark adaptation (Figure 9) (40).

But fish possess a more sophisticated retina than the mammalian because so much visual information processing goes on the retina as compared the mammal, where the equivalent visual processing takes place in the brain (Dowling's original concept of simple mammalian retinas versus non mammalian complex retinas, (41)). So, the question of plasticity in the adult normal mammalian retina had not been established until recently.

However, in 1984, Peichl and Bolz (42) exposed retinas to kainic acid to induce structural remodeling (Figure 10) which they described as dose-dependent morphological changes in horizontal cells of adult mammalian retinas (cats and rabbits). Of course, they found that high concentrations of kainic acid killed the cells, but when exposed to sublethal doses, horizontal cells contracted their dendritic fields and sent sprouting processes into the inner retina. Their conclusions were, quote: "It appears that kainic acid can induce neuronal growth as well as degeneration and that the potential for morphological plasticity is still present in neurons of the adult mammalian retina". So, under certain experimental conditions, it appeared that some retinal neurons could remodel and plasticity was suggested for the first time in species other than fish.

We now know from studies of retinal degenerations that adult mammalian retinas can undergo substantial plastic and aberrant reorganization in response to damage. The rest of this chapter illustrates plasticity in the retina under traumatic and degenerative retinal disease.

7. The plasticity and remodeling that occurs in retinitis pigmentosa like diseases in mammalian retinas.

It has been already mentioned that classical histological examination of human retinas with retinitis pigmentosa (RP) or rodent models with this type of degeneration were being done in the 1960-70s, and gave the impression that, apart from photoreceptors degenerating (Figure 6), the remaining neural retina was normal. It took electron microscopy to show that there were changes other than photoreceptor degeneration that were also occurring in the neuropil of the inner retina.

In 1967 and later in 1974, there were ultrastructural studies in the literature on RP that documented an autosomal dominant form of the disease (43, 44). Papers by Szamier, Berson et al (45, 46) followed later. These papers all concentrated on the pigment epithelium and state of the rods and cones in the diseased retinas simply because that is all that seemed to be recognizable as retinal elements by electron microscopy at the time. The rod photoreceptors in all these examples were degenerating or totally absent. The cones of the fovea were best preserved (Figure 11, a) but outside the fovea, cones were reduced to inner segment stubs (Figure 11 b). Higher magnification of the foveal cones showed they had disorganized outer segment discs (Figure 11, c and d), but presumably these cones were functional because the patient had corrected vision of 20/25 in the same eye examined by EM (Figure 11) (43). The foveal inner retina was not examined in this RP retina and inner retina in the parafoveal area was an indistinguishable tissue of vacuoles and debris (Figure 11b).

Kolb and Gouras (43) were also able to look at the bone spicules in this human RP retina (Figure 12). This electron micrograph shows that cells comprising the pigment clump are of the same type as the cells of the peripheral pigment epithelium. This observation pointed out that RPE cells had migrated into the neural retina, thus forming the characteristic bone spicules of advanced retinitis pigmentosa seen in fundus photography (Figure 4). This early finding could now be interpreted as plasticity and remodeling of retina in response to degenerating retinal integrity.

It was not until almost two decades later that another paper came out that examined aberrant plasticity in retinal tissues. The 1993 paper from Chu, Humphrey and Constable (47) showed that the RCS rat demonstrated retinal remodeling (though they called it disorganization) of horizontal cell processes in the degenerate retina (Figure

Figure 7. Ramón y Cajal's illustration of developing retina from 1933 (33).

13). Interestingly, they also noted that the "disorganization" was not uniform across the retina with the most "disorganized" horizontal cells in the posterior pole where all outer nuclear layers had been lost. These horizontal cells also showed marked morphological aberrations with "swelling" or hypertrophy.

In 1995, Li, Kljavin and Milam (1) reported that rhodopsin positive neurites extended from the photoreceptor layer down into the inner retina and ganglion cell layer in 15 human RP samples (Figure 14). This was the very

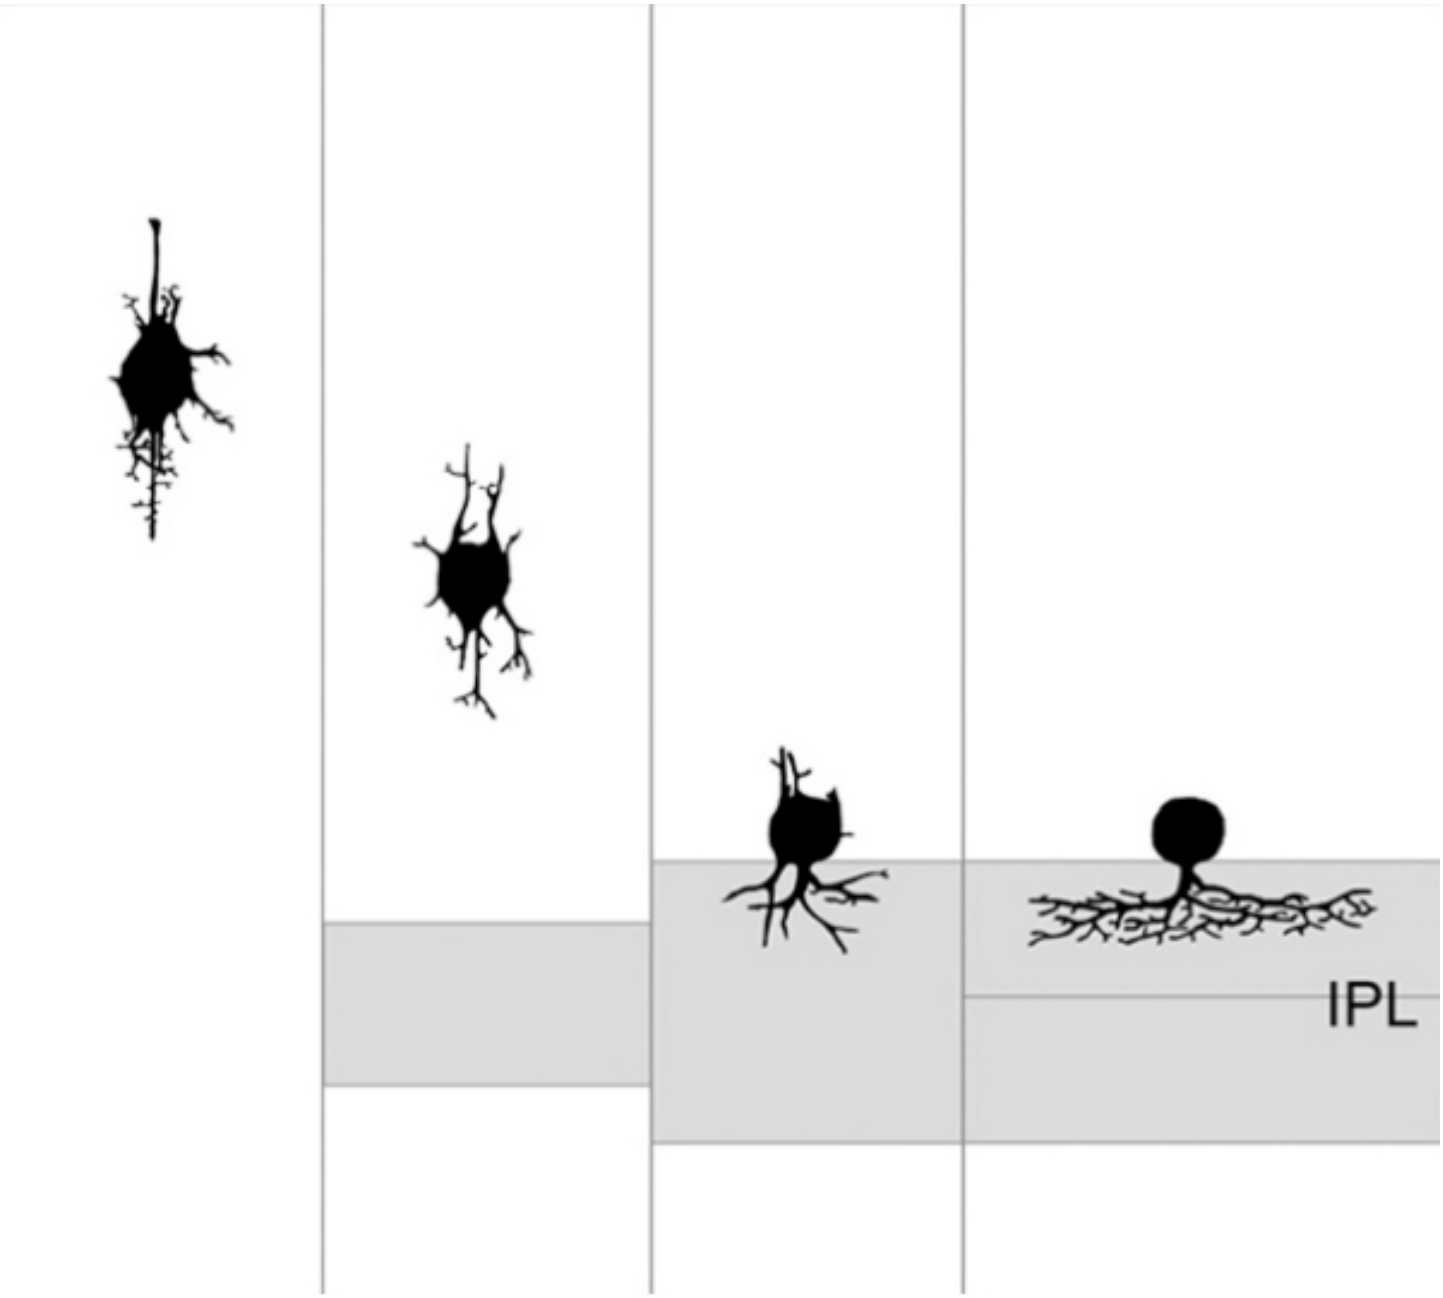

Figure 8. Proposed sequence of amacrine cell neurite development from serial EM studies from Hinds and Hinds, 1978 (34).

first paper that showed neurites sprouting from photoreceptor cells and demonstrated conclusively that rhodopsin delocalized into the membrane of the photoreceptor cell, apparently after mis-trafficking. The authors mention in the paper that "the rod neurites in the human RP retinas resemble the long, branched processes formed by rods cultured on Müller cells or on purified N-CAM". It turned out that they were more correct than they imagined as we will see later, Müller cells form the conduits or scaffolding for cellular migration in the degenerate retina. The Li et al paper (1) was also seminal in that the authors were thinking about potential implications for therapies in this manuscript and suggested that these changes to the "retinal microenvironment may impede function integration of transplanted photoreceptors", ringing the warning bell for the biological transplant community that largely went ignored for a number of years.

Three years later, in 1998, Lewis, Linberg and Fisher (25) explored horizontal and rod bipolar cells in experimental retinal detachment (Figure 15). They conclusively demonstrated aberrant sprouting of fine

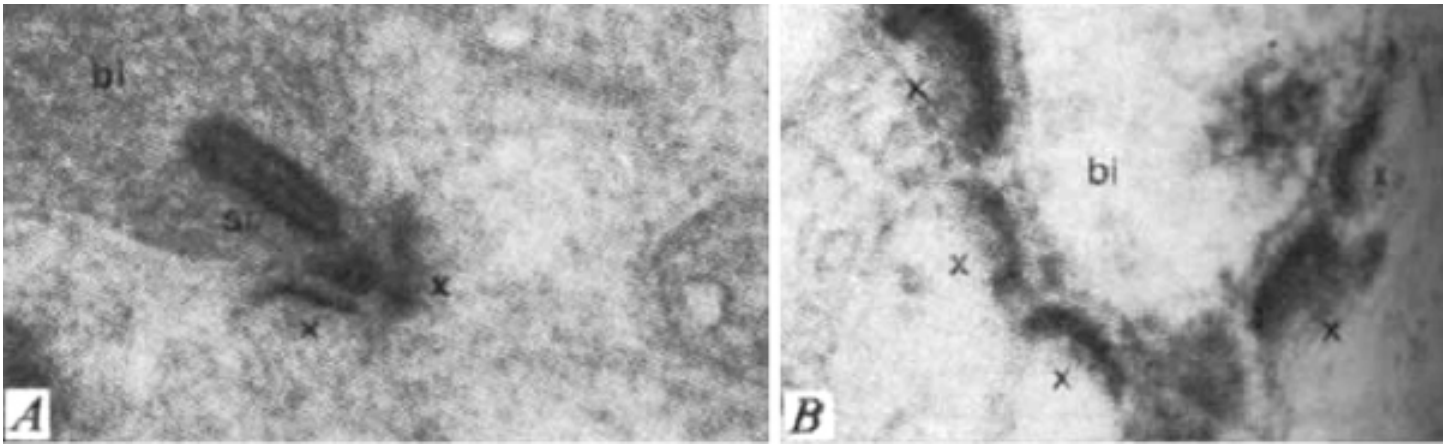

Figure 9. Bipolar terminals (bi) in the inner plexiform layer of the Nannacara (cyclid fish) retina. A. In the light-adapted animal, a bipolar-cell ribbon synapse with two postsynaptic elements, either ganglion or amacrine cell processes (x). Note the pentalaminate structure of the synaptic ribbon (s.r.). B. In the dark-adapted fish, a bipolar terminal flanked by five synaptic processes (x). It does not contain any ribbons. Os-EPTA; magnification x 48,000. From Wagner, 1973 (40).

dendritic processes from rod bipolar cells projecting into the outer nuclear layer (ONL) in response to retinal detachment in the feline retina. They also noted horizontal cell processes growing into the ONL and concluded that processes from horizontal and rod bipolar cells "lengthen after retinal detachment, perhaps in response to a withdrawal of their presynaptic targets, the photoreceptor synaptic terminals. The important thing with respect to interventions for blinding diseases is that these authors also invoked the implications of sprouting inner retinal neurons for therapies like retinal photoreceptor transplant. This work is documented extensively in another chapter here on Webvision, Cellular Remodeling in Mammalian Retina Induced by Retinal Detachment.

Two years later in 2000, Fariss, Li and Milam (4) examined rod photoreceptors, amacrine cells and horizontal cells in human RP retinas and demonstrated aberrant sprouting in those cell classes, particularly in GABA positive amacrine cells and calbindin positive horizontal cells (Figure 16). They also noted that rod neurites that projected into the inner retina, and at least contacted the somas of GABA positive amacrine cells, though no mention of synaptic connectivity was noted. This study continued the previous work, and included GABAergic amacrine cells into those neurons in the retina that contribute to the rewiring phenomenon that was starting to emerge. Also of note in this paper, the authors note that these changes may form the basis for some of the psychophysical abnormalities noted by patients (phosphenes and visual hallucinations) as well as form the basis for progressive visual function decline in patients with RP and again reiterated from the 1995 paper (1) that these alterations may complicate vision rescue strategies.

Also in 2000, Strettoi and Pignatelli (6) showed in the rd mouse (48), an animal model of RP, bipolar and horizontal cells undergoing "morphological modifications accompanying photoreceptor loss" (Figure 17). The authors concluded that these modifications were dependent upon photoreceptor loss and again raised the specter of potential impact on retinal rescue models.

The year 2000 was also the year our research lab came into the retinal degenerative community with some reticence. Robert Marc had published 5 years previously, the first paper using Computational Molecular Phenotyping (CMP) (49) and we were busy using these technologies to explore mammalian and non-mammalian retinas. CMP is a fusion of 3 techniques including anti-hapten IgG libraries, tissue array fabrication and computational pattern recognition. CMP allows for simultaneous quantitative probing of multiple immunolabels (3-20 or more) with hapten-specific IgG probes, with subcellular resolution in all cells. The technique profiles the metabolic state of every cell in a tissue. Figure 18 is a typical 3-space reconstruction of molecular data in human retinal tissue that uses red (r), green (g) and blue (b) color space to visually present differential labeling of small-molecule concentrations in tissues. In Figure 18, we can see taurine, glycine and

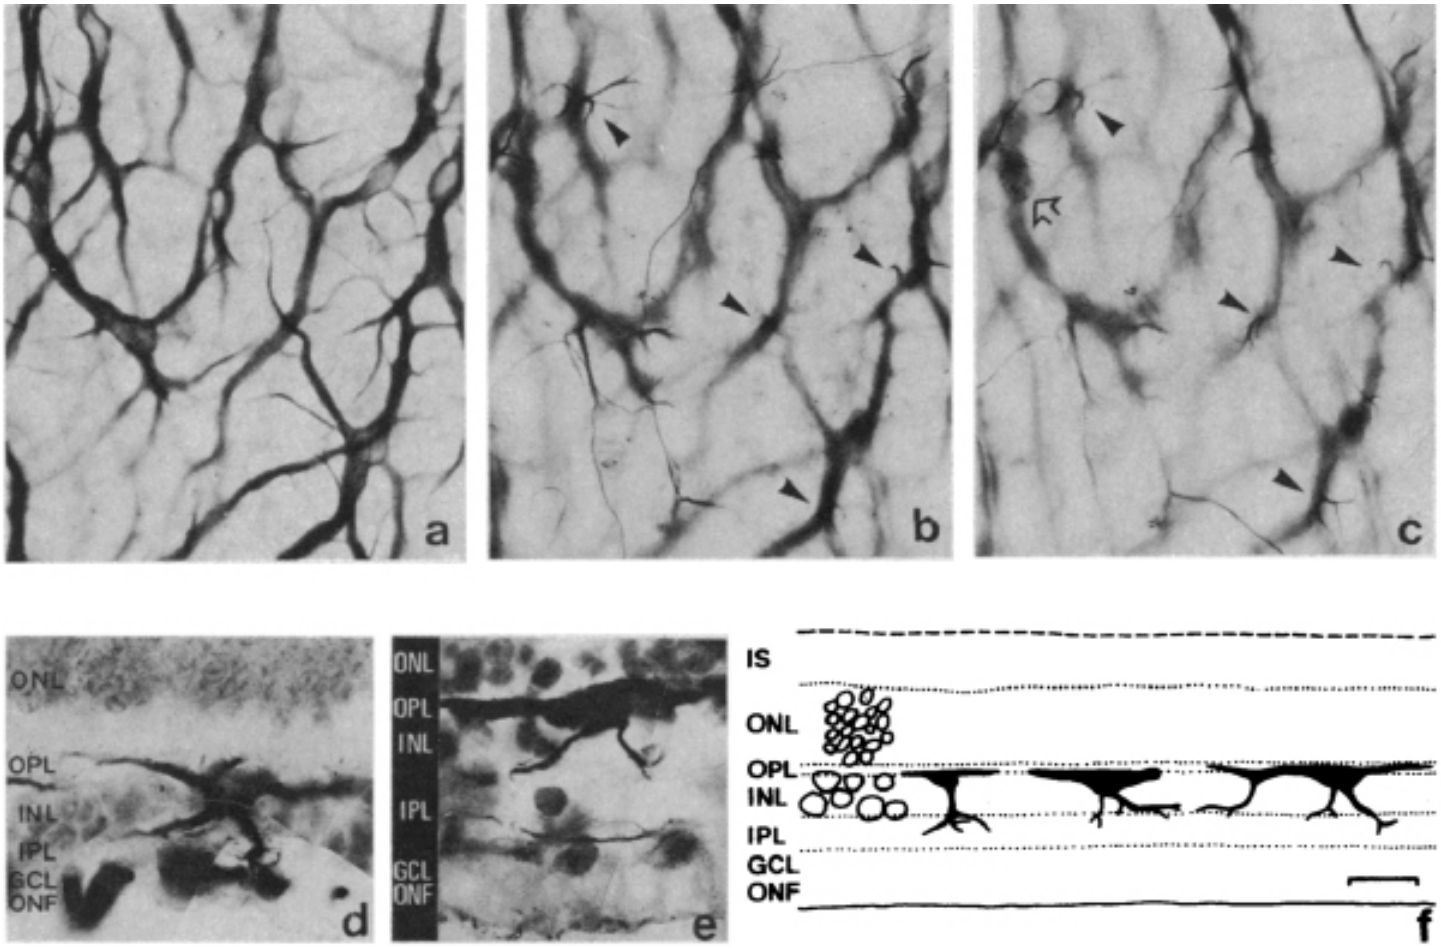

Figure 10. Sprouting A-type horizontal cells. (a to c) Micrographs of a field near the visual streak of a rabbit retina treated with 100 nM of KA. (a) Focal plane at the horizontal cell plexus (OPL and INL boundary); somata and dendrites in focus. (b) Focus at the INL, showing sprouts (some indicated by arrowheads) that branch off main horizontal cell dendrites and enter the INL. (c) Focal plane at the boundary of the IPL and ganglion cell layer (GCL), where the sprouts end in short fine branches (some indicated by arrowheads). The open arrow points to a ganglion cell. All horizontal cells in this field showed sprouting. (d and e) Sprouting horizontal cells in 35-µm vertical sections. Each horizontal cell shows two inward sprouts in addition to its normal OPL dendrites. The relative thickness of the layers in cat (d) and rabbit (e) retina differs. The ganglion cell layer and optic nerve fiber (ONF) layer are thin and disorganized due to KA- induced degeneration. (f) Schematic of vertical section of cat retina, showing sprouting horizontal cells. The OPL dendrites are incomplete where they leave the section. IS, photoreceptor inner segments. Scale bars: 20 µm (a to c and f) and 10 µm (d and e). From Peichel and Bolz, 1974 (42).

glutathione represented, revealing the vascular choroid in blue at top, the RPE in pink, photoreceptor cell classes in orange, ON-cone bipolar cells with low concentrations of glycine in light green, due to coupling with AII and other glycinergic amacrine cells, and their fine processes extending down into the IPL in bright green.

We were interested in, and intensely focused on, the normal circuitry of the retina and decidedly uninterested in pathology, but two events conspired to bring us into the field. The first event was a generous gift by Ann Milam of some human RP tissues to examine. At this point, we knew relatively little about retinal remodeling and were largely unaware of these few studies mentioned above. That said, upon processing the tissues that Dr. Milam had sent us, the following image is the first thing we saw.

This first image that came out of that initial analysis is shown in Figure 19. We were unprepared for what it revealed to us. In fact, it is fair to say that since we had no context to understand what we were seeing, we were completely flummoxed as the topology looked nothing like retina. In this image with the small molecular mapping as in Figure 18, you can see that the entire topology of the retina is altered. What should have been

photoreceptors up at the top was now a Müller cell seal. Müller cells are in dark red. Glycinergic amacrine cells in bright green are jumbled and altered in their lamination and appearance. Isolated RPE cells are seen with punctate light green labeling throughout the retina and unknown glutathione rich cells are colored blue. Despite some curiosity, we did not know what to do with these tissues and set them aside returning to what we knew, the normal vertebrate retina.

The second event that brought us into the study of retinal degenerative diseases was a colleague, Jeanne Frederick who came by the lab with aged samples of GHL, mutant rhodopsin, mice (adRP mimic) that she and Wolfgang Baehr had created (27), asking if I might be interested in the retinas of "some old, blind mice". The tissues Dr. Frederick was offering were osmicated and in blocks ready to be sectioned for transmission electron microscopy (TEM) and examined. CMP is compatible with TEM analysis, so we decided to see what aged mouse retina from a degenerate model looked like and we were stunned to see that these GHL mouse retinas looked precisely like the tissues from the human RP retinas that Ann Milam had sent and exhibited the same progressive degeneration as human RP retinas (Video 20).

The problem with this was that there were more than a few papers that stated definitively that the neural retina was refractory to photoreceptor loss. To explore this conflict, we set out over the next couple of years to track as many retinal degenerative examples as we could find using both naturally occurring models and engineered models including the S334ter rat, P23H rat, RCS rat, rd1 mouse, the GHL mouse, TG9N mouse, nr, or, chx10, pcd, rd2, rho-/-, rdcl, hrhoG, GC1&2 DKO, rhoDCTA mouse models as well as the P347L rabbit and the P23H pig. We also examined induced models like the light damage models and oxidative stress models. Colleagues from all over the planet were more than gracious in assisting us and some like Matt LaVail went above and beyond by contributing dozens of samples collected over the previous 30 years of work. The fundamental truth that came out was that everywhere we looked in retinal degeneration, despite what was in much of the retinal transplant and vision rescue literature, we saw retinal remodeling from the molecular to the histologic scales.

The stunning thing was how little work was in the literature at this time. For example, when we reviewed the literature in 2003, there were fewer than 30 papers in retinal degeneration that mentioned anything about inner retina neurons.

The remarkable thing about the community being misinformed about the state of the retina is that the histology in advanced forms of the disease, is dramatically altered from the normal appearance of the retina. One of the explanations might be that rodent models rarely get older than a year of age and for many investigators, once the photoreceptors were degenerated, they did not bother waiting longer for the more dramatic changes to ensue. That said, while aged rodent models of retinal disease are uncommon, there have been plenty of opportunities to study advanced human disease. Our explorations of advanced human RP have revealed dramatic alterations in the glial substrate as well as shown new structures termed microneuromas that form from neuritic sprouting from all neuronal cell classes in the retina (Figure 21).

It is also important to note that retinal remodeling and plasticity are not exclusive to RP and RP-like disorders. In addition to human RP and animal models of RP, we've examined human AMD tissues and found extensive evidence of remodeling and retinal plasticity involving bipolar cells and Müller glia stress responses (22). Figure 22 is from a patient with an early geographic atrophy diagnosis. Notably, there are a couple other papers in the literature documenting remodeling in AMD (8, 50).

An induced model, light induced retinal degeneration (LIRD) in albino mice/rats, represents a coherent stress insult to photoreceptors that results in massive loss of photoreceptors followed by subsequent retinal remodeling and reprogramming (29). Again, overall anatomical structure of the neural retina, particularly the inner nuclear layer, inner plexiform layer and ganglion cell layer seems normal or close to normal. However early in LIRD, key synaptic markers in inner retina demonstrate rapid inner retina responses to photoreceptor stress that lead to functional reprogramming of neuronal responses. This reprogramming is a result of AMPA GluR2 subunits

largely associated with inner retinal processing, exhibiting rapid changes in protein level. GluR expression in LIRD changes over 60 days post light damage, with low conductance AMPA receptor GluR2 subunits increasing 65% while high conductance KA receptor GluR5 subunits decrease 50%. AMPA receptor GluR1 subunits show no significant change in expression (51). Later in LIRD, there are massive changes and neuronal "escape" from the neural retina where bipolar and amacrine cells are observed leaving through breaks in Bruch's membrane, into the choroidal space (Figure 23).

Another non-RP model of retinal plasticity we have explored is the DBA/2J mouse model of glaucoma. Cuenca (52) demonstrated remodeling events in the ON-rod bipolar cells and horizontal cells in an increased pressure intraocular model in adult albino Swiss mice. Work in our lab in collaboration with Monica Vetter and Alejandra Bosco demonstrated remodeling events of GABAergic amacrine cell processes (Figure 24), which shows that negative retinal plasticity is not limited to photoreceptor deafferentations.

8. The TgP347L rabbit and P23H porcine models of retinitis pigmentosa

In addition to the mouse models, there are two viable large eye models of RP currently available. One, the P23H pig (53) shown in Figure 25 contains a Pro23His (P23H) rhodopsin (RHO) mutation that is the most common form of autosomal dominant RP (adRP) observed in humans. Porcine P23H models of RP show progressive loss of photoreceptors and loss of ERG b-wave (53). These porcine models demonstrate aberrant Müller cell signatures seen in human (Figure 22) and other models of retinal degeneration (Figure 30). Progressive loss of photoreceptors followed by loss of visual percepts, as measured by ERG (53), is just like the human rodent and rabbit (22). Porcine tissues also exhibit neuritic sprouting in both the GABAergic and glycinergic amacrine cell populations prior to retinal photoreceptor degeneration, suggesting that there are stressors in the system that induce downstream responses in the inner neural retina.

The P347L TG rabbit was generated by Mineo Kondo and Hiroko Terasaki as a large eye model of autosomal dominant RP (54). The rabbit expresses a rhodopsin proline 347 to leucine transgene (Figure 26). Drs. Kondo and Terasaki approached us that same year to evaluate this model and compare it to models of RP as well as human RP. This work was published in 2011 documenting the progression of retinal degeneration and subsequent remodeling of the sensory and neural retina (21). We have analyzed degeneration, remodeling and reprogramming at the molecular, physiological, and the histological levels and have shown that disease progression in the TgP347L rabbit closely tracks human cone-sparing RP, including the cone-associated preservation of bipolar cell signaling, and the triggering of glutamate channel reprogramming.

The TgP347L rabbit as well as the P23H pig model are attractive as models of retinal disease for many reasons. This model is a large eye model and there is a substantial existing knowledge base in ophthalmology including retinal anatomy and circuitry. Some advantages of the TgP347L rabbit is the relatively fast disease progression combined with a manageable and affordable approach making the TgP347L rabbit an excellent model for gene therapy, cell biological intervention, progenitor cell transplantation, surgical interventions, and bionic prosthetic studies.

Because of the similarity of the TgP347L rabbit to human adRP, most of the remodeling specific discussion that follows will derive from data from that model system.

Retinal degeneration in the mammalian retina occurs in phases. *Phase 1* is typified by photoreceptor stress, which is the beginning of early remodeling & clinically occult reprogramming events at the cellular and molecular levels. *Phase 2* of retinal remodeling involves the microglia, Müller glia and RPE cells, as the Müller glia begin to exhibit signs of cell stress and reactivity to the degenerating retina. Müller cells also begin to hypertrophy and grow up between photoreceptor cells to initiate the Müller cell seal. Cell death in the ONL begins to occur in *Phase 2* as well. *Phase 3* is where we begin to see neuritic sprouting from all neural cell classes

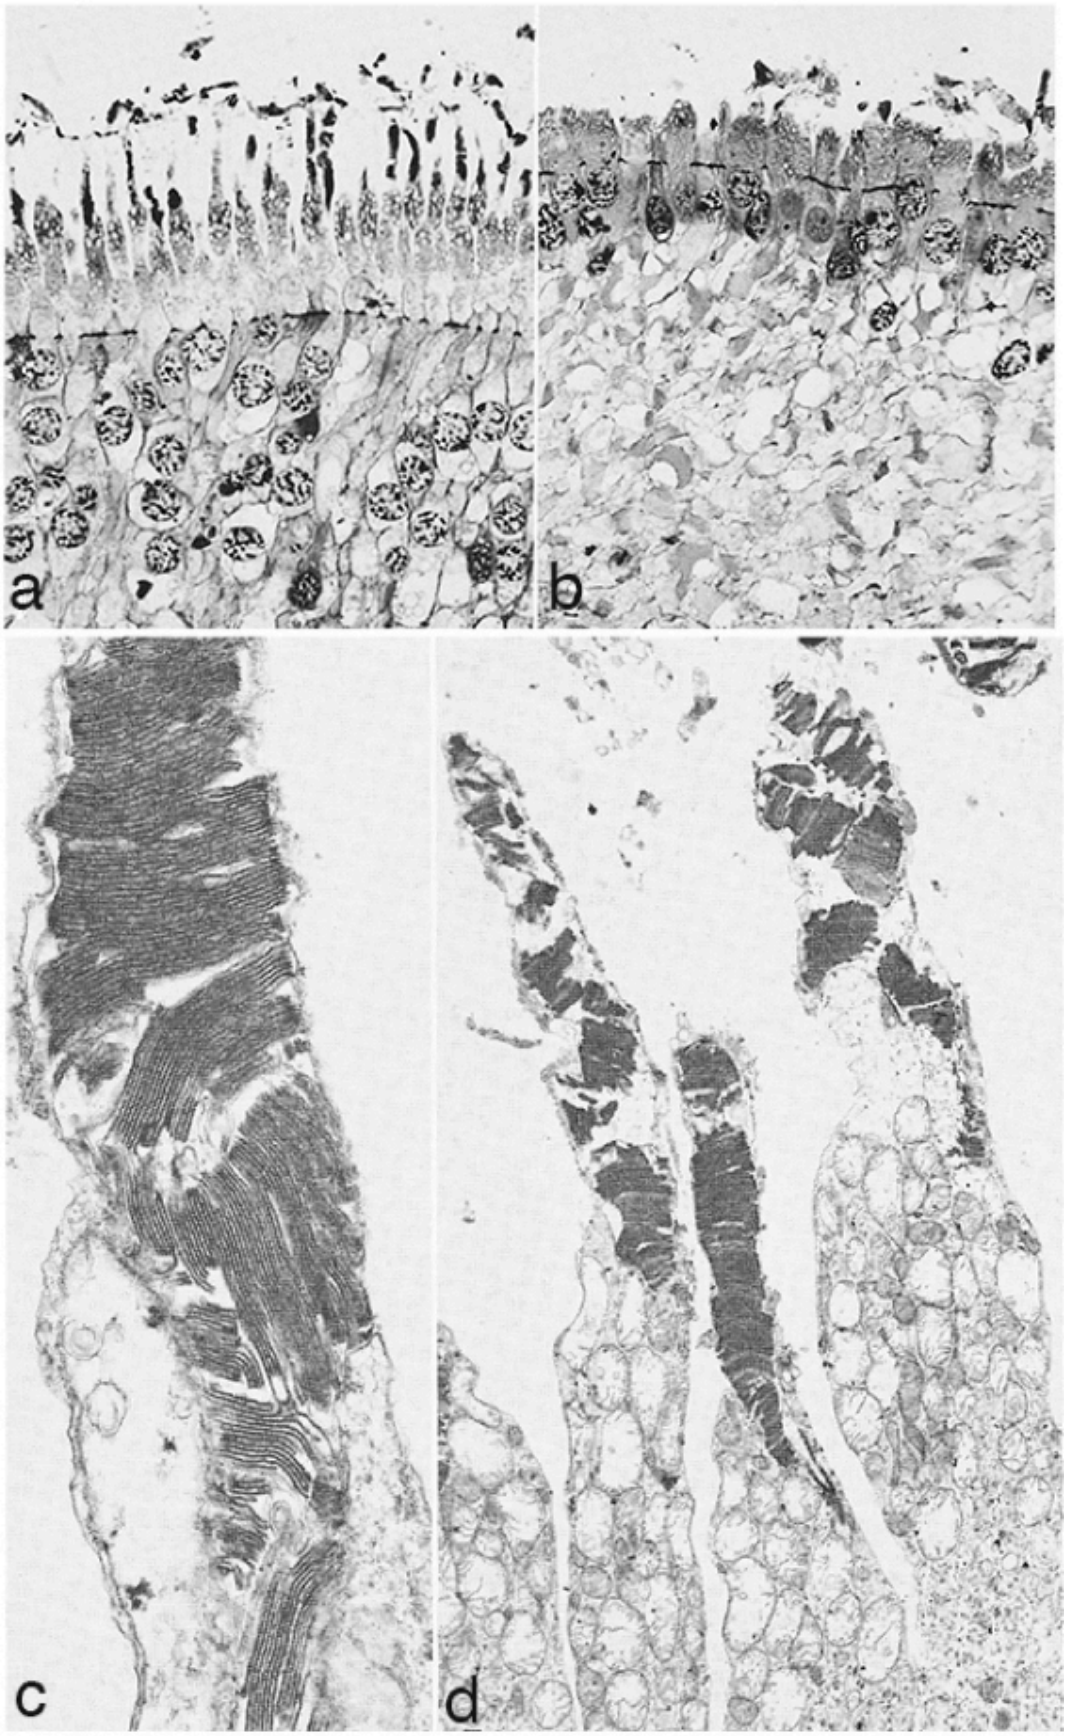

Figure 11. Light (a, b) and Electron micrographs (c, d) of cone photoreceptors in the foveal region of retina of a patient with autosomal dominant retinitis pigmentosa. The inner segments are normal in length but wider than normal for the fovea. The outer segments have broken disorganized discs often at unusual angles to each other. From Kolb and Gouras, 1974 (43).

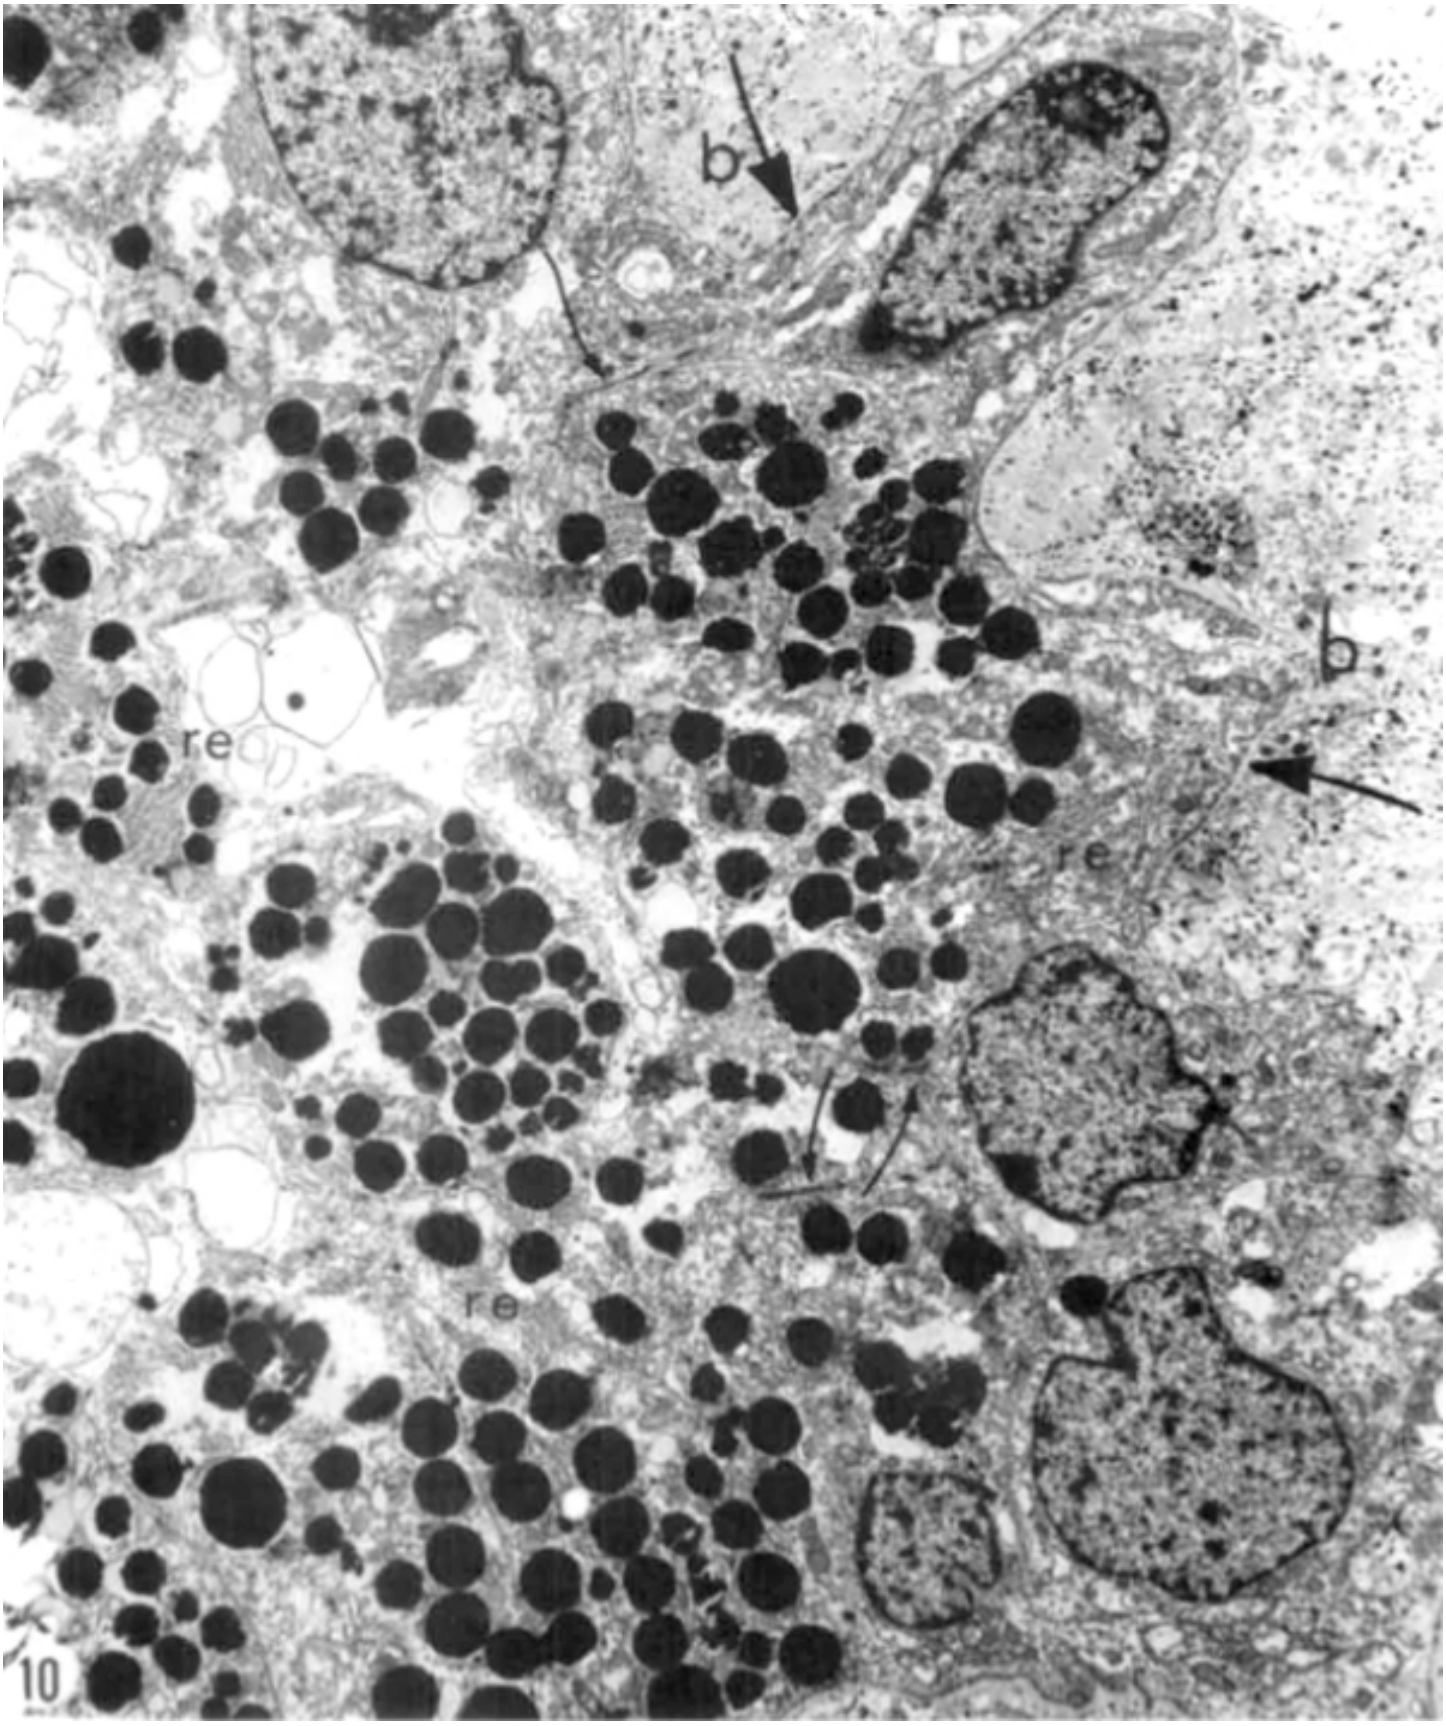

Figure 12. Electron micrograph of a portion of bone corpuscular pigmentation. The cells comprising the pigment clump appear to be of the same type as the cells of the peripheral pigment epithelium. The surface is folded due to the projecting cells, each of which has basement membrane material (b, thick arrows). Each cell contains melanin granules and rough endoplasmic reticulum (r.e.) and is joined to neighboring cells by zonulae adherens and gap junctions (thin arrows). From Kolb and Gouras, 1974 (43).

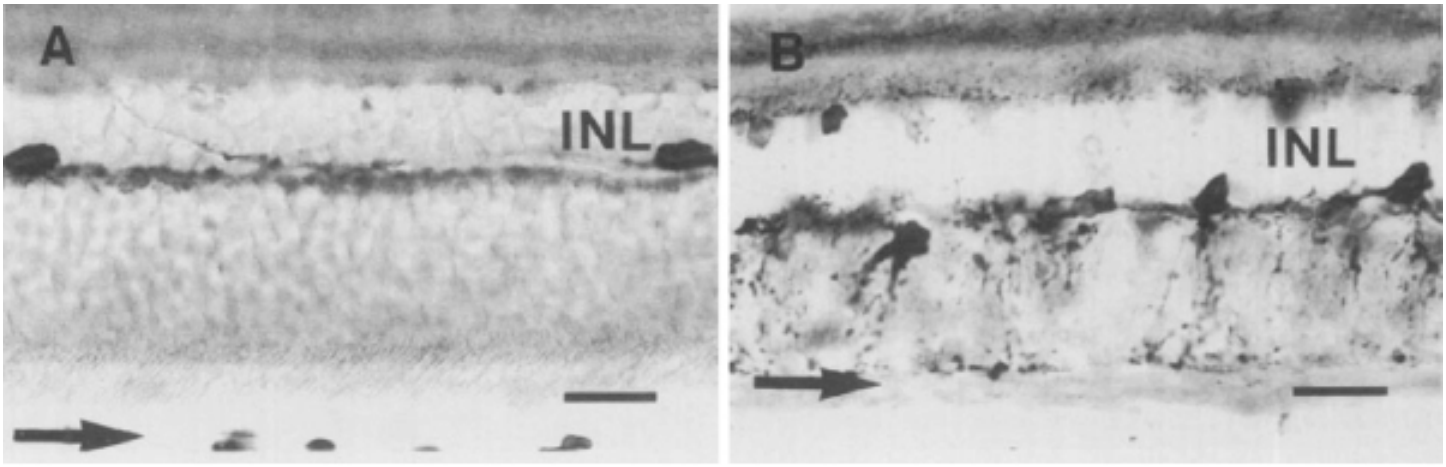

Figure 13. Sprouting of horizontal cell dendrites in RCS rat retinas. Fifty-micrometer-thick cross-sections from RCS-rdy+ (A) and RCS (B) rat retinas oriented with the ganglion cell layer uppermost (the ganglion cell layer is not visible). INL = inner nuclear layer. Arrows indicate the pigment epithelium. A. In RCS-rdy+ retinas a monoclonal antibody against the 28kD calcium-binding protein (28-kDa CaBP) labelled horizontal cell processes were confined to the narrow plexus of the OPL and the cell somas were confined to the outer INL. Bar = 25μm. B. In the RCS rat retinas the 28-kDa CaBP labelled horizontal cell processes extended throughout the outer nuclear layer and debris zone, and were tortuous and swollen. Some of the somas were displaced from the INL, as is evident in the cell on the far left in this micrograph. Bar = 25μm. From Chu, Humphrey and Constable, 1992 (47).

resulting in new neuronal circuits. Neuronal cell death also begins to occur in the bipolar, horizontal and amacrine cell populations. The end stage of retinal remodeling is a neural retina bereft of cells and unable to provide coherent visual pathways to higher centers for processing.

Progression of retinal degeneration and remodeling in the Tg P347L rabbit closely tracks the sequelae of events seen in human RP, though it appears to happen at an accelerated rate, progressing to total photoreceptor loss at 1yr of age. At 12-16 weeks in the TgP347L rabbit, *Phase 1* of retinal remodeling has begun early in the retinal degenerative process, before photoreceptors have degenerated. The photoreceptor structure appears largely intact except for some disorganization in the outer segments of photoreceptors. Some portions of outer segments break off and appear to remain in the subretinal space, rather than being phagocytosed by the RPE (Figure 27). The most compelling feature of this region is the large numbers of small, vesicular rod photoreceptor outer segments that break off and appear as a rhodopsin "froth" in the subretinal RPE/photoreceptor interface space. We speculate that this "froth" increases oxidative cell stress in RPE and photoreceptor cells.

By 40 weeks in the Tg P347L rabbit, some opsin expression can still be found in cones, however, it is delocalized, much as described in Li et. al in 1995 (1). While photoreceptors can still be found in abundance, the rhodopsin delocalization into the membrane surrounding the cell body suggests substantial photoreceptor cell stress (22).

Figure 28 shows glutamine immunoreactivity in *Phase 1-2* in the Tg P347L rabbit retina at 4 months, where the glutamine signal begins to demonstrate alterations between Müller cells. Glutamine is present in most retinal neurons, but most notably in Müller cells. It is also found at high concentrations in the RPE cells, but at 4 months, glutamine levels in isolated Müller cells are revealing multiple metabolic states, a result never observed in normal retina (21).

Further into *Phase 2* at 10 months in the Tg P347L rabbit retina, glutamine synthetase (GS) levels also show quantifiably different levels of expression (Figure 29). GS mediates the recycling of glutamate, GABA and ammonia to form glutamine, and becomes dramatically unregulated in some Müller glia, explaining the mosaicked levels of glutamine observed in Figure 28, but also revealing specifically that nitrate reduction and amino acid degradation pathways are being altered in the degenerate retina (21).

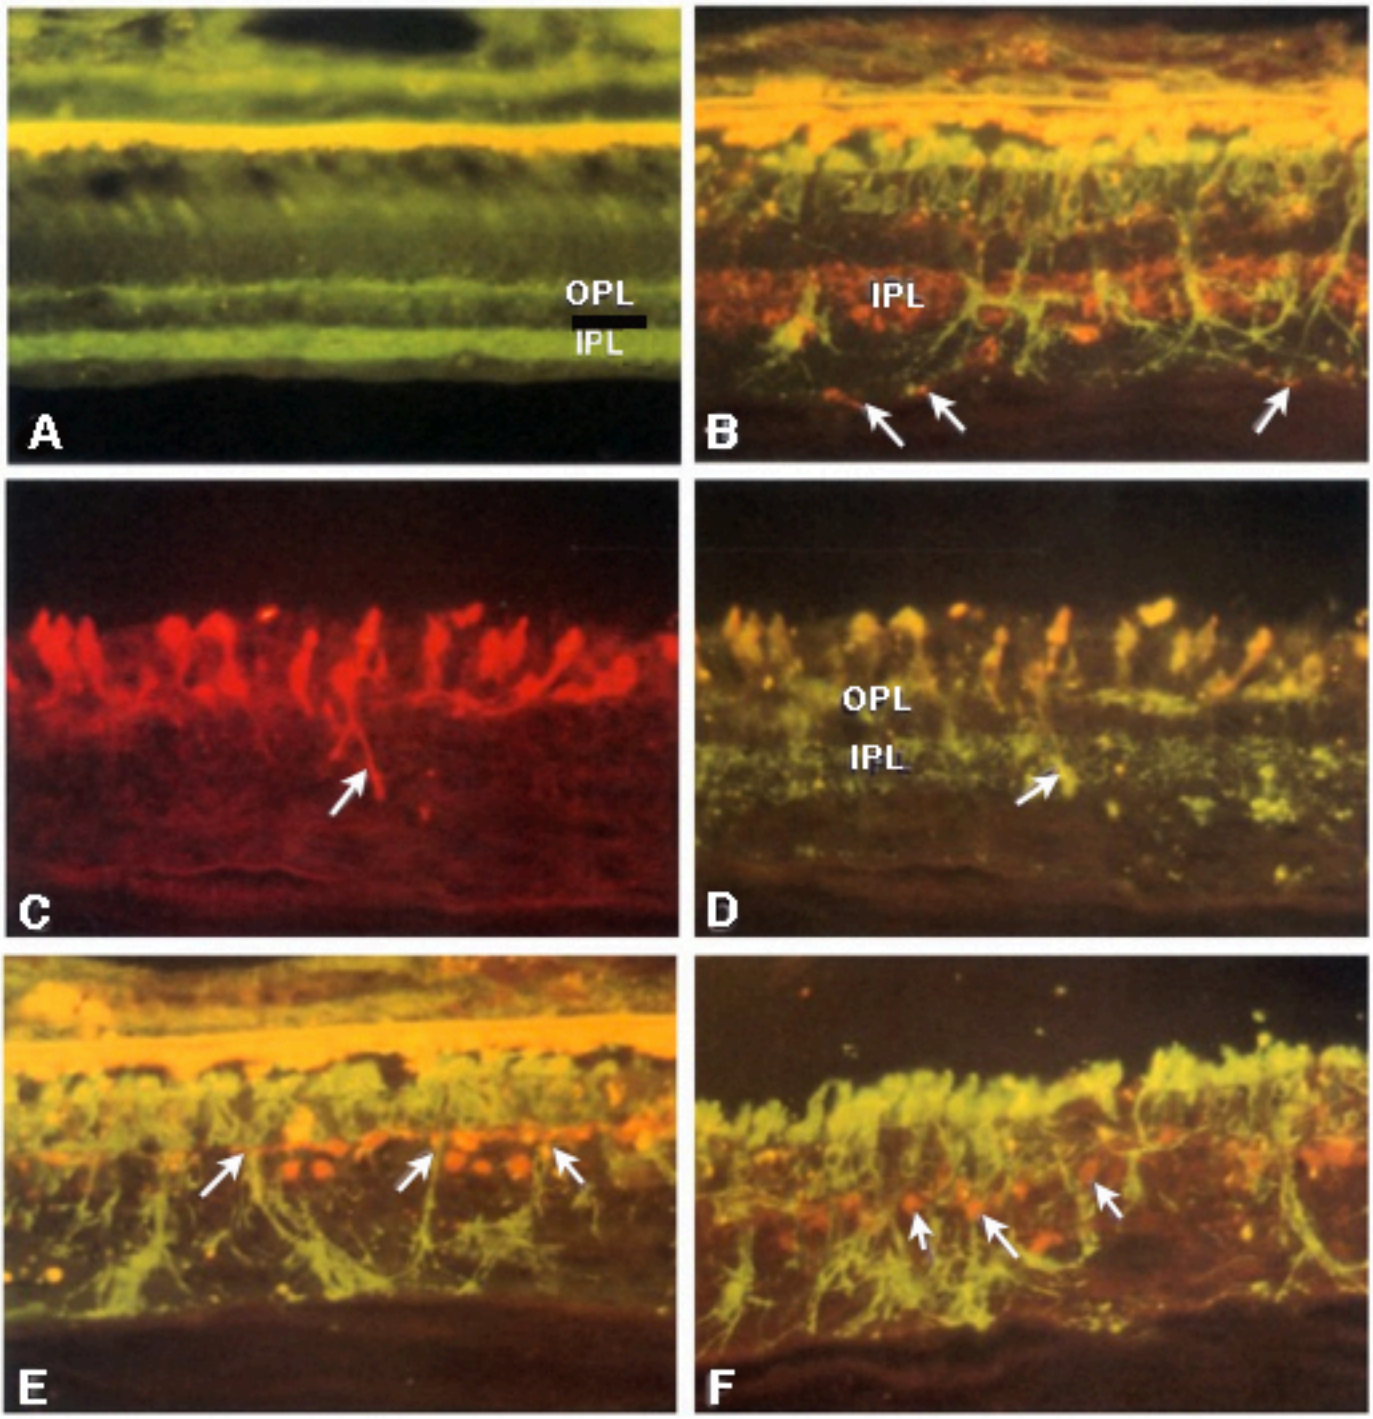

Figure 14. Normal and retinitis pigmentosa (RP) human retinas after immunofluorescence labeling. A. Distribution of SV2 synaptic vesicle protein in the inner (IPL) and outer (OPL) plexiform layers of a normal retina. The yellow band corresponds to autofluorescent lipofuscin in the retinal pigment epithelium. B. Double labeling for SV2 (rhodamine, red) and rhodopsin (FITC, green) in an RP retina. The anti-SV2 labels the OPL and IPL, plus bulb-shaped varicosities (arrows) on the rhodopsin-positive rod neurites. C. Cones in the peripheral region of an RP retina labeled for cone transducin alpha, which fills the cone cytoplasm. Some cone axons (arrow,) are abnormally long and branched, extending into the inner plexiform layer (see D). D. Section in C is double labeled for cone transducin alpha (rhodamine) and synaptophysin (FITC) in both the IPL and the OPL. The cones are labeled with both antibodies, and the cone axon (arrow) extends into the IPL. E. Double labeling for calbindin (rhodamine) and rhodopsin (FITC) in an RP retina. The rhodopsin-positive rod neurites pass through the band of calbindin-positive horizontal cell processes (arrows). Five amacrine cells are also labeled with anti-calbindin. F. Double labeling of L-7 protein (rhodamine) and rhodopsin (FITC) in the peripheral region of an RP retina. The rhodopsin-positive rod neurites course between and past the labeled rod bipolar cells (arrows) and reach the inner limiting membrane. Magnification, 280X. From Li, et. al. 1995 (1).

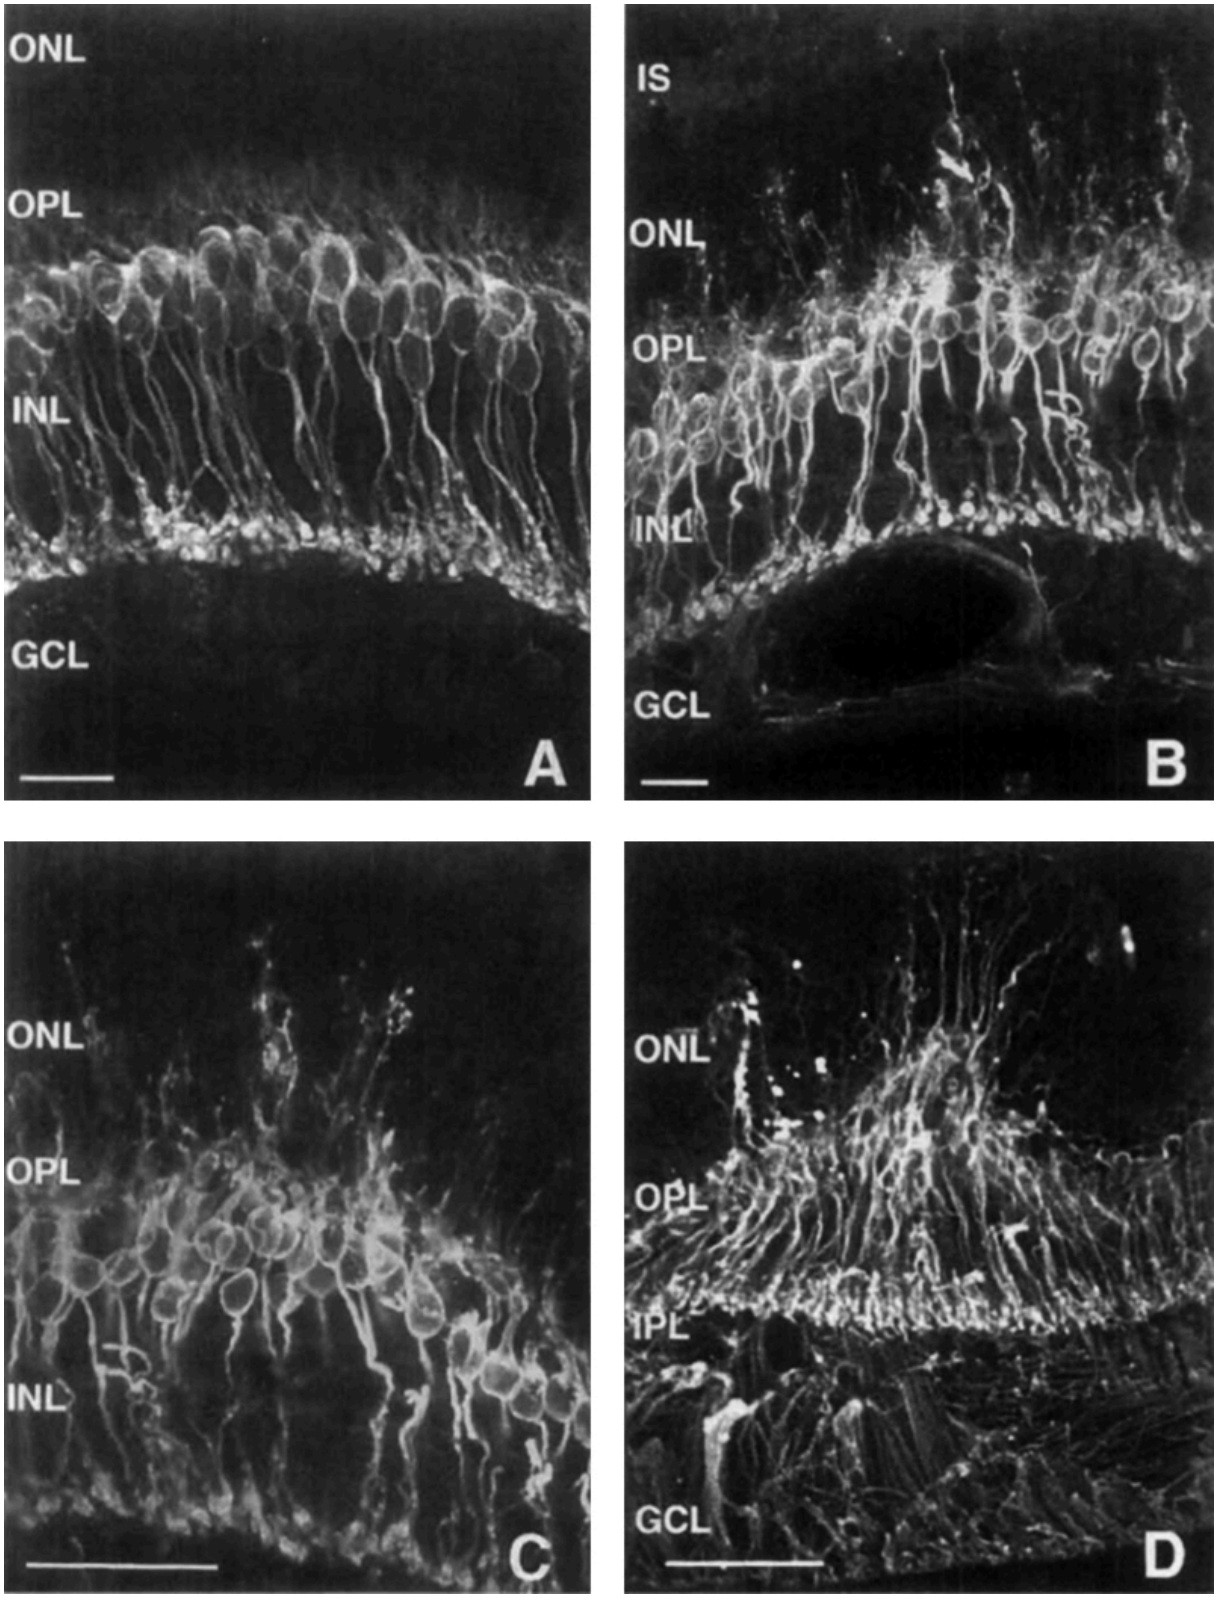

Figure 15. Anti-protein kinase C labeling of normal (A) and detached (B, C, D) retinal sections from cat. A. Normal retina. Labeling occurs only in the rod bipolar cells, including the fine dendritic processes in the outer plexiform layer (OPL), the cell bodies in the inner nuclear layer (INL), the axon, and the axon terminal. B. 1-day retinal detachment. Labeling is present in bipolar cell processes extending into the outer nuclear layer (ONL). Faint labeling also begins to appear in other cell types in the ganglion cell layer (GCL). C. 1-day retinal detachment. Higher magnification of the bipolar cell labeling in the ONL in a different area than shown in C. D. 28-day retinal detachment. Low magnification showing labeled bipolar cell processes extending into the ONL. The fainter signal in the inner retina is from other cell types, including Muller cell and astrocyte processes, and does not extend past the inner plexiform layer (IPL). A, C, and D are projections of nine images; B, is a projection of 13 images. Bars, 20 μm. From Lewis, Linberg and Fisher, 1998 (25).

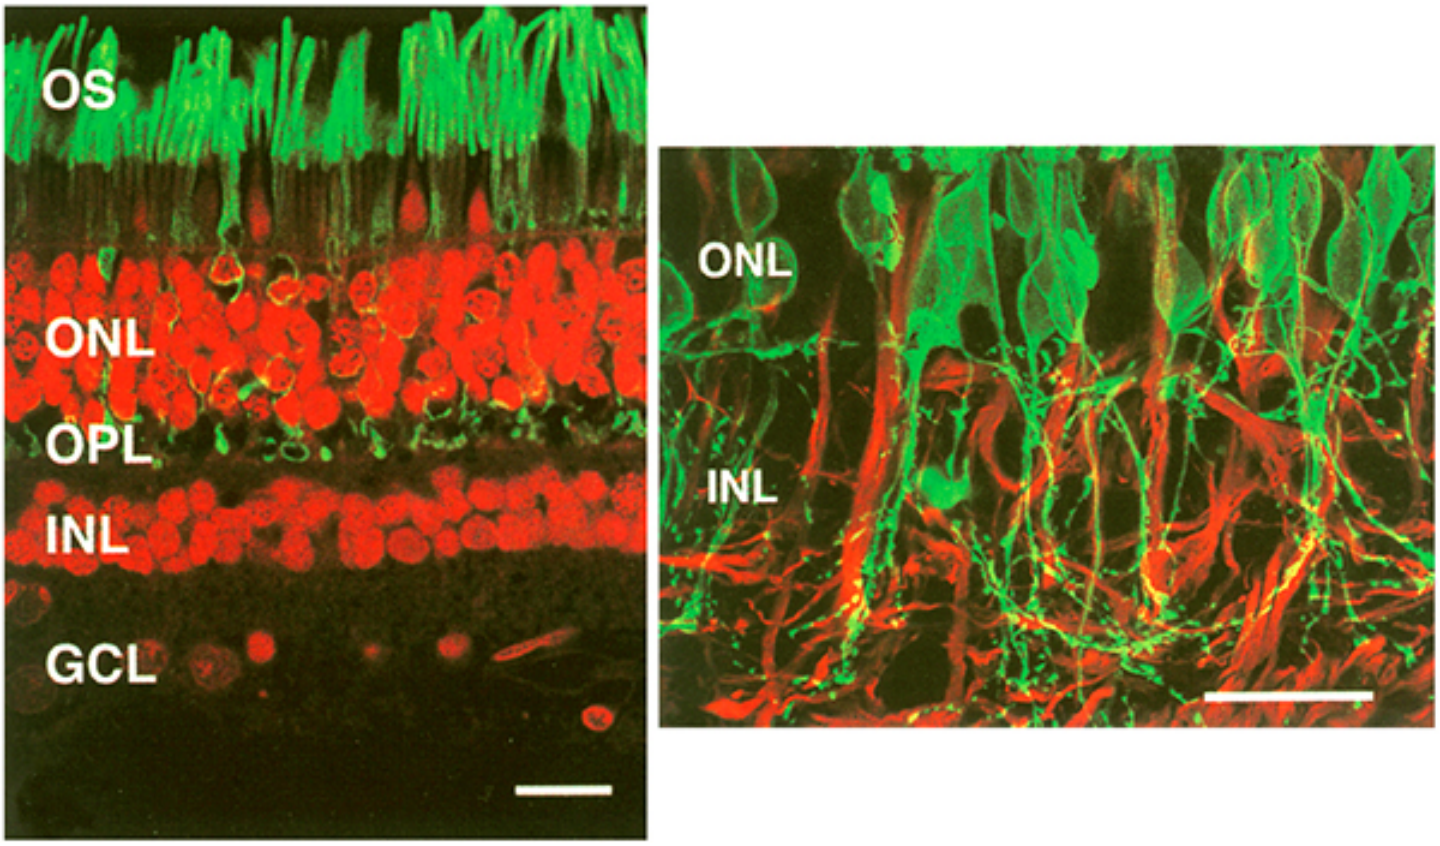

Figure 16. Immunolabeling of rod photoreceptors with anti-opsin (green) in normal human and in retinitis pigmentosa retinas. Nuclei in the outer nuclear layer (ONL), inner nuclear layer (INL), and ganglion cell layer (GCL) are stained red with propidium iodide. Scale bar = 20 µm. (Left image) Normal retina (UW-0802-95). Opsin immunolabeling (green) is strongest in the outer segments (OS) and weak in the plasma membranes of rod somata in the outer nuclear layer and synapses in the outer plexiform layer. (Right image) Retinitis pigmentosa retina (FFB 340). Localization of opsin (green) in rods in the outer nuclear layer (ONL) and glial fibrillary acid protein (red) in reactive Müller cells (red). The rod neurites are closely associated with the surfaces of the glial fibrillary acidic protein–positive Müller cells. INL = inner nuclear layer. Scale bar = 25 µm. Figure from Fariss, Li and Milam, 2000 (4).

CMP visualization in the 10 month old TG P347L rabbit retina in *Phase 2-3* with τQE :: rgb (τ-taurine, red; Q-glutamine, green; E-glutamate, blue) visualization (Figure 30) allows retinal pigmented epithelium and Müller cells to be observed independent from all other cell classes. In this visualization, L-glutamate labeling in combination with taurine demonstrates 3 surviving cones protruding above the Müller cell seal (pink cells). Additionally, the mosaicism in the Müller cell signatures is evident demonstrating the pathological heterogeneity of small molecular signals. In this region of retina, the Müller cell seal is essentially complete, isolating the neural retina from the RPE and choroid and the retina is bereft of any photoreceptors save the 3 isolated cone photoreceptors in this region (21).

Phase 3 is typified by extensive, de novo neurite formation, new synapse formation and neuronal death. In the Tg P347L rabbit, the retina is fully involved in *Phase 3* remodeling by 10 months. Maximal projection confocal images of protein kinase C immunoreactivity (PKC), rhodopsin 1D4 immunoreactivity (Rho 1D4), and a nuclear stain (DAPI) as red, green and blue respectively, demonstrate not only the reduced rhodopsin immunoreactivity associated with degenerate rod photoreceptors, but also bipolar cell axons that have become multipolar cells, projecting along the top border of the IPL (Figure 31). These processes extend outside of the normal lamination of the bipolar cell population, coursing across the IPL, forming swellings also suggestive of synaptic connections and implying new retinal connectivities (21). These bipolar cells also are downregulating iGluR and mGluR6 expression, results observed previously in rodent and human retinal degenerative diseases (31).

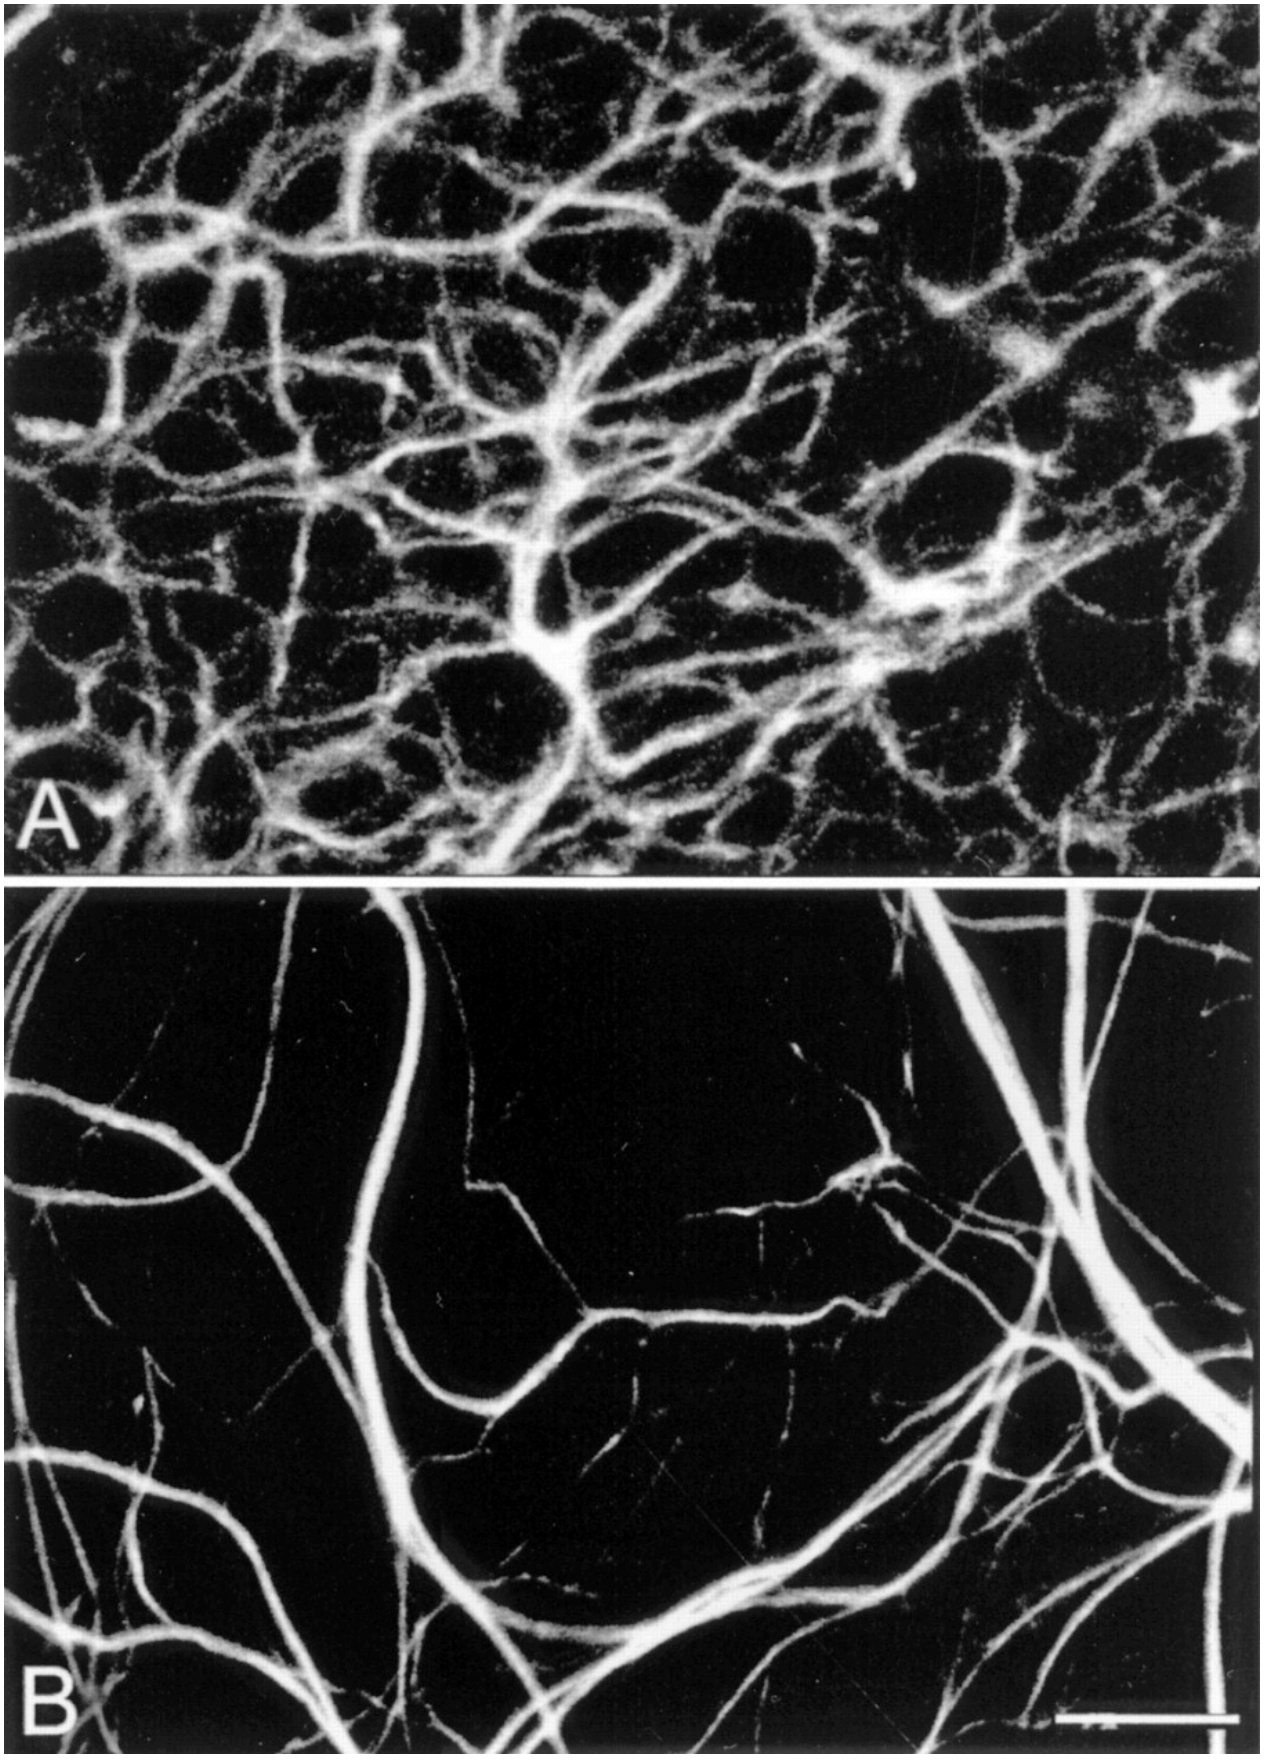

Figure 17. Whole-mount staining of horizontal cells with neurofilament antibodies. Compare the tight network made by horizontal cell axonal endings in the OPL of wt mouse retinas (A) to the loose arrangements of hypertrophic process in the rd mouse (B). From Strettoi and Pignatelli, 2000 (6).

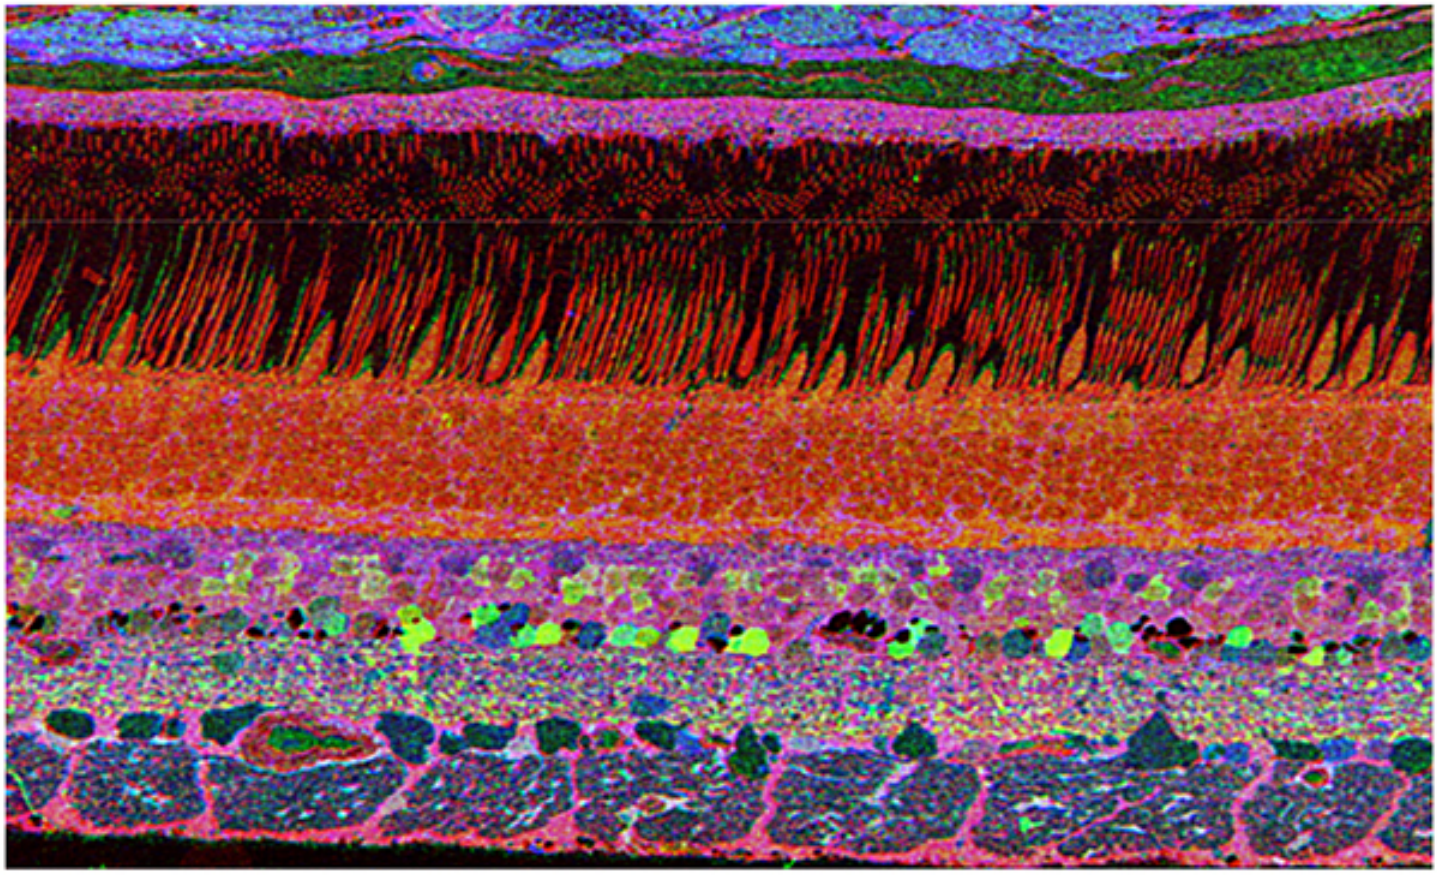

Figure 18. Human retina with taurine, glycine and glutathione assigned to red, green and blue color channels respectively, revealing varied cell classes.

In another region of Tg P347L rabbit retina at 10 months, *Phase 3* remodeling can also be documented through persistent neurite formation of horizontal cells. In Figure 32, a maximal projection confocal image shows immunohistochemistry of PKC, calbindin (a calcium binding protein) and DAPI as red, green and blue respectively, demonstrating calbindin labeling in horizontal cells. Horizontal cell processes are seen projecting down into the IPL in an aberrant fashion (21). Calbindin has been used extensively before to examine alterations in the horizontal cell populations (4) and these results correlate nicely with those observed in the human retina.

Examining neuritic sprouting from amacrine cells in the Tg P347L rabbit in *Phase 3* at 10 months shows new GABAergic and glycinergic neurite formation. Figure 33 is a γGE :: rgb image, visualizing photoreceptor cells, bipolar cells, GABA+(γ) and glycine+(G) amacrine cells, and glutamate+ (E) ganglion cell superclasses. Overall the lamination of the IPL appears normal, but this belies excitatory and inhibitory cell populations in these retinas that are creating new neurites, seen here as fine filamentous magenta signals running underneath the Müller cell seal seen in Figure 30, and above most remaining bipolar cell populations (21).

Figure 34 shows GABA labeling in *Phase 3* of remodeling in the Tg P347L rabbit retina at 10 months, revealing GABAergic amacrine cell sprouting. Again, the overall lamination of the IPL revealed by GABA immunoreactivity appears normal despite early GABAergic sprouting events, including persistent neurite formation, new synapse formation and neuronal death (21). This is still early in *Phase 3*, prior to large scale topographic reorganization which occurs as Müller cells continue hypertrophic responses and additional numbers of cells from each cell class undergo cell death.

Sprouting from amacrine, bipolar, horizontal and ganglion cell populations can continue to elaborate, forming large tangles of GABAergic, glycinergic and glutamatergic processes into microneuromas, or tufts of neuropil

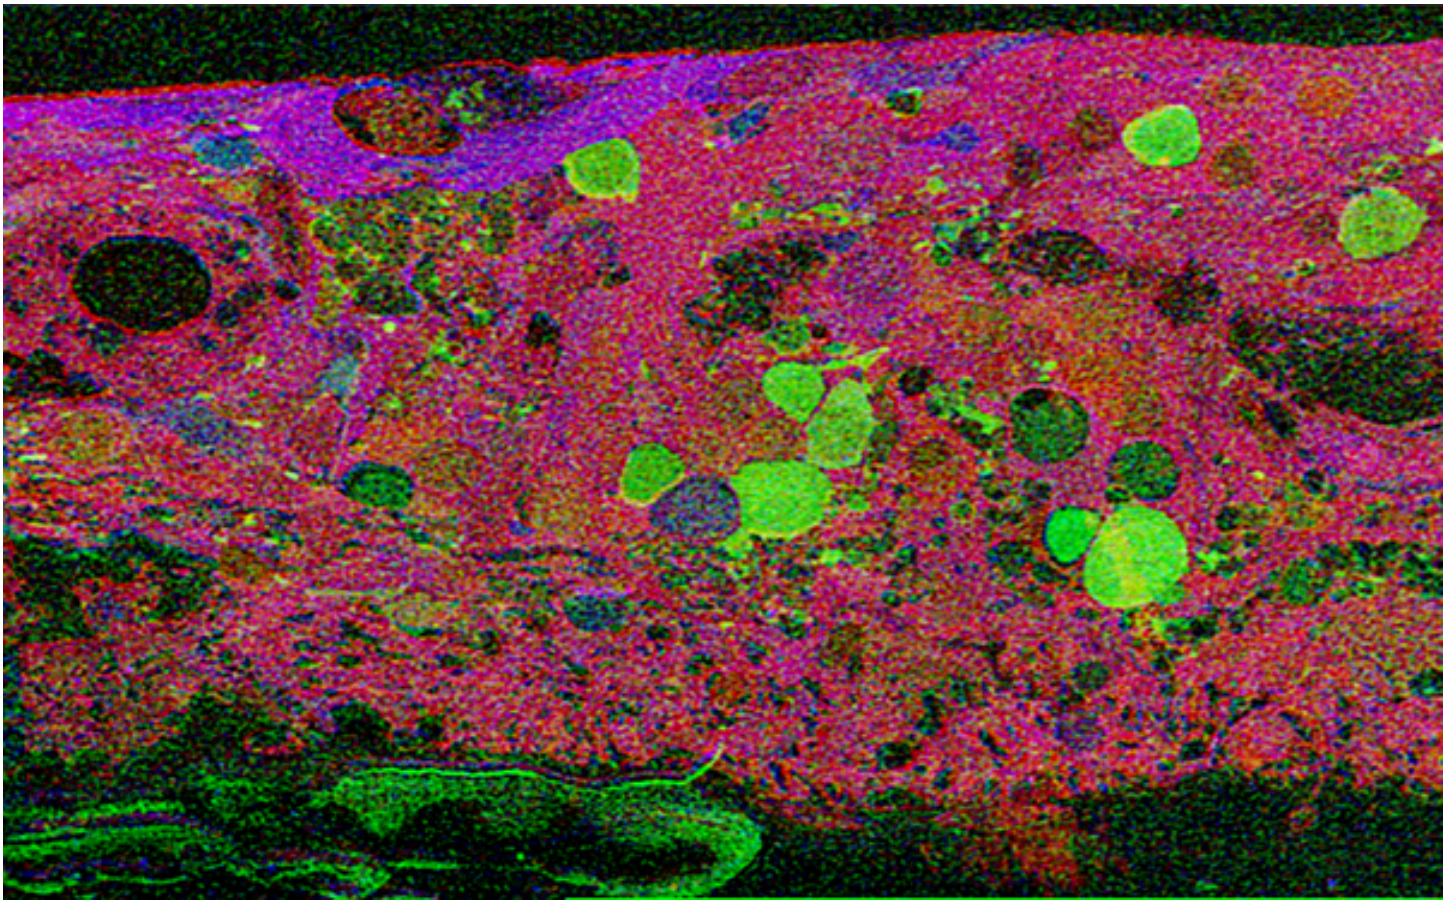

Figure 19. Late stage molecular imaging of human retina from a patient with RP with taurine, glycine, glutathione mapped to red, green and blue color channels respectively.

Video 20. An image of a GHL mouse retina with taurine, glutamine and glutamate mapped to red, green and blue color channels respectively. A video showing a digital morphing animation of retinal degeneration, spanning 700 + days in the life of a GHL Tg mouse retina is linked to the image.

Download video

formed de novo, post retinal maturation and development. These microneuromas break traditional rules of plexiform lamination and can be seen in Figure 35 in the hrhoG mouse, erupting out of the IPL and coursing up to the top of the retina underneath the RPE.

By late stage in *Phase 3*, persistent neurite formation, new synapse formation and neuronal death continue with all cell classes participating. As cell classes continue to sprout processes from bipolar, amacrine, horizontal and ganglion cells, many processes begin to co-fasiculate and run together in microneuroma structures, complete with synaptic connectivity. Figure 36 is a collection of neuritic processes moving from one location to another within an area of Müller cell seal. Microneuromas are not silent structures as they contain both ribbon and conventional synapses with a number of synaptic arrangements including, but not exclusively, amacrine > amacrine, bipolar > amacrine, and amacrine > bipolar, and bipolar > bipolar (9).

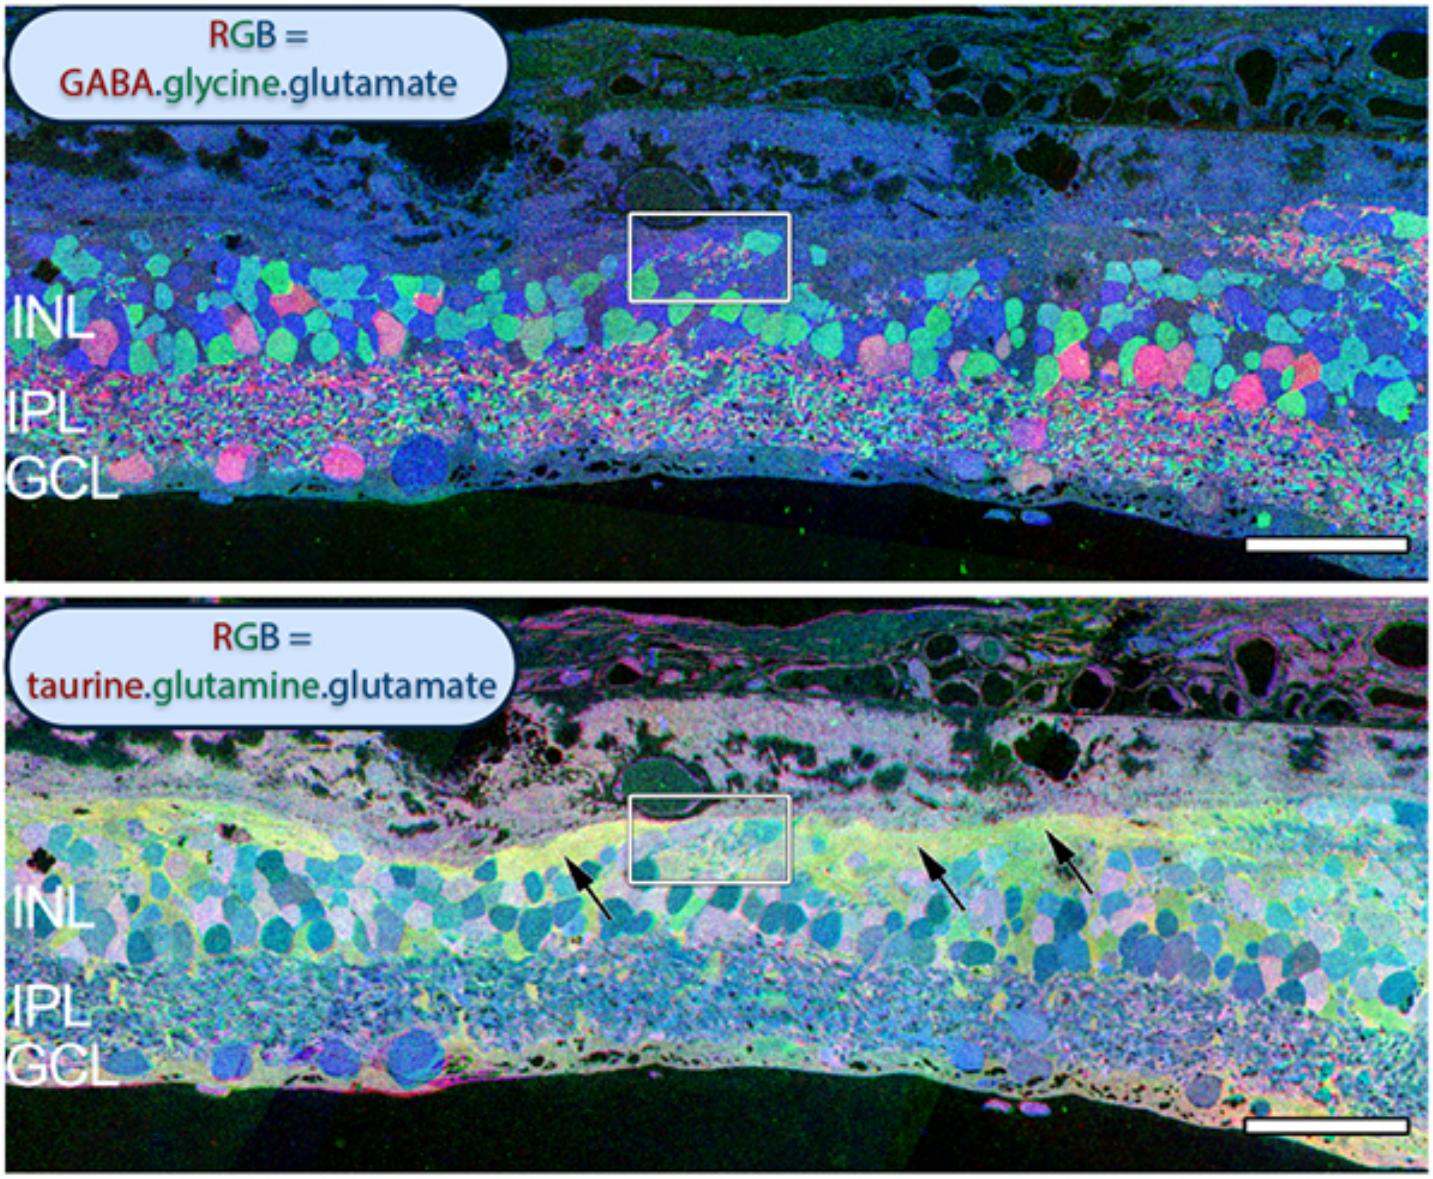

Figure 21. Human retina from a patient with advance autosomal dominant RP. GABA, glycine, glutamate (red, green, blue) mapping in the top panel reveals novel tufts of neuropil, termed microneuromas (box) with amacrine cells abutting Bruch's membrane and the choroid. The bottom panel shows taurine, glutamine, glycine (red, green, blue) mapping of the same region demonstrating Müller cell revision and Müller cell seal formation (arrows) walling off the neural retina. Scale bar = 90µm.

9. The earliest changes in the retina occur before obvious histological changes occur.

In models of RP where rods and cones die simultaneously, bipolar cells lose dendrites and all iGluR/mGluR responsivity. From *Phase 0-1*, rod bipolar cells down-regulate GluR expression in the dendrites. In *Phase 1-2*, rod and cone photoreceptor stress and subsequent cell death happen, while dendritic modules are lost. In *Phase 3*, wider retinal remodeling ensues, resulting in sprouting and formation of new axonal modules. In models of RP where cones outlive rods, some bipolar cell dendrites switch targets. In normal rod bipolar cell architecture, dendrites from rod bipolar cells bypass cone pedicles. In *Phase 0-1*, as in rod/cone dystrophies, rod bipolar cells down regulate GluR expression in the dendrites. In *Phase 1-2* with rod stress and death, dendritic modules are lost. In late *Phase2/Phase 3*, some rod bipolar cells form sprouts that contact cone pedicles, making peripheral

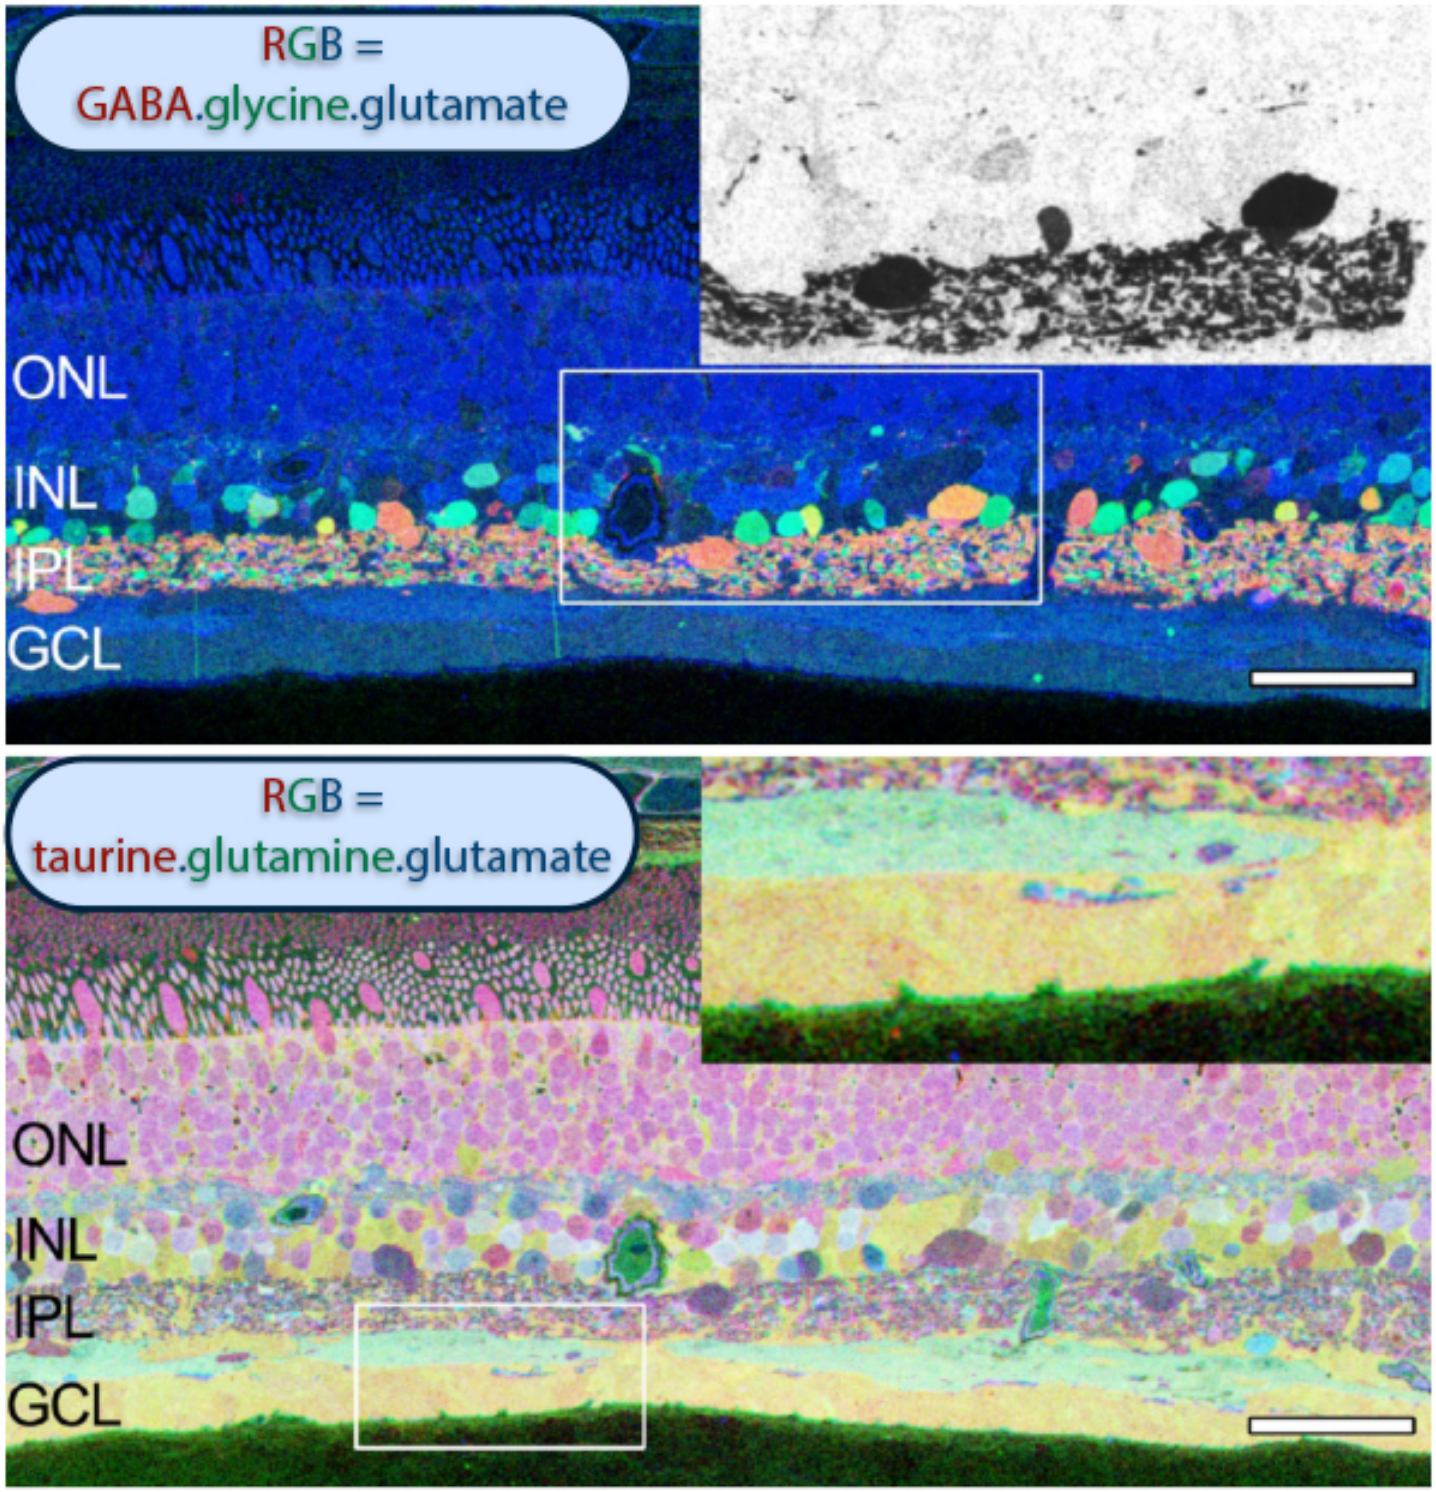

Figure 22. Early-stage human geographic atrophy/AMD. The top panel shows GABA, glycine, glutamate (red, green, blue) mapping in early stage human geographic atrophy/AMD tissue demonstrating processes arising from both glycinergic and GABAergic amacrine cells (GABAergic processes extending into the outer plexiform layer in inset). These processes are the beginnings of microneuroma formation. The bottom panel shows taurine, glutamine, glutamate (red, green, blue) mapping that demonstrates alterations in Müller cell signatures, notably an increase in the amount of taurine in subsets of Müller cells indicative of Müller cell stress (inset). Scale bar = 90μm.

contacts on cone pedicles. Video 37 and Figure 38 summarize the degenerative phases that a retina with RP type degeneration goes through, as described above. In human RP, it is clear that the peripheral retina goes into

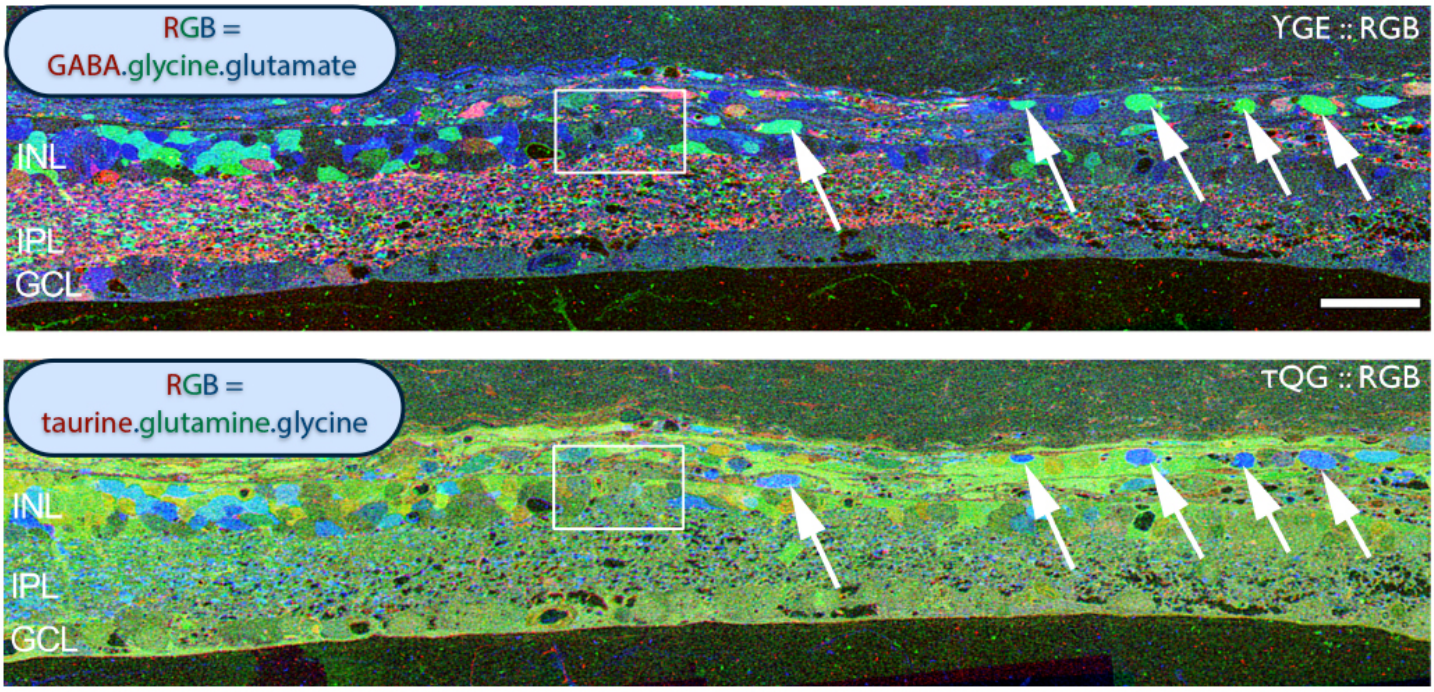

Figure 23. Neural emigration in a rat light damage model of retinal degeneration. Top panel. γGE::RGB: GABA, glycine, glutamate mapped as red, green, blue, demonstrates both GABAergic and glycinergic amacrine cells in addition to bipolar cells escaping the neural retina into the choroid (arrows). Bottom panel. τQG::RGB: taurine, glutamine, glycine mapped as red, green, blue, demonstrates Müller glia with glycinergic amacrine cells embedded among them, passing outside of the retina through a break (box) in Bruch's membrane. Scale bar = 90μm.

Phases 1-3 long before the central retina and fovea does. The RP patient eyes that have been looked at with good anatomical techniques have *Phase 3* retina in the periphery and phase 1 in the fovea (4, 43, 45, 46, 55).

10. Conclusion

Fundamentally, in every instance of retinal disease and every model of retinal degeneration examined to date, the survival of cones appears to at least delay the gross onset of *Phase 3* remodeling. This can be seen in local patches of retina where cones persist with preserved bipolar cell dendritic structures. Even when cones are severely compromised and lack outer segments, visual pigment expression and are altered in morphology, as long as cones are present, the retina appears to maintain its state in *Phase 2*. This may suggest the involvement of integrins, or demonstrate that mere connectivity through the established circuit is enough to maintain Ca^{++} signaling and gene expression profiles. At the very least, it provides evidence that prolonging cone survival is a substantial advantage to maintaining vision or making subsequent vision rescues, such as survival factors, stem or progenitor cell transplantation, fetal retinal sheet transplantation, and gene therapies, more successful.

As we move forward into genetic models with various treatments designed to delay or recover vision loss, we need to consider the potential shown by plasticity in the retina. Retinal remodeling in *Phase 1* and *Phase 2* might for instance, be reversible and may in fact respond to the right therapeutic interventions. However, by the time the retina enters *Phase 3*, with its alterations to wiring and neuritogenesis, cell migration and cell death, it is likely too late. The problem with gene therapies for rods and cones is that they depend upon photoreceptor survival. If we can prolong cone survival, this might point the way to a "cure". However, as we noted above, photoreceptor involvement in retinal degenerative disease begins long before the photoreceptors die. This begins to define "windows of opportunity" where gene therapies might succeed, and suggests that combination gene therapy with survival factor administration might be a reasonable approach to prolong photoreceptor survival through delivery of neurotrophins.

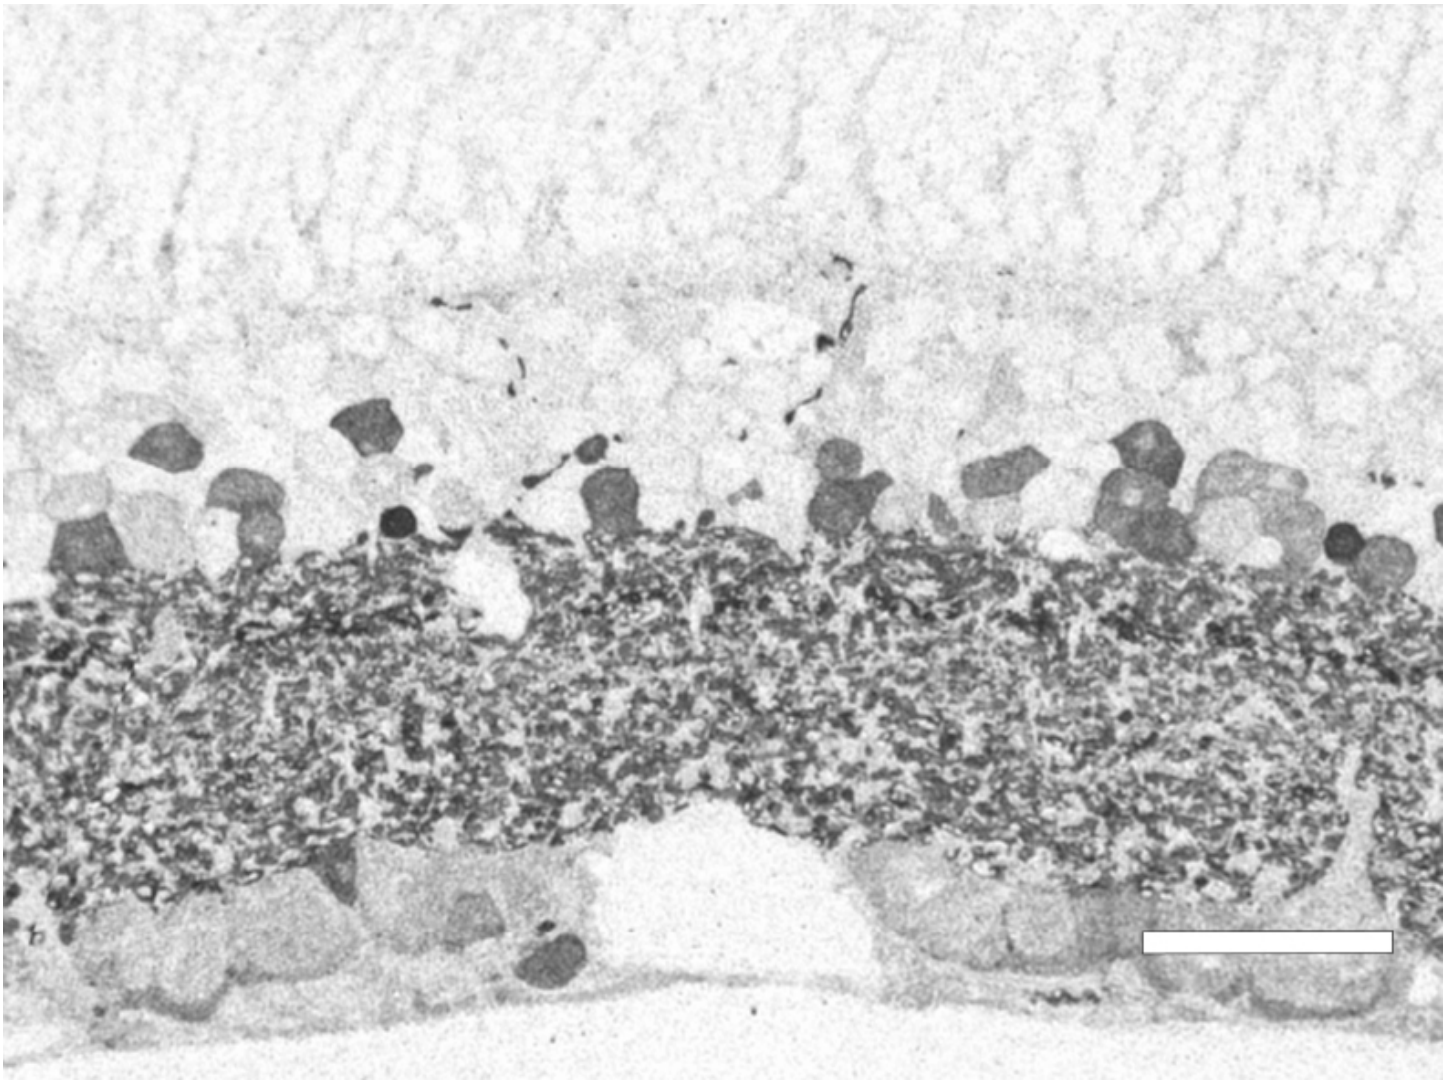

Figure 24. Retina from a 23-month-old male DBA/2J mouse labeled for GABA. The staining demonstrates aberrant GABAergic amacrine cell remodeling with new neurites projecting upwards into the outer plexiform layer. Scale bar = 30μm.

About the authors

Bryan William Jones, Ph.D., is Associate Research Professor at the John A. Moran Eye Center at the University of Utah. His work involves disorders of retinal degeneration and how those diseases affect the intrinsic retinal circuitry including the implications for rescue of vision via gene therapy, and retinal bionic or biological implants. Other research efforts involve exploring metabolomics for application in understanding physiology and medicine and for drug development.

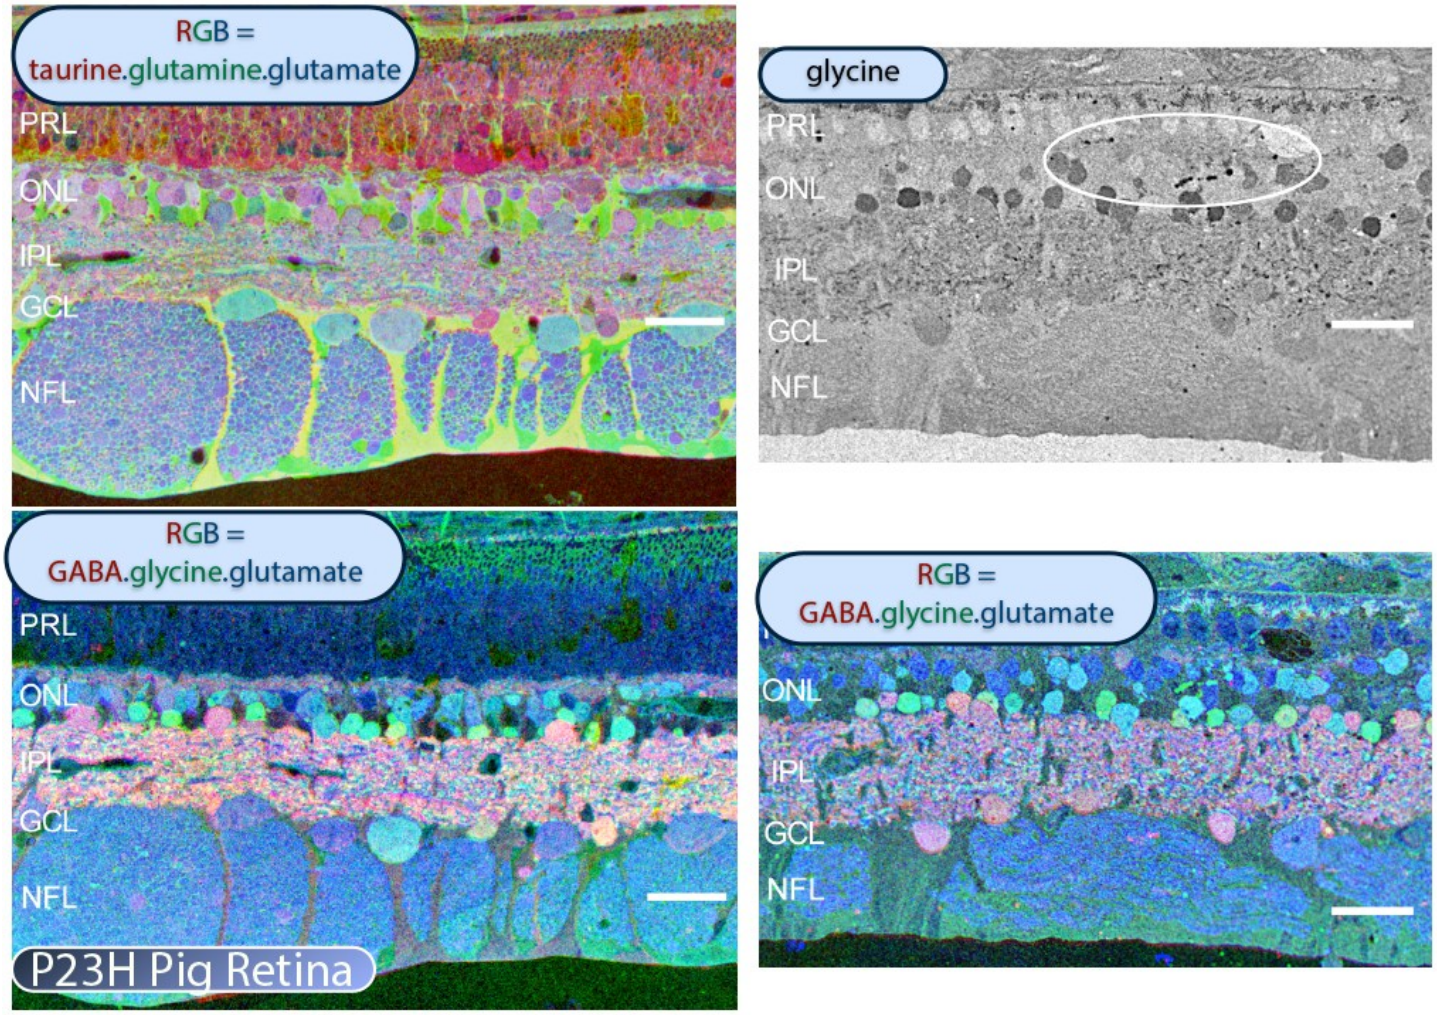

Figure 25. Early stage porcine P23H model of retinal degeneration. Top left, Taurine, glutamine, glutamate (red, green, blue) showing reduced photoreceptor outer segment length and early stages of Müller cell stress and alteration of molecular signatures (green/yellow). Bottom left) GABA, glycine, glutamate (red, green, blue) of same region showing normal appearing OPL, IPL and neuronal signatures. Top right, glycine immunohistochemistry demonstrating early retinal remodeling/sprouting in the glycinergic amacrine cell populations. Bottom right) GABA, glycine, glutamate (red, green, blue) mapping demonstrates dramatically truncated photoreceptor outer and inner photoreceptor segments with the glycine signal shown in the glycine image at top right, in the green channel demonstrating remodeling events. Scale bar = 30μm.

Robert E. Marc, Ph.D., is Distinguished Emeritus Professor of Ophthalmology at the John A. Moran Eye Center at the University of Utah. Professor Marc taught for 37 years at the graduate level, graduated 9 PhDs, and supervised 10 post-doctoral fellows. Robert is currently the co-owner of Stray Arrow Ranch, and CEO

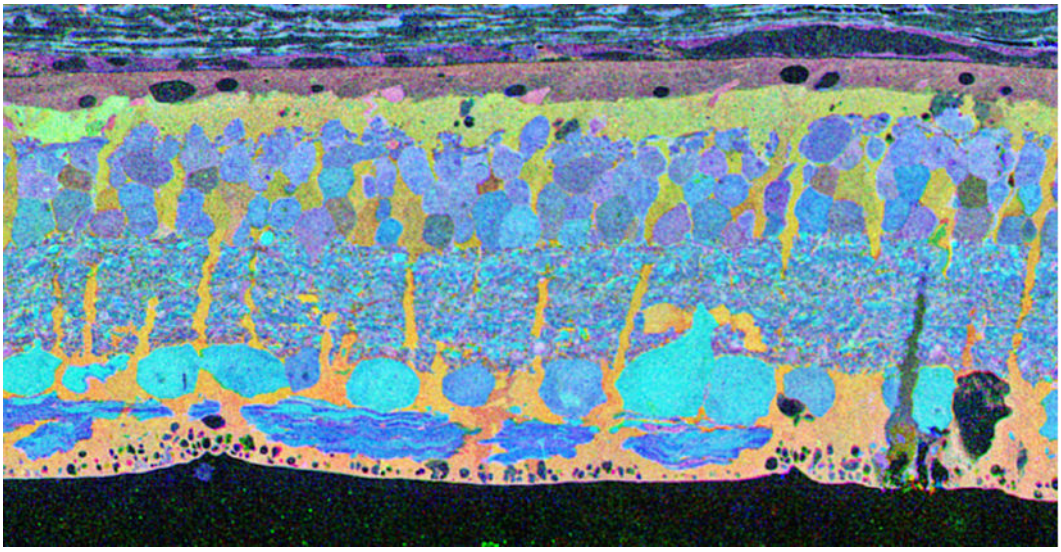

Figure 30. τQE :: rgb (taurine, glutamine, glutamate as red, green, blue) visualization in the 10 month Tg P347L rabbit retina. The Müller cell seal in this region is almost complete. Four to five remnant cone photoreceptors are evident in this image as light pink structures embedded in the Müller cell seal.

Figure 26. The founder TgP347L rabbit seen with low light illumination. The TgP347L rabbit precisely mimics autosomal dominant RP in the human including the photoreceptor degeneration, bipolar cell, horizontal cell, amacrine and ganglion cell involvement. Glial cell involvement is also appropriately represented with Müller cell seal formation. The second large eye model and our favorite animal model for autosomal dominant RP is the TgP347L rabbit.

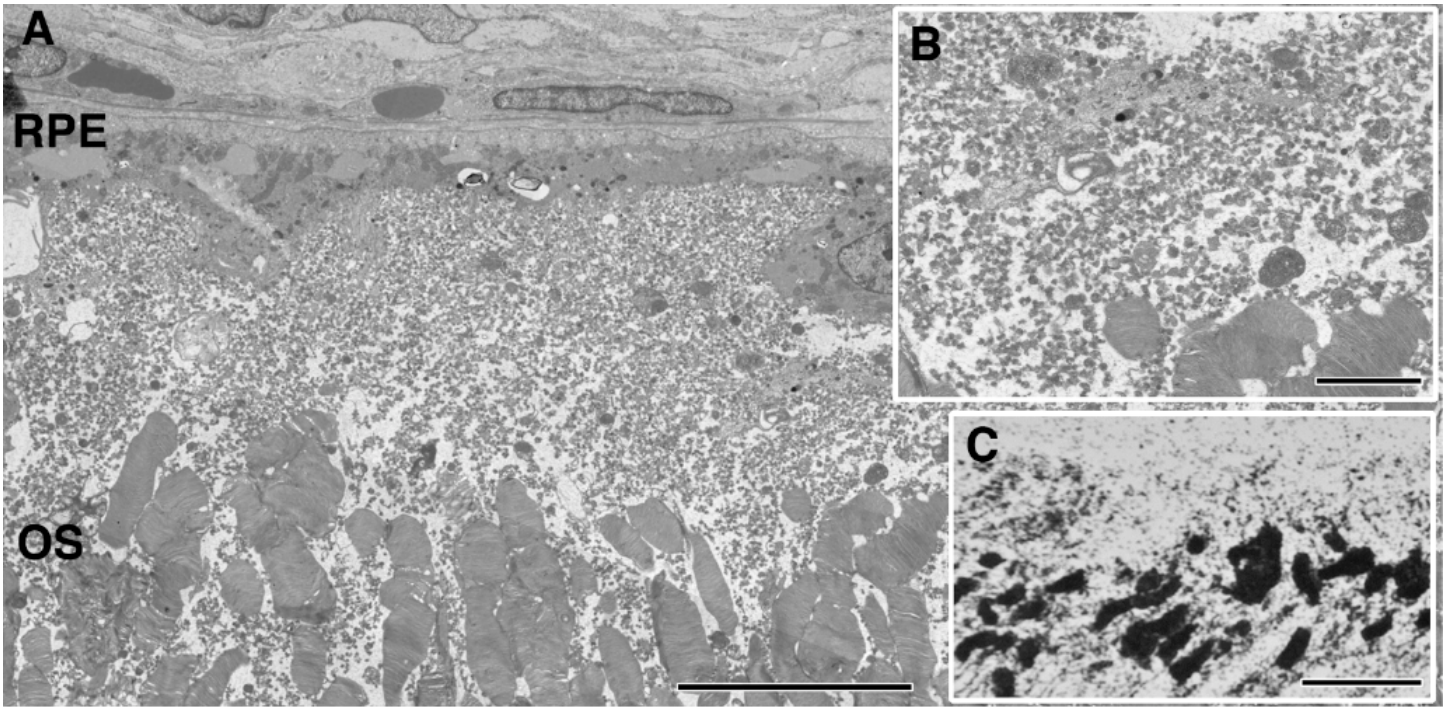

Figure 27. TEM of the photoreceptor/RPE interface in a 16-week old TgP347L rabbit. A) Debris found in the subretinal space composed of vesicles from 40-300nm in size. Scale bar = 10μM. B) Inset is a higher magnification view of the debris around outer segments. Scalebar = 2μM. C) All vesicles are immunoreactive for rod opsin. Scale bar = 10μm.

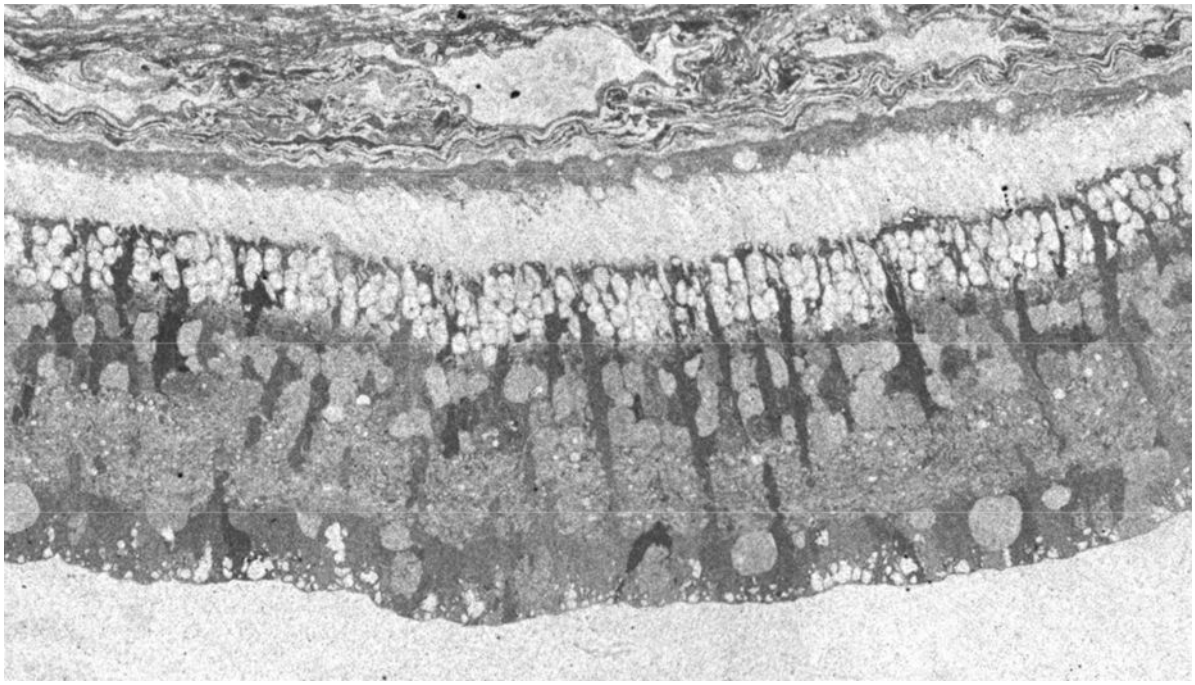

Figure 28. A 4-month-old Tg P347L rabbit retina showing varying glutamine signals in the Müller cells.

of Signature Immunologics. He is credited with the creation of Computational Molecular Phenotyping, developing channel mapping and visualization technologies as well as building the first comprehensive connectome with the resolution and features required to identify neurons and map connectivities.

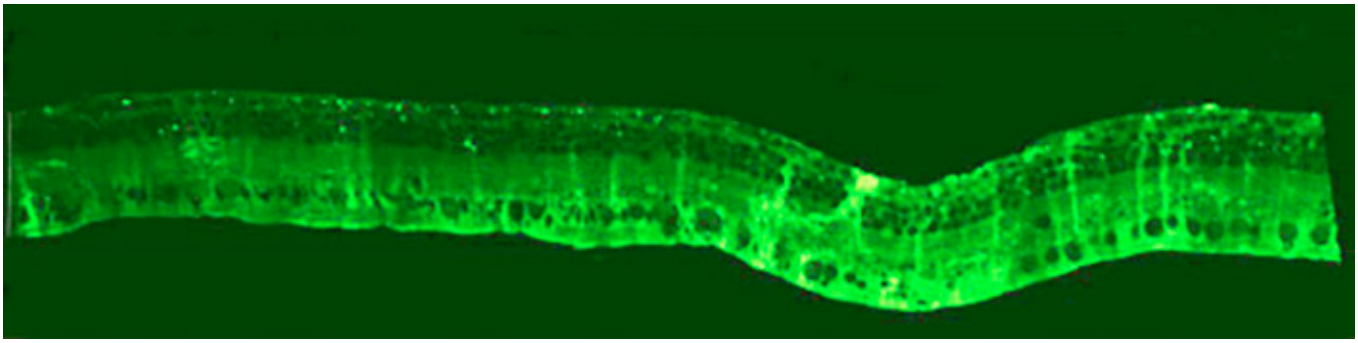

Figure 29. A panoramic image composed of 6 panels of a 10-month-old Tg P347L rabbit retina showing mosaicked glutamine synthetase expression.

Rebecca L. Pfeiffer, BA/BS, is a Graduate Student of the Interdepartmental Program in Neuroscience in the Marc Lab at the John A. Moran Eye Center at the University of Utah. Her research focus is on understanding the progression of retinal disease. This is being evaluated using a combined metabolomics and connectomics approach to evaluate the multiple stages of retinal remodeling and its impact on both neurons and surrounding glia.

Acknowledgements

Our thanks to Mineo Kondo and Hiroko Terasaki for making this work possible:

Mineo Kondo, M.D., Ph.D., Professor of Ophthalmology, Mei University Graduate School of Medicine, Tsu, Japan and is responsible along with Hiroko Terasaki for the generation of the P347L rabbit. Mineo's work focuses on using the electroretinogram for the diagnosis of various retinal diseases as well as exploring animal models of human retinal and optic nerve diseases.

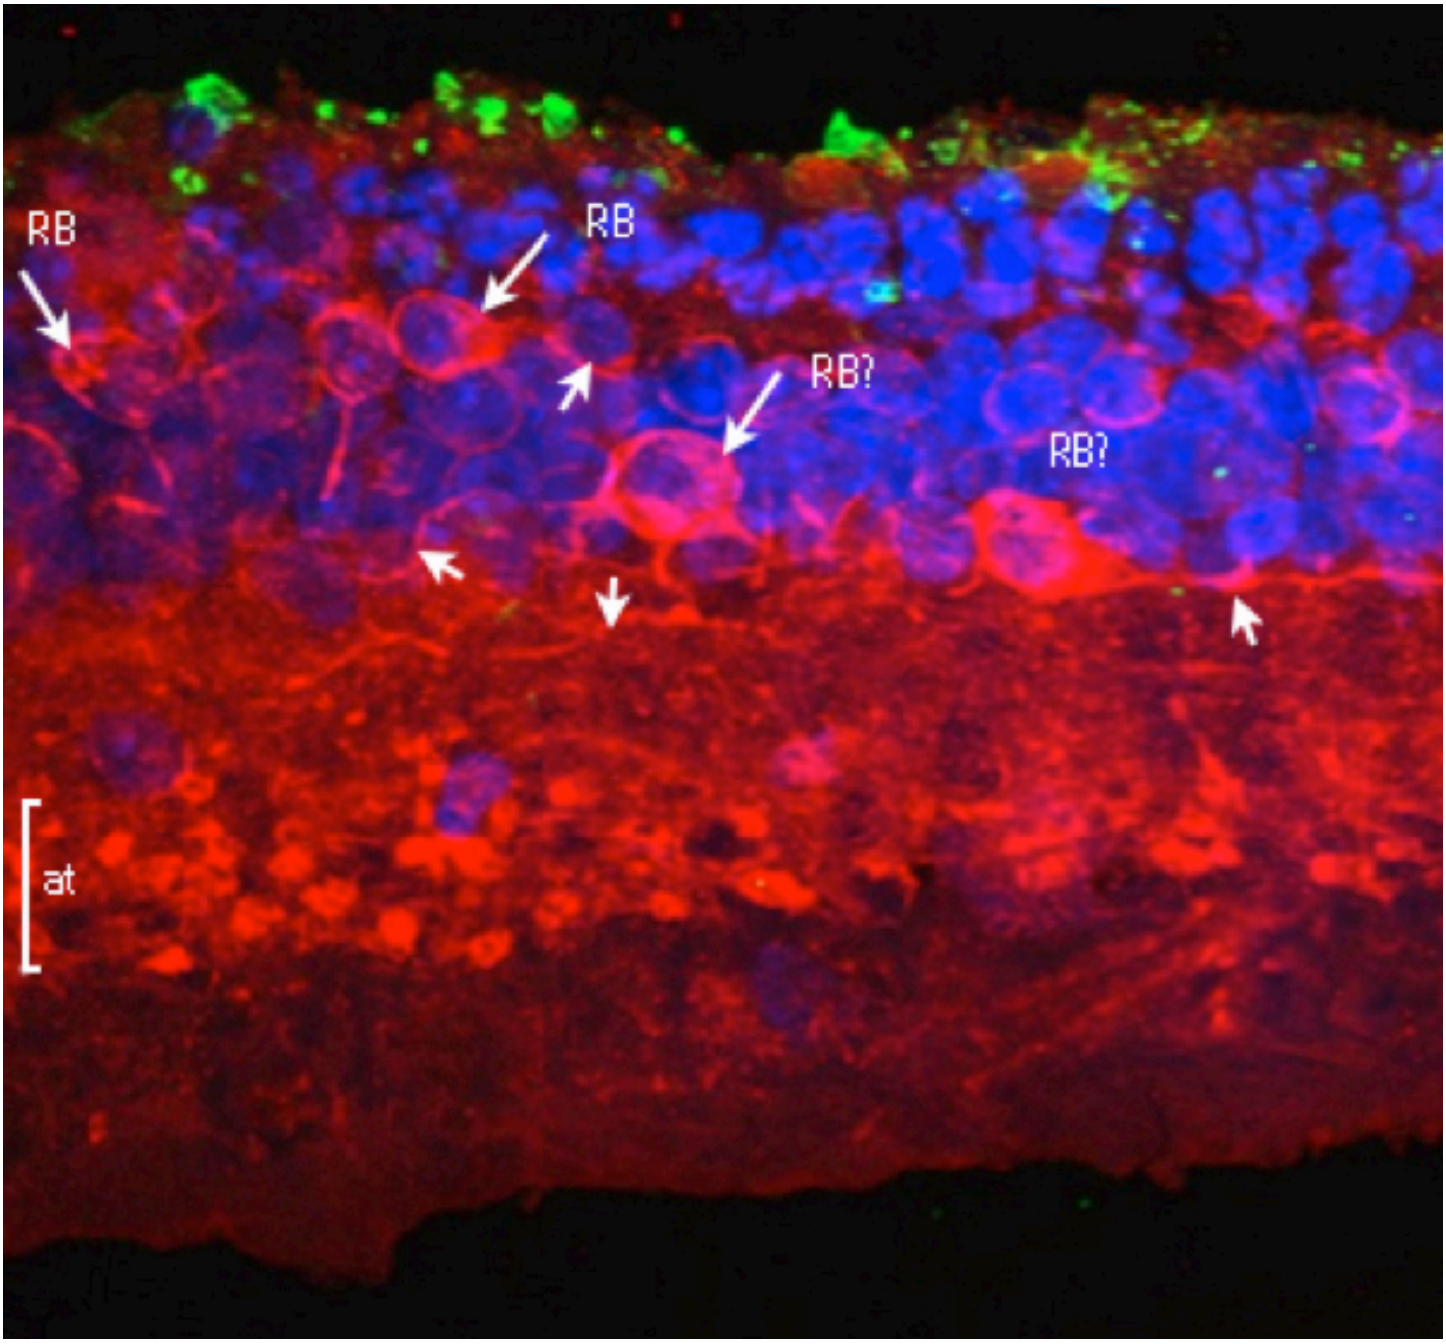

Figure 31. Maximal projection image of PKC (red), Rho 1D4 (green), and DAPI (blue) in the Tg P347L rabbit retina. Figure demonstrates reduced rhodopsin immunoreactivity (green spots in ONL) and some rod bipolar cells (red) with aberrant dendrites and axons (small arrows) compared with normal rod bipolar axon terminals in the lower IPL (white bracket , at).

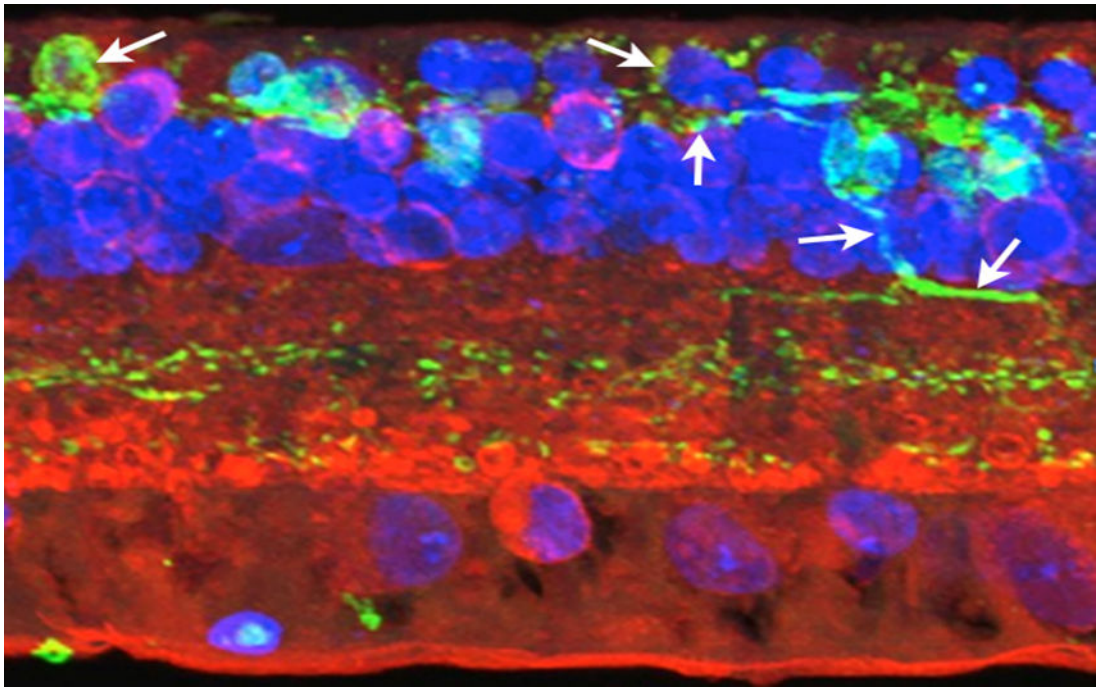

Figure 32. Maximal projection image of PKC (red), calbindin (green), and DAPI (blue) in the Tg P347L rabbit retina. Figure demonstrates calbindin labeling in horizontal cell abnormalities. Horizontal cell processes can be seen projecting into the IPL and ramifying therein.

Hiroko Terasaki, M.D., Ph.D., is Professor and Chairman of Ophthalmology at Nagoya University Hospital. Hiroko is responsible, along with Mineo Kondo for producing the P347L rabbit model of retinal degenerative disease. Professor Terasaki received her medical and ophthalmological training at the Medical School of Nagoya University under the tutorship of emeritus Professors Hiroshi Ichikawa, Shinobu Awaya, and Yozo Miyake. She was also trained at the Schepens Eye Research Institute in Boston, MA under the guidance of Professor Tatsuo Hirose.

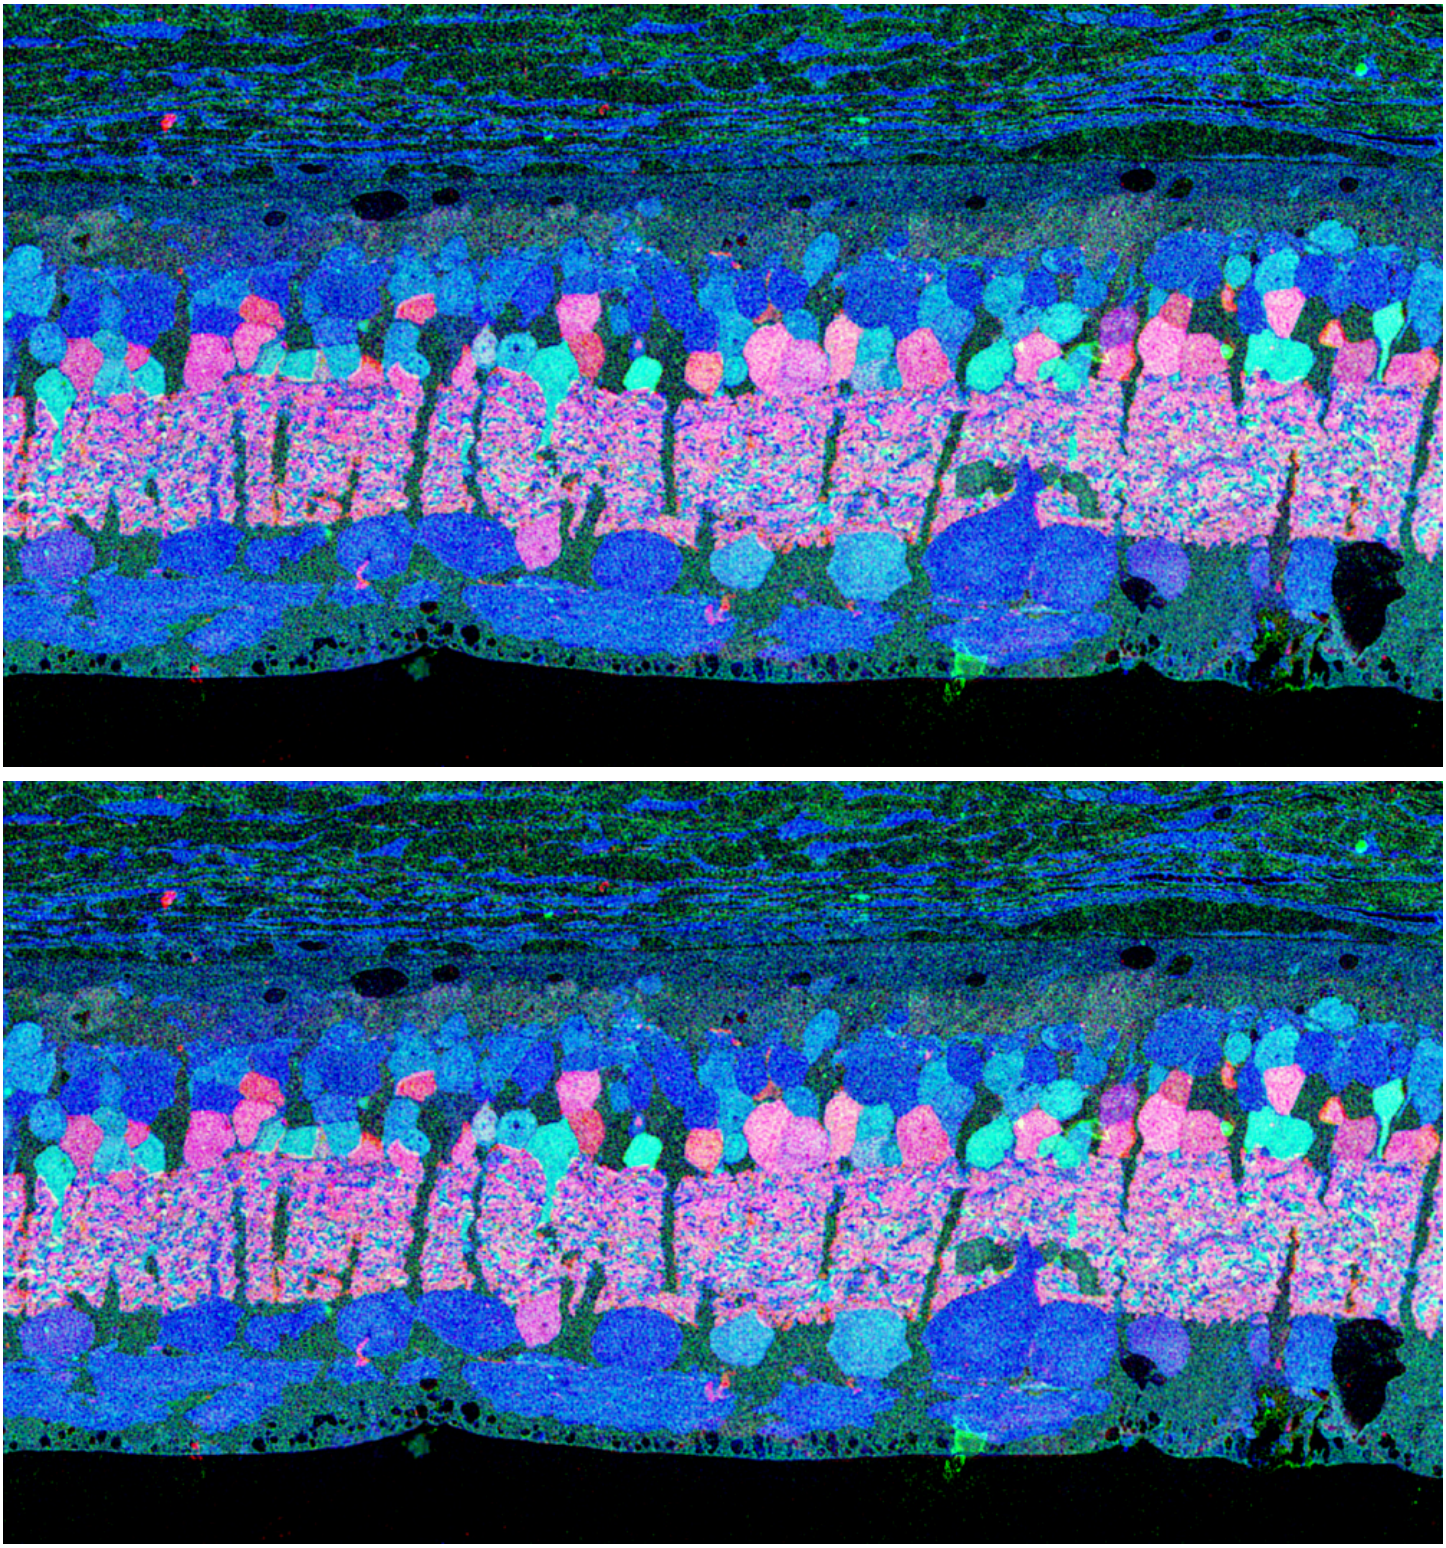

Figure 33. γGE :: rgb (tyrosine, glycine, glutamate as red, green, blue) visualization of the rabbit Tg P347L retina demonstrating photoreceptor, bipolar cell, GABA, and glycine amacrine cells and ganglion cell superclasses. Sprouting of both GABAergic and glycinergic amacrine cell processes can be visualized in the red and green channels with processes from both cell superclasses appearing outside their normal lamination.

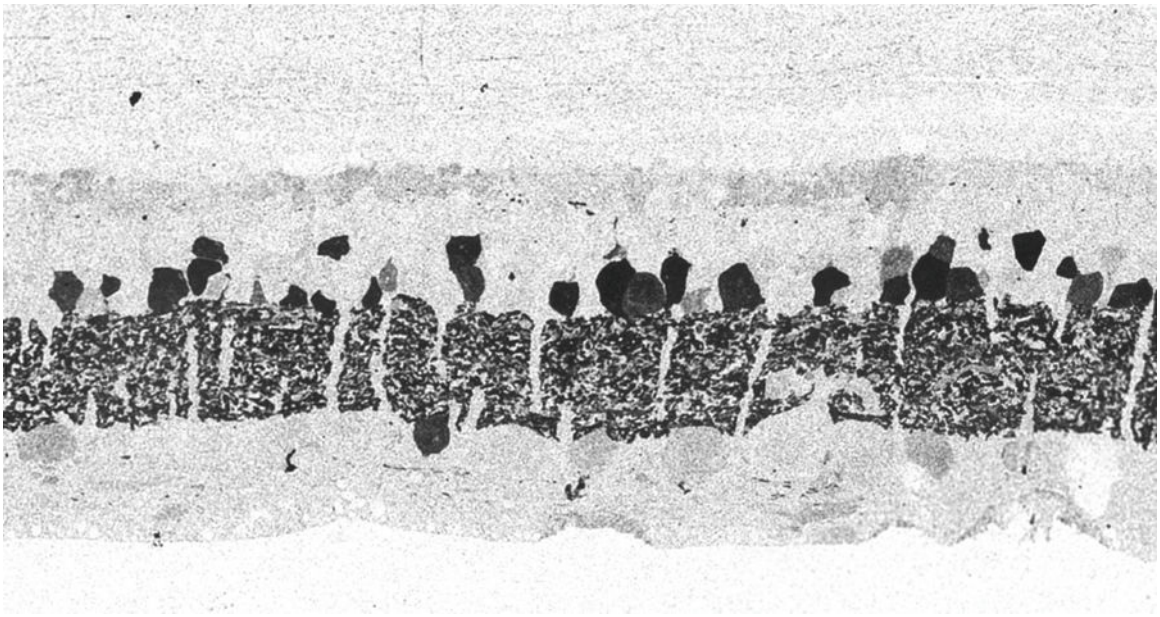

Figure 34. GABA channel from Figure 33 showing increased expression of GABA in the Müller cells and anomalous neurites from GABAergic amacrine cells running beneath the Müller cell seal.

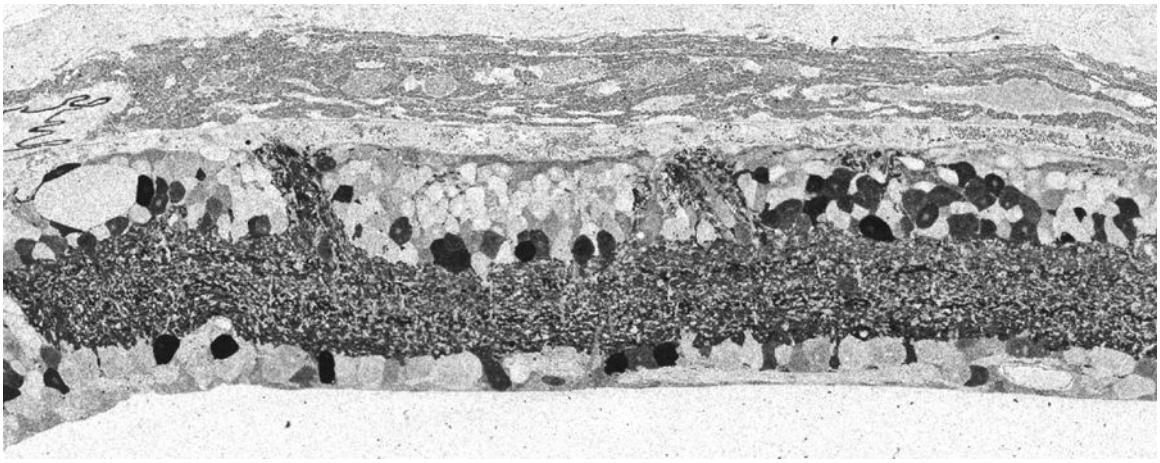

Figure 35. GABA channel showing elaboration of microneuroma formation in an 10.5 month old hrhoG mouse.

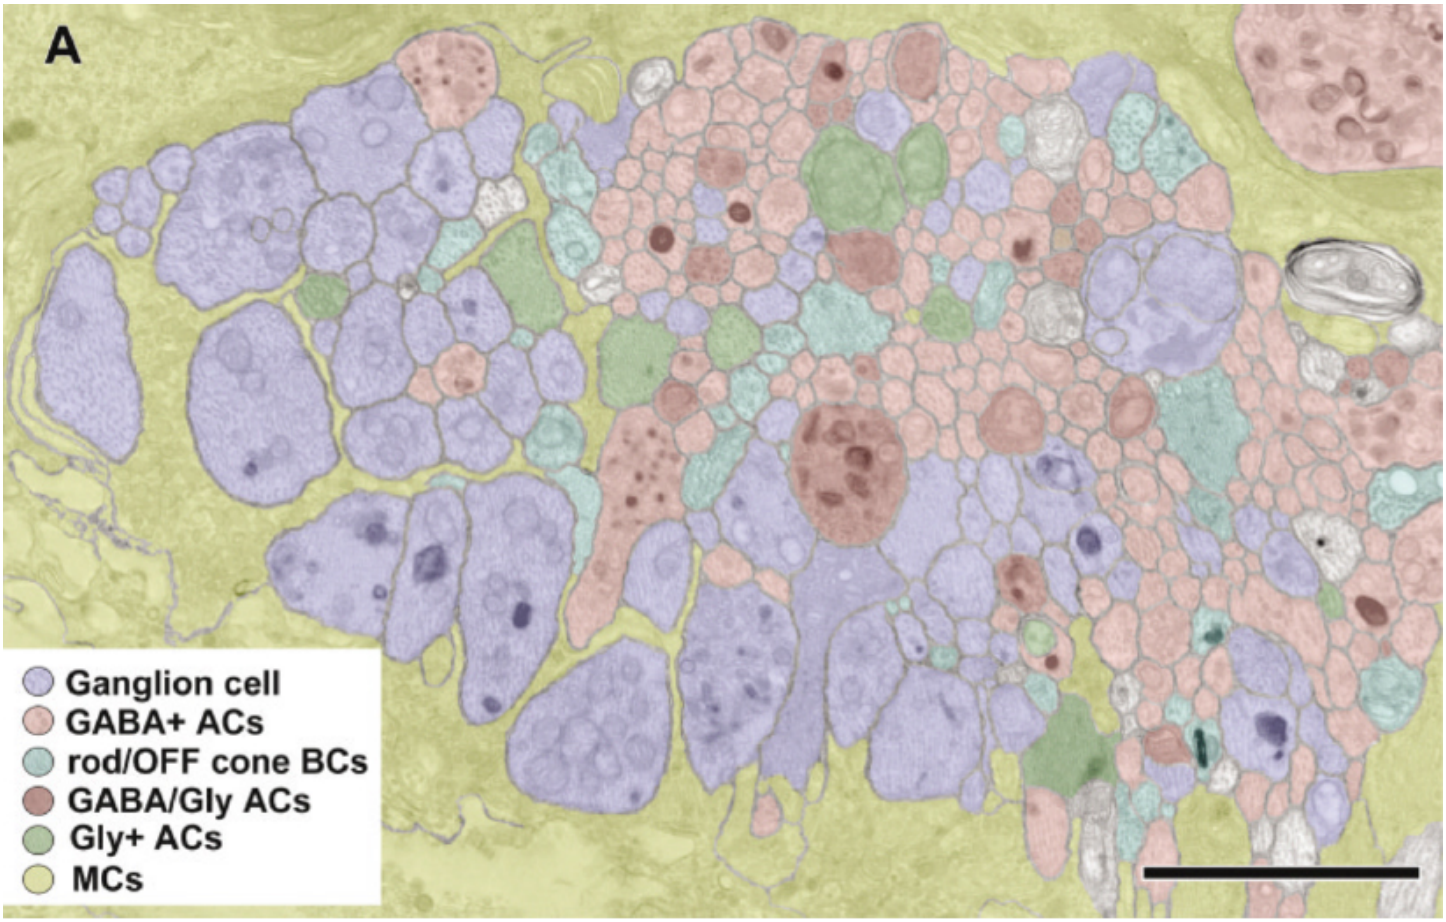

Figure 36. A microneuroma fascicle approximately 2 μm away from the distal margin of the neural retina underneath the Müller cell seal in an RCS rat retina. Six classes of neurons are color-coded according to their CMP signatures: ganglion cells (blue; high glutamate, low taurine); GABAergic amacrine cells (light red; high GABA); glycinergic amacrine cells (olive; high glycine); a mixed glycine+ and GABA+ class (dark red); bipolar cells (cyan, high glutamate, high taurine); Müller cells (yellow, high taurine, high glutamine). Unclassified elements are not colored.

Age-Related Macular Degeneration (AMD)

Gregory S. Hageman, Karen Gehrs, Lincoln V. Johnson, and Don Anderson

Created: January 1, 2008.

Introduction

Age-related macular degeneration (AMD), the leading cause of worldwide blindness in the elderly, is a bilateral ocular condition that affects the central area of retina known as the macula. The macula lutea, which derives its name from the deposition of yellow xanthophyll pigments (see chapter on simple anatomy), is located temporal to the optic disc and is bounded by the temporal superior and inferior vascular arcades (Fig. 1). Although the macula comprises only four percent of retinal area, it is responsible for the majority of useful photopic vision. The fovea lies at the center of the macula (Fig. 1, asterisk) and is approximately 2mm in diameter. The fovea is particularly well seen in vertical section view using ocular coherence tomography techniques in living eyes (Fig. 2). The fovea contains the highest density of cone photoreceptor cells and is the only region of the retina where 20/20 vision is attainable. The macula accounts for almost 10% of the entire visual field. Thus, lesions developing in this region can have a major impact on visual function.

AMD has a tremendous impact on the physical and mental health of the geriatric population and their families. Prior to 1990, AMD of all forms was often referred to as "senile macular degeneration" or SMD, a reflection of the fact that the vision loss associated with AMD manifests late in life when most affected individuals are looking forward to enjoying retirement activities and maintaining independence. Instead, millions with AMD suffer bilateral central vision loss such that they can no longer drive, read a newspaper, prepare meals, or enjoy recreational activities. For many patients, the visual impairment associated with AMD means a loss of independence, depression, increased financial concerns and the need to adapt to vision loss at a time when they are likely suffering from other debilitating conditions (1-5).

The cost to society is only now being appreciated. A recent analysis of AMD in Australia predicts that the disease costs $2.6 billion per year (6). This is projected to grow to $6.5 billion by 2025, a total cost of $59 billion over the next 20 years. A treatment that reduced the progression by only 10% would save Australia $5.7 billion over that same period of time. Similar analyses for the United States are lacking, but given the demographics and higher cost of medical care in the US, the costs would be projected to as much as twenty-fold higher.

Clinically, AMD is classified into the nonexudative "dry" or atrophic form and the exudative "wet" or neovascular form. More severe vision loss is typically associated with the "wet" form that occurs in about 15% of all patients with AMD but up to 20% of legal blindness from AMD is due to the "dry" form (7).

Clinical Aspects of AMD

Clinical Presentation of AMD

Although autopsy studies have documented histological and ultrastructural changes associated with AMD in the retina, retinal pigment epithelium (RPE), choriorcapillaris and choroid in middle age, the disease typically does not manifest clinically before age 55 (10). AMD is generally thought to progress along a continuum from atrophic or "dry" AMD (Figs. 3 and 4) to neovascular "wet" AMD with approximately 10% - 15% of all AMD patients eventually developing the wet form. Occasionally patients with no prior signs of dry AMD present with exudative changes as the first manifestation of the condition. The typical clinical sign of "dry" AMD is pigment disruption and drusen (small yellowish deposits in Figs. 3maculardegen.F4maculardegen.F5-6) in the retina. Drusen may be small "hard" (small with discrete margins) or "soft" (larger with indistinct edges) (Figs. 3-maculardegen.F4maculardegen.F56). They lie between the RPE and an adjacent basement membrane complex known as Bruch's membrane (BM) (See later Figs. 13-maculardegen.F14maculardegen.F1516). Geographic

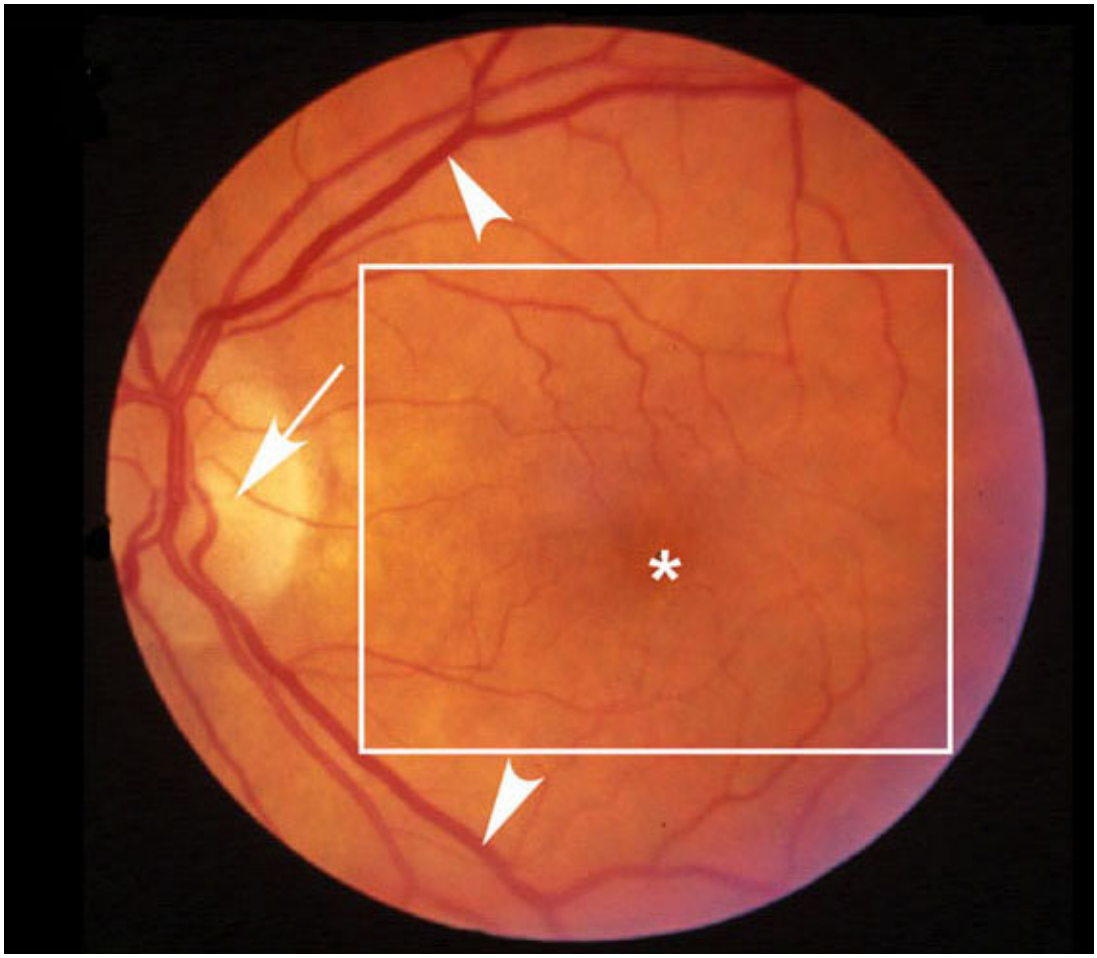

Figure 1. Normal macula of an elderly patient. The asterisk represents the location of the fovea, which lies directly in the visual axis. The macula (boxed area), which is adapted for high acuity vision, is located temporal to the optic nerve (arrow). It is approximately 6mm in diameter and centered on the fovea. The vascular arcades are indicated by arrowheads.

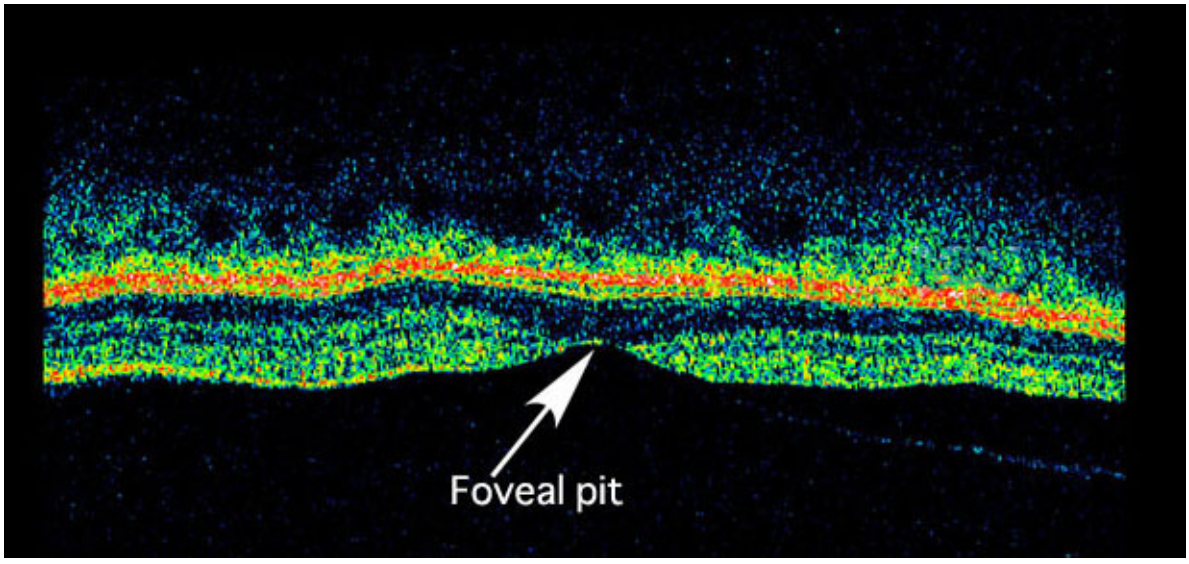

Figure 2. Ocular coherence tomogram (OCT) of a normal macula. The central area of depression (arrow) represents the fovea, corresponding to the asterisk in Figure 1. Ret, retina.

atrophy (GA) and RPE changes are also observed in dry AMD (Fig. 7). Several classification schemes have been developed that subdivide dry AMD into categories based on the number and size of drusen, amount of GA, and degree of pigmentary changes in the macula (25-28).

Angiography using sodium fluorescein dye is commonly performed when signs of AMD are observed and and particularly when exudative changes are suspected.

The natural history of dry AMD is progressive, with gradual loss of visual function that may span over many years time. Many patients with dry AMD are asymptomatic and unaware of the disease. In 10-15% percent of patients with dry AMD the deterioration is more rapid and extensive and they suffer significant vision loss due to geographic atrophy.

In approximately 10-15% of patients the condition progresses to the "wet" or neovascular form. Left untreated, the natural history of wet AMD advances further to a cicatrical stage referred to as a disciform scar. This process usually takes place over several months and typically results in a 4-8 mm diameter fibrotic scar underlying the macula accompanied by a central scotoma with severe central vision loss in one eye (Fig. 11). Patients with neovascular AMD in one eye have a 4 - 12% per year cumulative risk of developing neovascular AMD in the fellow eye. Thus, the risk of bilateral loss of central vision is high in those with the neovascular form of the disease (30).

The designation of exudative or "wet" AMD implies that fluid, exudates and/or blood are present in the extracellular space between the neural retina and the RPE (i.e. the subretinal space) and/or, as in the case of RPE detachments, between the RPE and Bruch's membrane (i.e. the sub-RPE space).

The neovascular tissue associated with exudative AMD is most commonly referred to as choroidal neovascularization (CNV) because it originates from the normal choriorcapillaris and extends through a dehiscence in Bruch's membrane into the subretinal or sub-RPE space. Sometimes multiple soft drusen become confluent and create large pigment epithelial detachments (PED's), which represent an elevation of the retinal pigment epithelium under the retina (Fig.10). Neovascularization associated with PEDs can be difficult to visualize clinically or image using fluorescein angiography; therefore, it is difficult to treat (29).

The following figures show pictures of different patients' retinas with advanced cases of AMD of the wet form. Fig. 8 shows a color fundus picture (a) and an early (b) and late fluorescein angiogram (c) from an individual with a classic choroidal neovascularization (CNV). Subretinal blood and fluid (arrowhead depicts edge) is clearly visible within the macular region in (a). The blood vessels have a lacey appearance (asterisk) in the early angiogram. Marked leakage of fluorescein (asterisk), with indistinct edges of hyperfluorescence (white area) is clearly visible in the late angiogram.

Fig. 9 shows a similar set of fundus pictures from an individual with occult choroidal neovascularization. A single, small punctate region of hemorrhage (arrow) and a ring of exudates (arrowhead depicts edge) appear more pronounced than typically occur in classic CNV. This patients had a minimal hyperfluorescence in the early phase of the angiogram, in contrast to that observed in the early stage of classic CNV. Speckled macular hyperfluorescence is visible in the late stage angiogram (Fig. 9c).

In the case shown in Fig. 10, the individual had a macular pigment epithelial detachment (PED). A multilobulated, hyperfluorescent lesion with sharply demarcated borders (arrow) is clearly visible in the late stage angiogram of Fig. 10a, arrow. The OCT shown in Fig. 10b, contrasts with a normal OCT of the fovea (Fig. 2) by being a blister-like elevation of the retina and retinal pigment epithelial layer off Bruch's membrane and the choroid.

The end stage of such lesions of the macula as shown in the three previous patients is illustrated by the last patient (Fig. 11). The color fundus photograph shows that the patient has end stage (cicatricial) exudative AMD.

A large disciform scar (arrowhead) covers the whole macular region. Such a patient would be almost totally blind in that eye.

Pathology of AMD

Overview

Until quite recently, the majority of research on AMD and the development of therapeutics for the disease has focused upon late-stage neovascular events. No clear-cut sequence for the initiation and progression of AMD has been identified that would allow it to be monitored and treated in its earliest stages. Moreover, the pathologic correlates of the different clinical phenotypes of AMD remain poorly understood, and there is a paucity of animal models that accurately mimic the characteristic features of the disease. Nevertheless, recent discoveries are beginning to provide a much clearer picture of the relevant cellular events, genetic factors, and biochemical processes that are associated with early AMD. This new information should hasten significantly the development of clinically effective diagnostics and therapeutics for the treatment of this devastating condition.

Morphological Correlates of Early AMD

From a histopathologic standpoint, the earliest detectable changes associated with AMD occur at the interface between the macular retina and the underlying layer of connective tissue and blood vessels known as the choroid (66-70). At this location lie the outer segments of rod and cone photoreceptors, the retinal pigment epithelial (RPE) cells, a stratified basement membrane complex termed Bruch's membrane (BM), and the choroidal capillary bed or choriocapillaris (Figs. 12, 13, BV of choroid).

The initial clinical diagnosis of early AMD is based on seeing drusen - the hallmark indicators of disease - and/or pigmentary changes in the macula. Drusen look like yellow-white spots in the retina (Figs. 3-maculardegen.F4maculardegen.F5maculardegen.F67). They are extracellular deposits located between the retinal pigment epithelial (RPE) basal lamina and the inner collagenous layer of the elastin-containing Bruch's membrane as illustrated in the schematic of Fig. 13 (71); The normal retinal choroidal interface is shown in comparison to the drusen bearing abnormal interface. Fig. 14 shows an actual histological section of retina where drusen are seen between the choroid and Bruch's membrane.

Bruch's membrane consists of an elastin core flanked on both sides by a collagenous layer and a basal lamina (see Fig. 13) (76-79). It is widely believed that the barrier properties of the RPE and Bruch's membrane limit cellular migration, especially the invasion of neovascular tissue from the choroid into the subretinal space. Our understanding of the molecular composition of Bruch's membrane, the molecular traffic that occurs across it, and the homeostatic mechanisms that maintain it, during normal aging as well as in AMD, is still rudimentary (80).

Links between AMD and structural abnormalities in Bruch's membrane have been documented in numerous histopathologic studies. Classically, these Bruch's membrane defects have been described as fragmentation or fracturing in association with calcification (81-85). Additional age-related changes in Bruch's membrane are typified by; a) Progressive thickening of the two collagenous layers; b) Modification and degeneration of collagen and elastin; c) Increased levels of advanced glycation end products, noncollagenous proteins and lipids; and d) Accumulation of several types of sub-RPE deposits (Fig. 13) (86-95). It has also been suggested that the age-related abnormalities in Bruch's membrane eventually lead to photoreceptor degeneration as a result of increased hydrophobicity, reduced permeability, and impaired nutrient exchange between the choroid and the RPE. Functionally, such changes result in an exponential reduction in the hydraulic conductivity of Bruch's membrane as a function of age (96-99). Much less is known about changes in Bruch's membrane hydraulic conductivity in individuals with AMD.

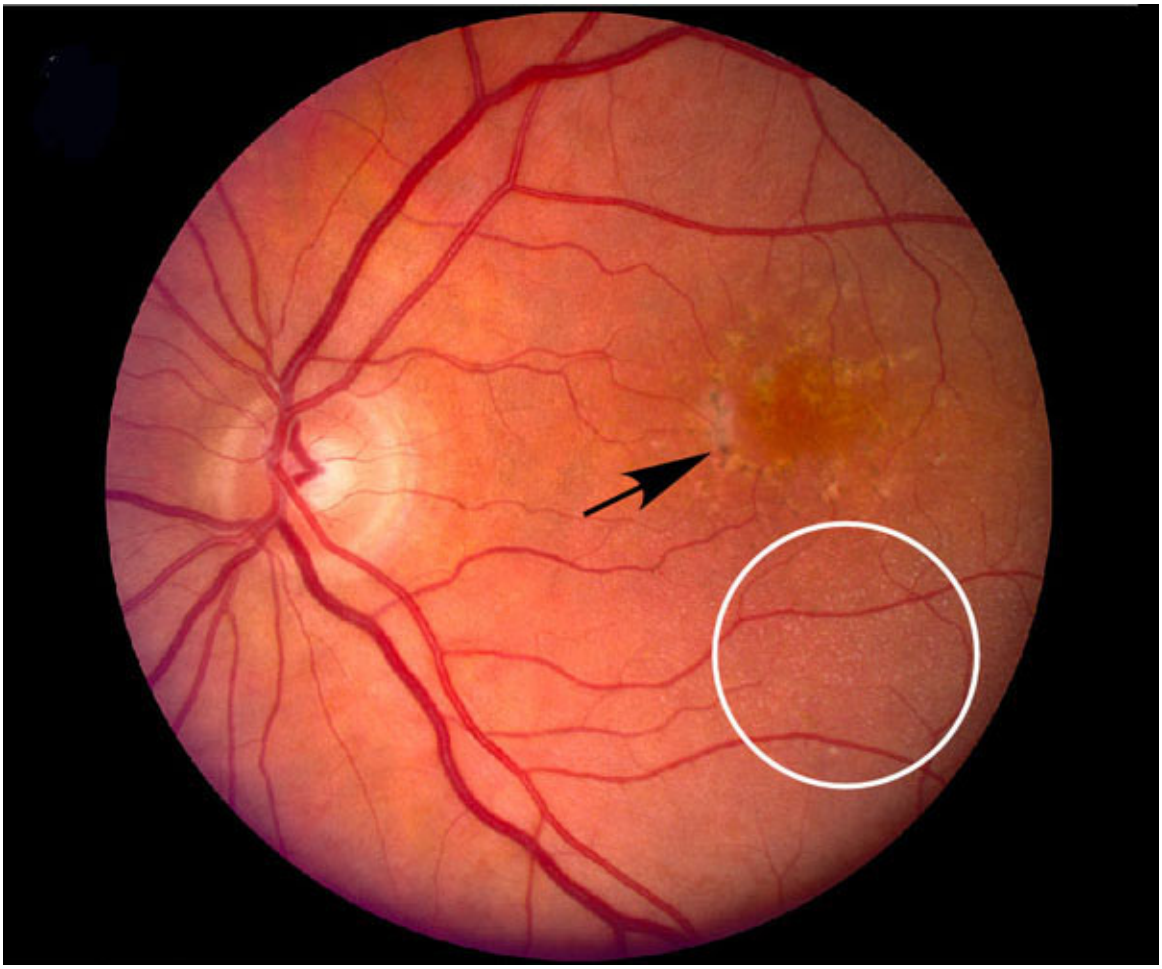

Figure 3. Color fundus photograph derived from an individual with early, dry AMD. RPE pigment disruption is present in the macula (arrow) and numerous small (< 63 microns in diameter) hard drusen are present inferior to this region (oval).

It has been proposed that topographic variations in Bruch's membrane may render the macula more susceptible to the ingrowth of new blood vessels from the choroidal vasculature that characterizes neovascular AMD. Morphometric data indicate that the elastic lamina of Bruch's membrane in the macula is 3-6 fold thinner and 2-5 fold less dense relative to that in the mid-periphery in individuals of all ages (100). Elastin fiber destruction in the macula could also play a key role in the initiation of neovascular events because elastin degradation peptides are highly angiogenic and possess macrophage recruiting activity (101).

In addition to drusen, basal laminar deposits (BLamD) and basal linear deposits (BLinD) accumulate within the extracellular environment of the RPE-choroid interface (Figs. 13, 15-maculardegen.F1617). These are identified based upon their morphological appearance and location. Both types of deposits have been proposed by various investigators to be involved in the pathogenesis of AMD (103). Neutral lipid (including esterified cholesterol) and apolipoproteins B and E are abundant in these basal deposits and in drusen in the eyes of aged donors and donors with a documented history of AMD (88, 94, 104-107).

Basal laminar deposits (BLamD) that accumulate between the RPE basal plasma membrane and its basal lamina (Figs.13, 15-maculardegen.F1617) do not appear to be specific to or 'diagnostic' for AMD. However, there is a strong relationship between macular BLamD and exudative AMD, disciform scarring, and visual loss (74, 84, 108-115). BLamD-like deposits are also seen in other macular disorders with a clinical appearance similar to what is observed in AMD. These include Sorsby's fundus dystrophy, Late Onset Retinal Degeneration (LORD), adult foveomacular pigment epithelial dystrophy and Malattia leventinese (116). The molecular composition and

Figure 4. Color fundus photograph from an individual with dry AMD. Numerous small and intermediate-sized drusen are visible in the macular region (oval).

origin of BLamD has not yet been identified (117-119), but its morphological similarity to long-spacing collagen is striking. Electron microscopy has revealed that its banding pattern matches that of type VI collagen (120).

Electron microscopy shows the changes that occur at the choroids RPB interface in AMD at a more detailed level. Figures 18 and 19 indicate a normal retinal choroidal interface (Fig. 18) compared with an abnormal AMD-like situation where there are drusen forming at this interface (Fig. 19).

BlinD lies between the RPE basal lamina and the elastic layer of Bruch's membrane (Fig. 20). The principal component of BLinD is a distinct form of membranous debris, thought to be comprised primarily of lipoprotein particles containing neutral lipids, including esterified cholesterol. It is likely that BLinD is derived from local ocular sources (e.g. RPE cells) (121). BLinD were initially described by Sarks and colleagues (122) as lipid-like vesicles with varying diameters.

It is believed that the pigmentary changes often observed in the macula of AMD eyes are attributable to degenerative changes in the highly melanized RPE cells (Fig. 20). This notion has gained wide acceptance because most of the early clinical signs and histopathological changes have been localized to this cell layer (123-126). It has long been recognized that the RPE is essential for the transport of ions, nutrients, and metabolites from the circulation to the neural retina and vice versa (127). If the RPE interface to the Bruch's membrane is broken down, amongst other things, blood vessels from the choroids can grow into this space (Fig. 21).

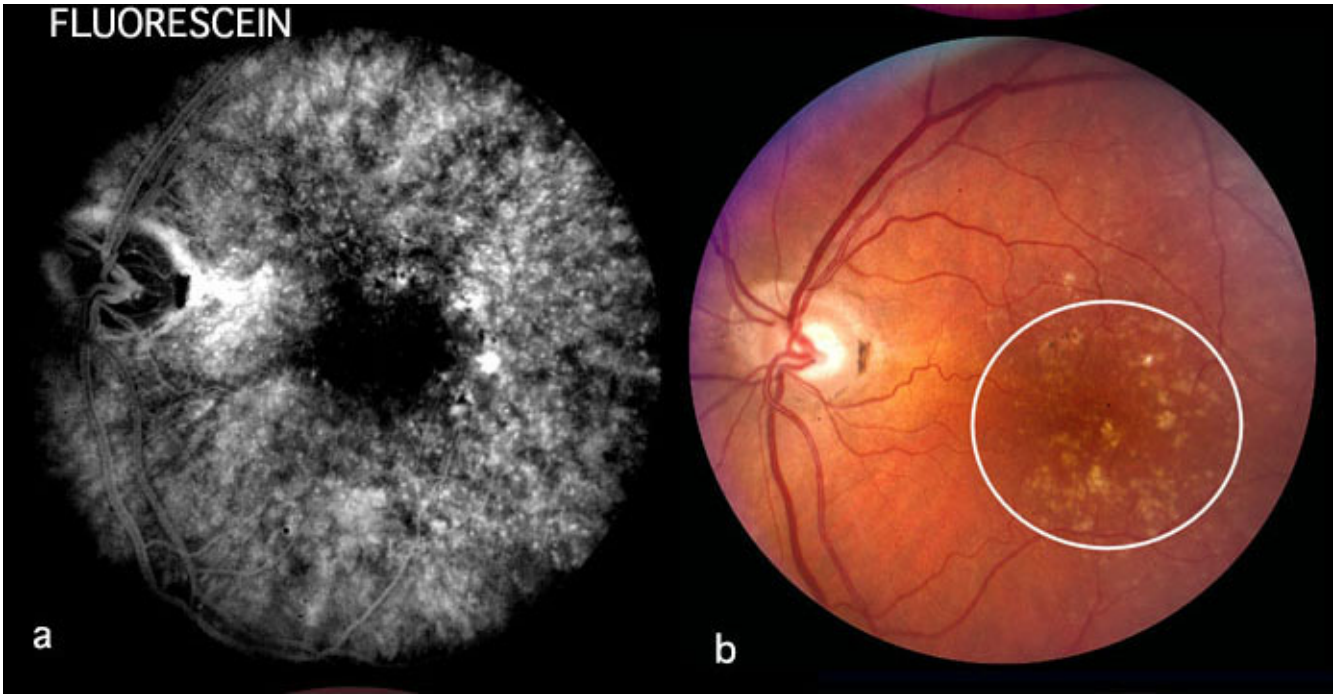

Figure 5. Corresponding fluorescein angiogram (a) and color fundus photograph (b) images from an individual with dry AMD. Although larger and confluent drusen are visible in the color image (circle), the number and extent of drusen distribution is appreciated even more clearly in the angiogram. The hyperfluorescent drusen observed in the angiogram are of uniform size and often referred to as cuticular drusen.

A viable RPE is also essential for normal photoreceptor cell metabolism and functioning of the visual cycle. Therefore, it is not surprising that RPE degeneration is accompanied by concomitant photoreceptor degeneration. RPE dysfunction in the macula, whether caused by local environmental insults and/or genetic defect(s), would have a profound impact on the overlying photoreceptors and, therefore, on central vision. However, the nature of the insult(s) that causes RPE dysfunction has yet to be ascertained, although a variety of hypotheses have been advanced over the years including genetic factors, ischemia, oxidative stress, phagocytic overload, cigarette smoke, lipofuscin toxicity and, most recently, microbial infection (128-134).

The choriocapillaris has also been suspected to play a role in the etiology of AMD. The density and diameters of the choriocapillaris capillaries decreases with age, and this decrease is even greater in patients with AMD. The overall loss appears most marked in regions of geographic atrophy (135, 136).

Physiology of early AMD

There is substantial evidence of photoreceptor involvement in early AMD, particularly in those patients with soft or large drusen in the macula (137-145). Contrast sensitivity, the rate of recovery after photostress, the amplitude and latency of the foveal electroretinogram (ERG) response, and dark adaptation are all affected adversely in early AMD patients, including those with normal visual acuity (140, 146-151). Fig. 22 shows the multifocal ERG responses from the macular area of a patient with AMD (see chapter on the clinical ERG, multifocal ERG). The responses of the fovea are reduced in amplitude. In the 3-D map (Fig. 23) it can be seen that the foveal area is flat, suggesting no cone activity, compared with the characteristic peak of responses in the normal retina.

It has been shown that photoreceptor cells in areas impacted by drusen exhibit morphologic and biochemical signs of degeneration, including decreased expression of synapse-associated proteins and increased expression of stress-response molecules. There are also drusen-associated reductions in photoreceptor cell densities, thus suggesting that degenerative changes in photoreceptors ultimately lead to cell death (152, 153).

Figure 6. Color fundus photograph from an individual with dry AMD, depicting the presence of numerous large (>125 micron diameter), calcified drusen deposited primarily within the peri- and parafoveal regions. Smaller drusen are present in the foveal region (asterisk).

Inflammation and AMD

Recent studies of the molecular composition of drusen have implicated local inflammation as a key element in the pathogenesis of AMD (154-160). Drusen contain numerous proteins related to the process of inflammation or its aftermath (106, 161-164). In particular, many of these proteins are associated with the complement cascade and its regulation. Some of the proteinaceous components in drusen and the sub-RPE space are activated complement components and fragments associated with assembly of the membrane attack complex (MAC) (162, 165-168). Other drusen components including vitronectin (161), clusterin, complement receptor 1 (CR1), and membrane cofactor protein (MCP-1) (164) are known complement regulatory proteins. Still others include known activators of the complement cascade such as cholesterol (169), C-reactive protein (155), and the amyloidogenic peptide amyloid b (153, 170). Metallic zinc, an amyloid b binding molecule, is also a drusen constituent (171). This compositional profile forms the basis for the conclusion that drusen are a manifestation of chronic, local inflammation at the level of Bruch's membrane.

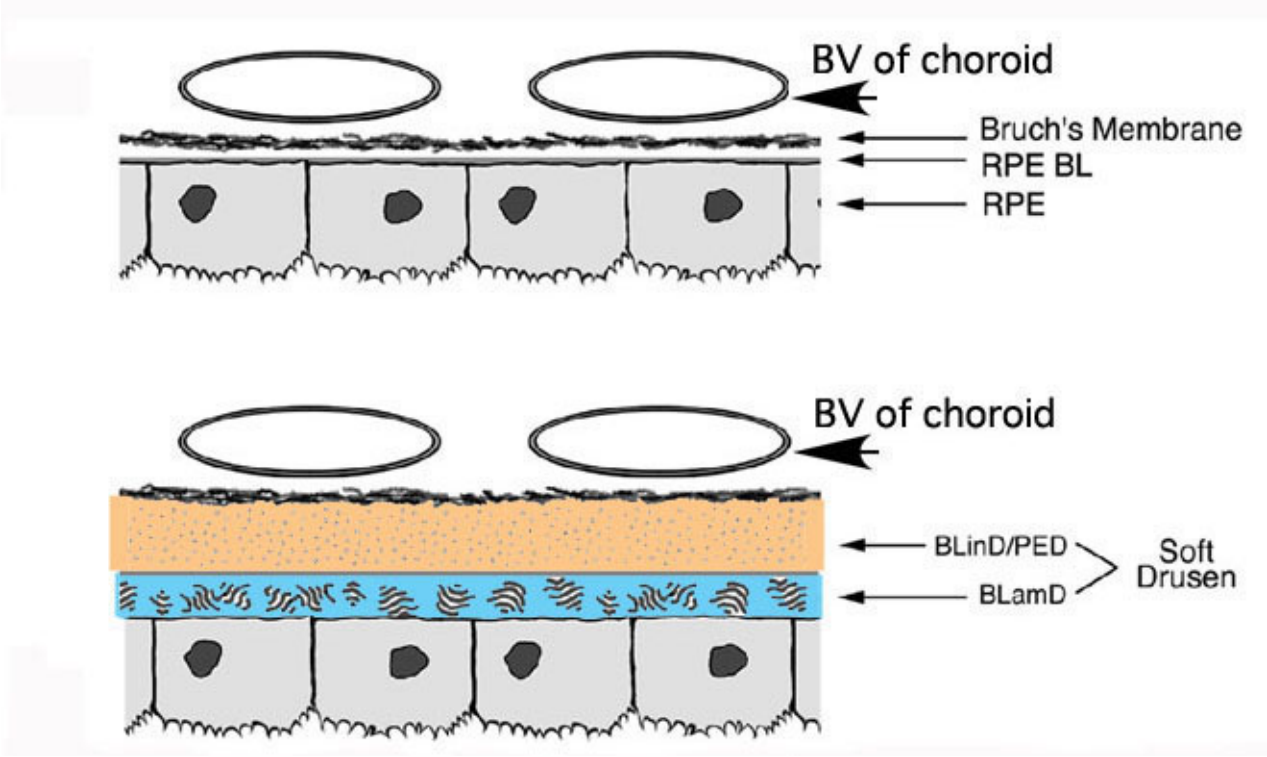

Figure 13. Schematic images depicting the choroid-RPE-retina interface in a normal retina and an AMD interface. The choriocapillaris-RPE interface in unaffected (top) and affected (bottom). The majority of early AMD-associated extracellular lesions - including drusen, basal laminar deposit (BLamD), and basal linear deposits (BLinD) - form along this interface.

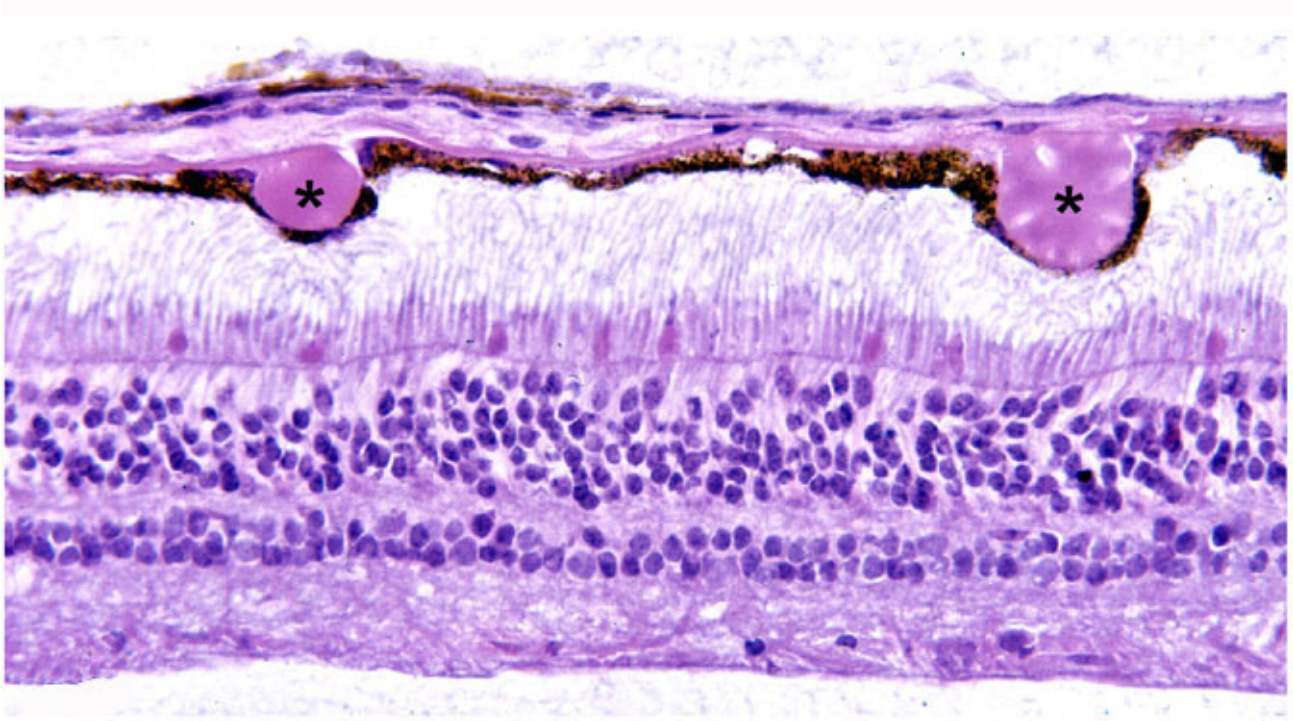

Figure 14. Histological section shows drusen (asterisks) forming between the RPE and Bruch's membrane in an early AMD case.

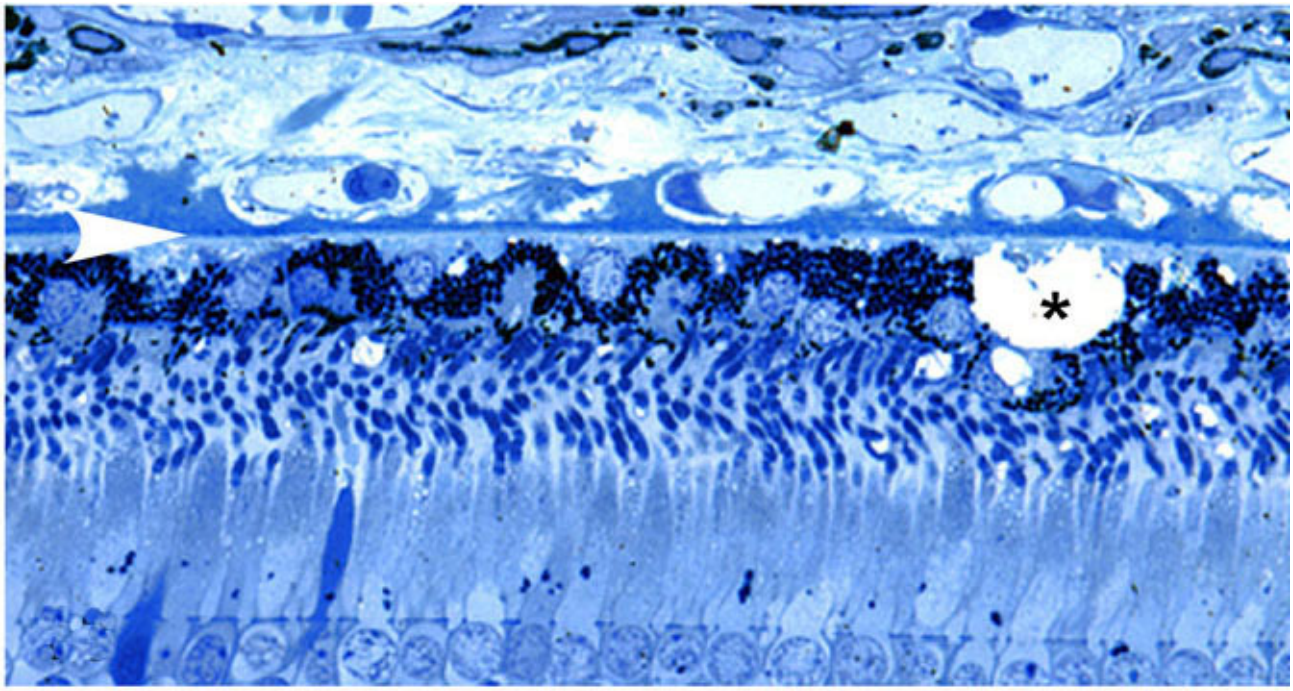

Figure 15. Drusen (asterisks), form between the RPE and Bruch's membrane.

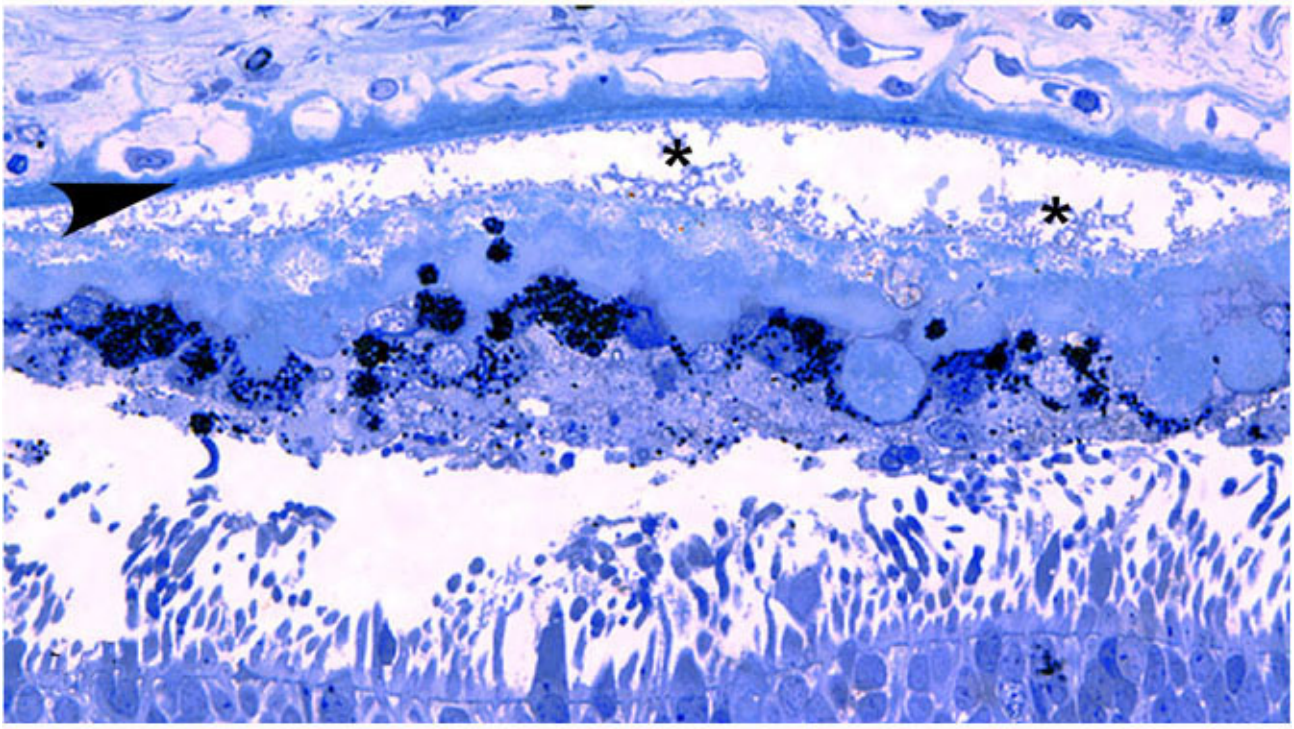

Figure 16. Extensive accumulation of BLamD (asterisks) is also commom between the RPE and Bruch's membrane.

The Complement System and AMD

Three complement pathways can be distinguished by the "triggers" that activate them. 1) antigen-antibody binding triggers the "classical pathway". 2) carbohydrate residues bound to invading pathogens trigger the "lectin

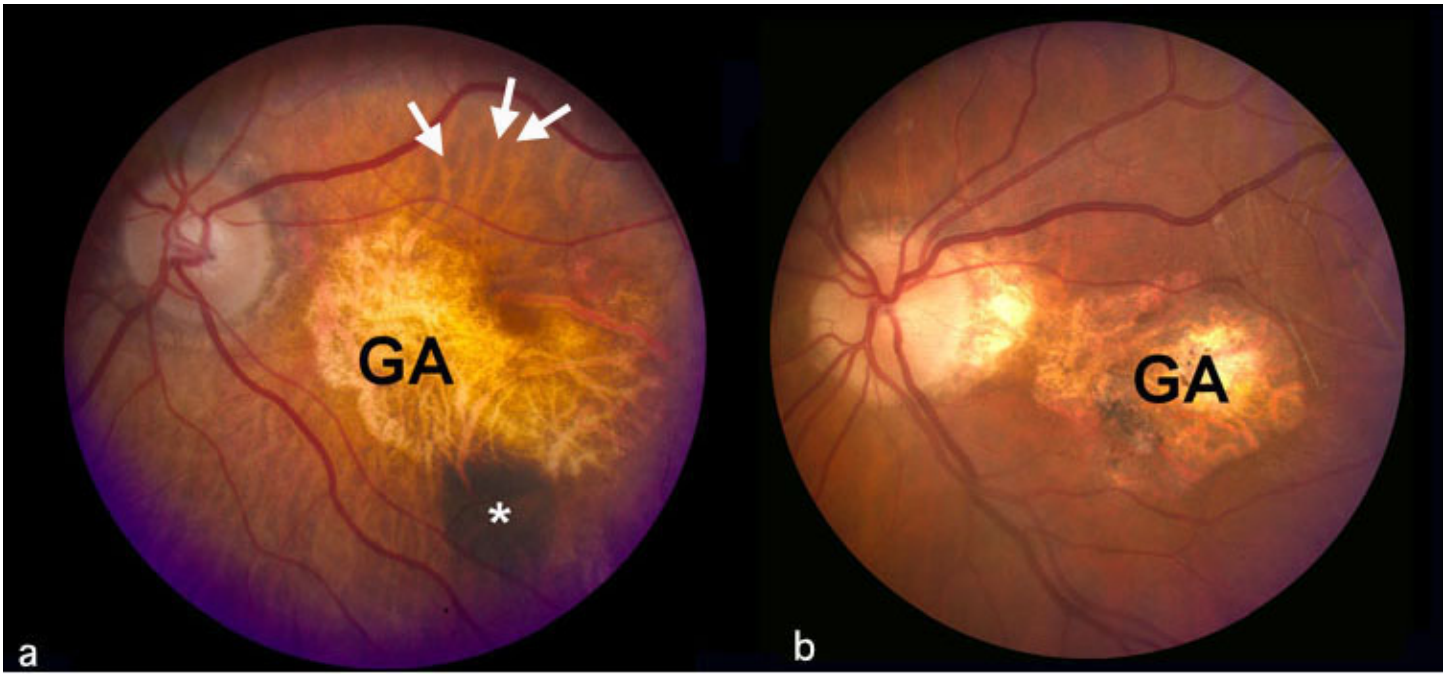

Figure 7. Color fundus photograph from two patients (a and b) with macular geographic atrophy (GA). The margins of the regions of RPE atrophy are clearly delineated (arrowheads). Choroidal blood vessels (arrows) are more easily visualized in these regions of atrophy because of the loss and/or absence of the RPE pigment. A choroidal nevus (asterisk) is indicated in eye a. These eyes would be expected to have poor central vision due to the extensive atrophy.

pathway. 3) A low level of spontaneous activation known as "tickover" characterizes the "alternative pathway". This continuous background level of activation is amplified rapidly by ubiquitous components present on the surfaces of many bacteria, viruses, as well as constituents present in cigarette smoke.

Complement Factor H, the Complement Alternative Pathway and AMD

Factor H is the main soluble inhibitor of the "alternative pathway" and, like most complement components, the liver is responsible for 80-90% of Factor H protein synthesis (190-192). We now know that variants in the gene encoding Factor H play a central role in one's susceptibility to AMD (see below). All of the available data are consistent with the conclusion that uncontrolled activation of the alternative pathway of complement at the level of Bruch's membrane is a key element in the process of drusen formation and a major contributing factor to the pathogenesis of AMD.

Although the liver is responsible for most circulating Factor H, the eye is also capable of producing it, in addition to other complement components. Not surprisingly, Factor H protein is also a molecular constituent of drusen (193). It co-localizes with its ligand C3b (a complement pathway component) in substructural spherules within drusen that contain amyloid b, further implicating these structures as candidate complement activators (170, 194). Factor H and the MAC co-distribute in drusen and at the interface between the RPE and choroid. Finally, Factor H and C5b-9 (MAC) immunolabeling are more intense in the macula compared to tissues from more peripheral areas in the same eye (Hageman and Mullins, unpublished).

We have advanced a working model of AMD pathobiology based upon our studies (155, 195) and the work of others (157, 196). In this model, RPE atrophy and the subsequent deposition of cellular debris in the sub-RPE space is construed as a local pro-inflammatory "seeding" event, leading to activation of the innate immune system at the RPE-choroid interface. Complement attack, in turn, induces significant bystander damage to macular cells and tissues, thus rendering them susceptible to additional RPE atrophy, photoreceptor

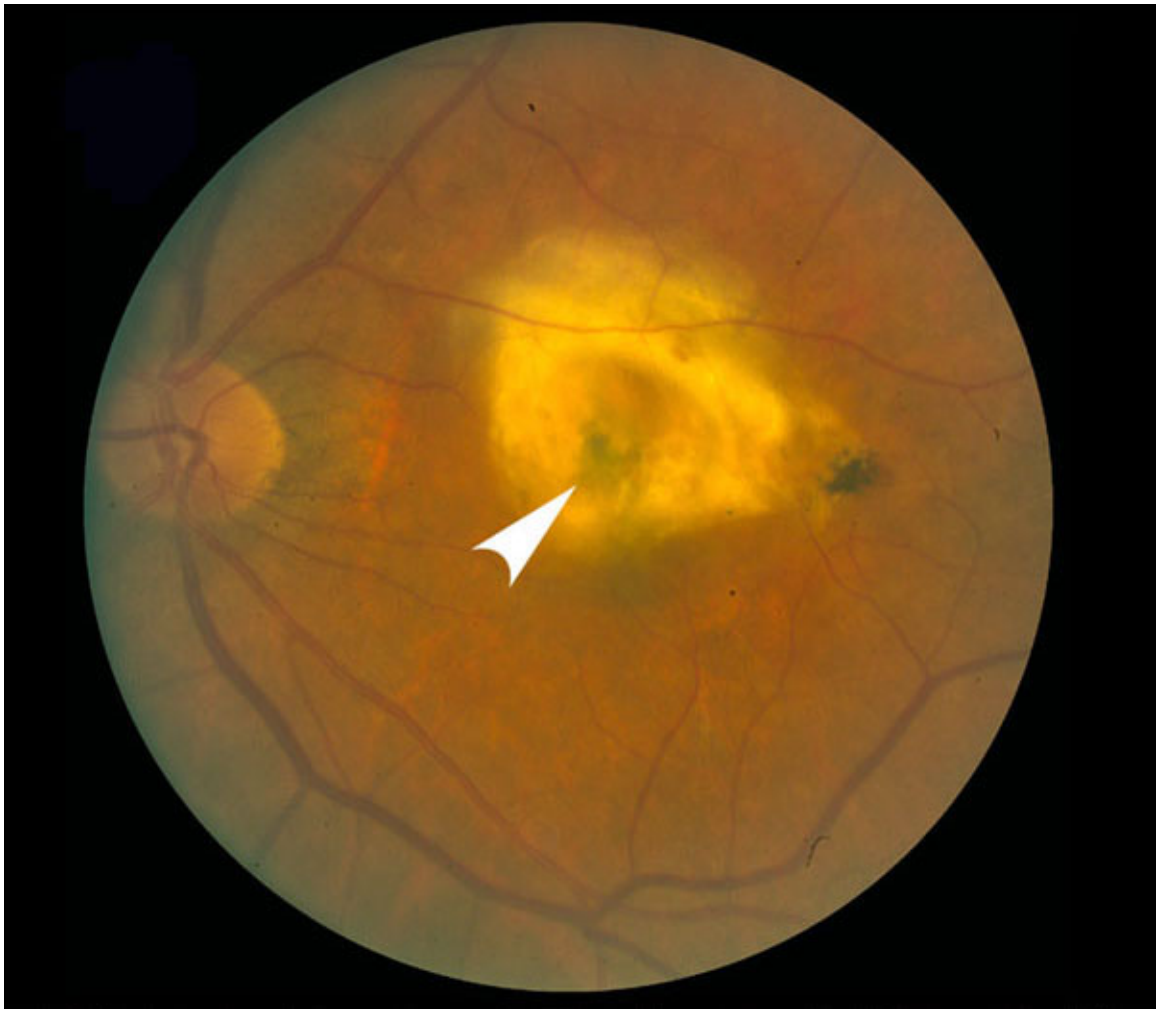

Figure 11. Color fundus photograph from an individual with end stage (cicatricial) exudative AMD. A large disciform scar (arrowhead) covering the macular region is distinctly visible.

degeneration, and CNV.(The reader, who is interested, can see diagrams showing the way the complement cascade works, in a paper by Ricklin and Lambris, 2007) (247).

Molecular genetics of AMD

Overview

AMD is often regarded as a group of complex, late onset diseases caused by the convergence of multiple risk factors (197, 198). Family history is a consistent risk factor according to most epidemiological studies of AMD conducted to date. Familial aggregation studies have shown that a genetic contribution is identified in up to 25% of AMD cases (199). Twin studies also support a genetic basis for the disease, with the concordance of clinical features (drusen and pigmentary changes) for both early and late onset disease being approximately twice as high in monozygotic (identical) twins compared to dizygotic (non-identical) twins (200, 201).

Genome-wide linkage analyses of extended families with AMD have identified a number of chromosomal loci that are linked to AMD (202-210). The most consistent occurs at chromosome 1q31 (211). Between 15-40% of multiplex AMD families segregate with a disease gene in the 1q31 region (205). Further analysis of this region reveals an allelic variant in exon 104 of the fibulin-6 gene (FBLN-6) in members of one AMD family, as well as in some sporadic AMD cases (212). A number of other candidate genes have also been linked to AMD. However,

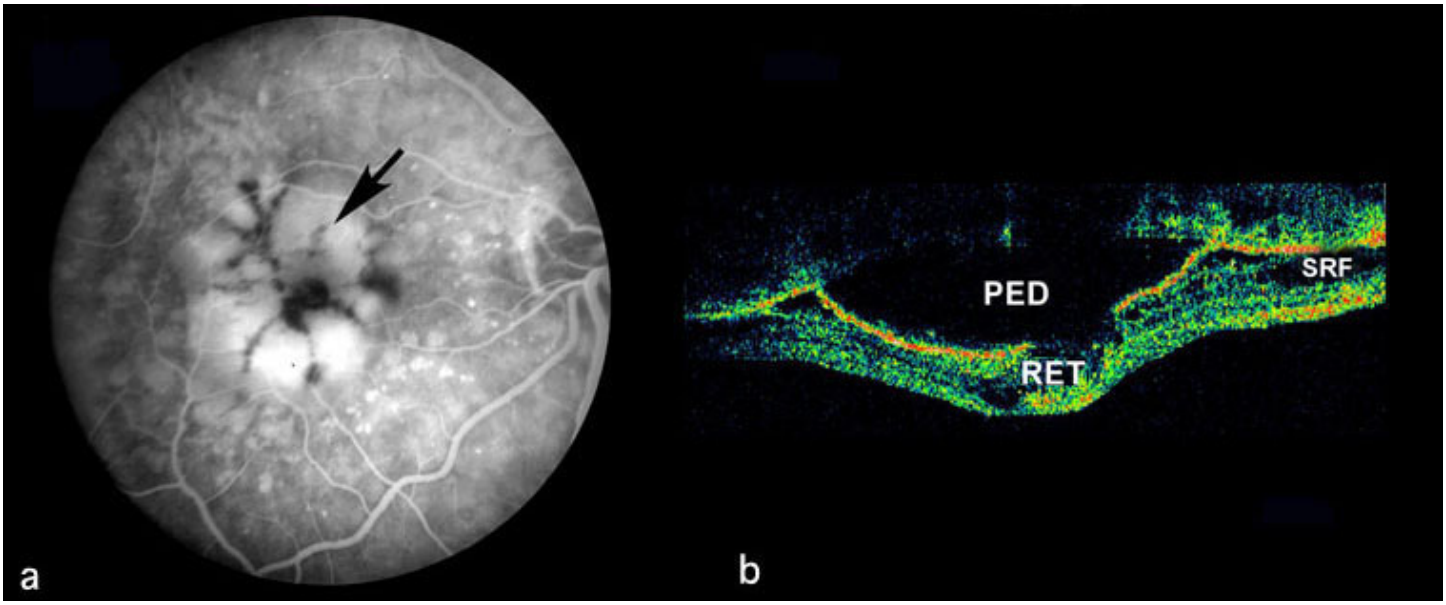

Figure 10. Corresponding angiographic (a) and OCT images (b) from an individual with a macular pigment epithelial detachment (PED). A multilobulated, hyperfluorescent lesion with sharply demarcated borders (arrow) is clearly visible in a 16. The blister-like elevation of the retina and retinal pigment epithelial layer, which correlates with the PED shown a, is appreciated in the OCT view (b). SRF, subretinal fluid; RET, retina.

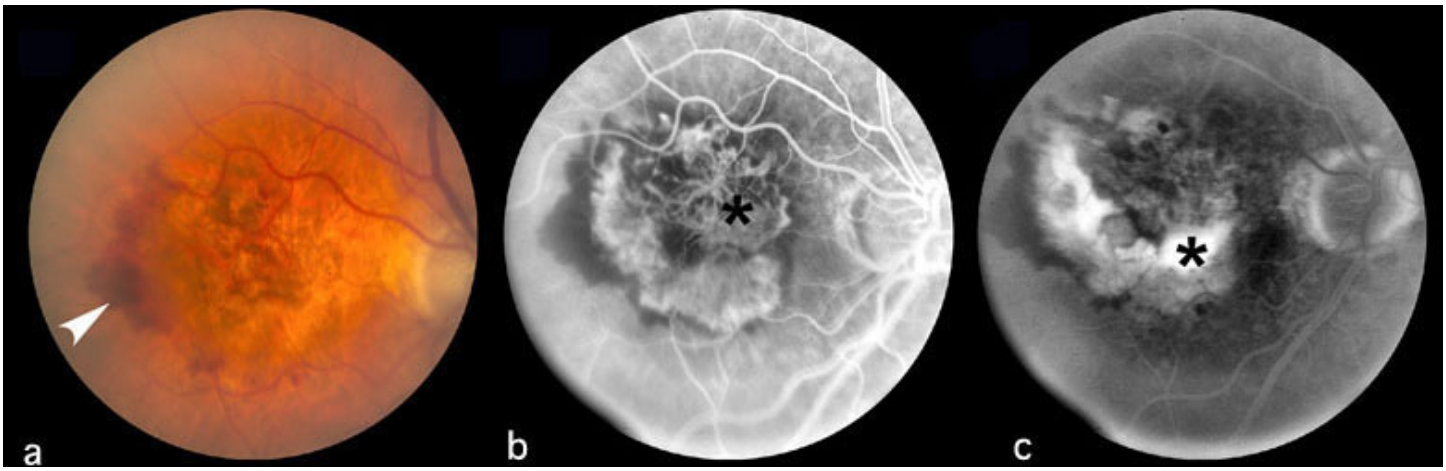

Figure 8. Color fundus photograph (a), early fluorescein angiogram (b) and late fluorescein angiogram (c). Arrowhead depicts edge of macular lesion. Note the lacey appearance of vessels (asterisk) in the early angiogram.

most of these results have not yet been replicated in subsequent studies. These genes include ELOVL4 (213), VEGF, VLDLR, and LRP6 (214), FIBLN5 (215) and TLR-4 (216).

In contrast, the e4 allele of the apolipoprotein E (APOE) gene has consistently been shown to be protective for AMD (217-219), whereas the e2 allele appears to influence progression and to result in an earlier age of onset (219). ABCA4 confers increased risk for AMD too (220).

In early 2005, four groups reported independently that common variants [single nucleotide polymorphisms (SNPs)] in the gene encoding complement Factor H (CFH) confer major susceptibility to, or protection from, AMD (193, 221-223). Individuals who possess a single copy of the risk-conferring CFH haplotype have 2-4 fold higher lifetime risk of developing AMD, and those with two copies possess a 5-7 fold higher lifetime risk. Haplotype analysis showed that a SNP in the CFH gene can account for up to 50% of AMD cases in the human

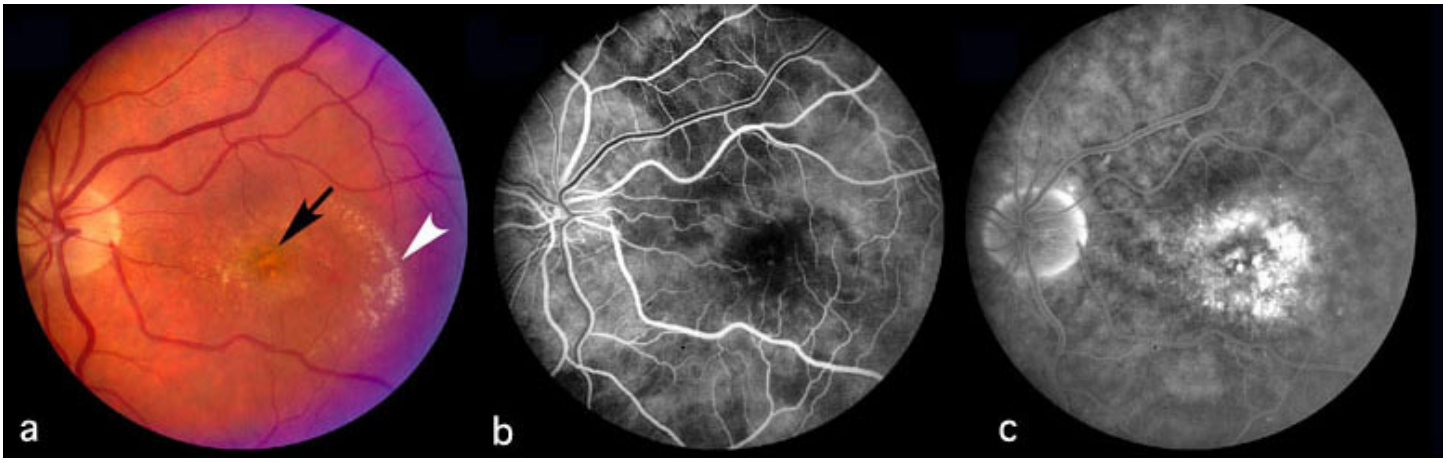

Figure 9. Color fundus photograph (a), early fluorescein angiogram (b) and late fluorescein angiogram (c) from an individual with occult choroidal neovascularization. A single, small punctate region of hemorrhage (asterisk) and a ring of exudates (arrowhead depicts edge) occur.

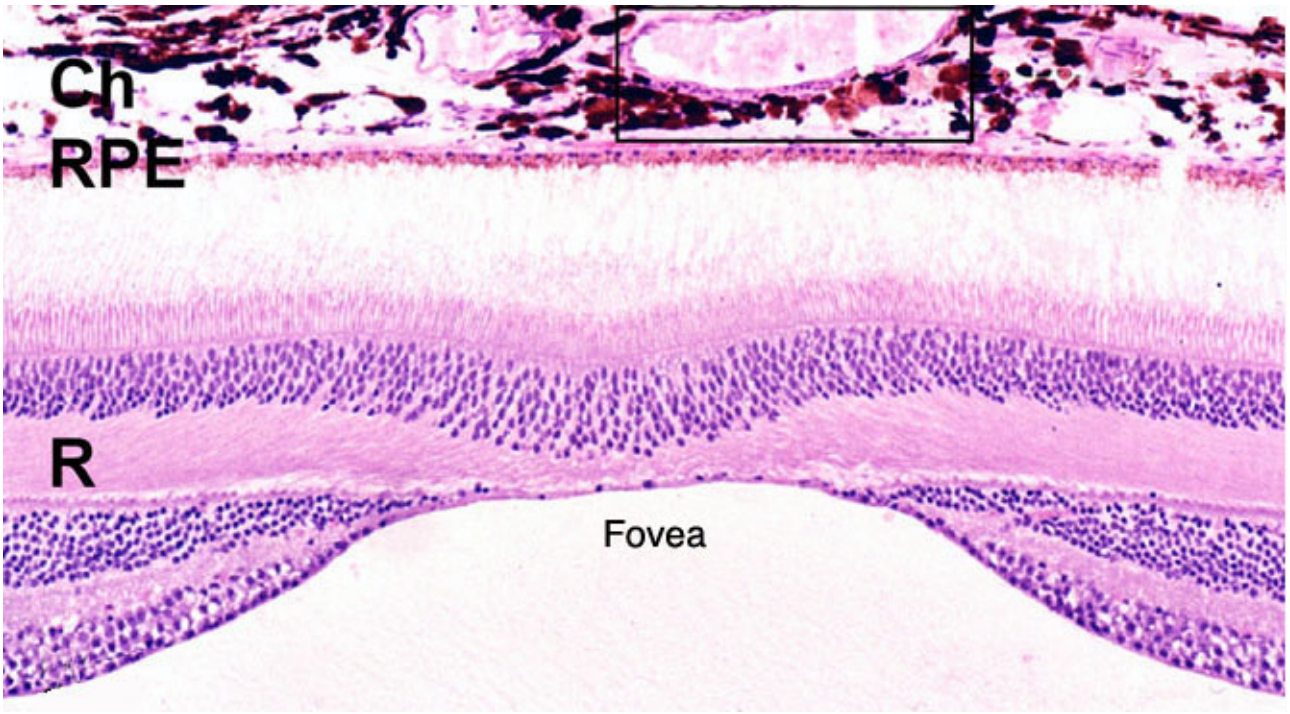

Figure. 12. Light microscopic image depicting the choroid-RPE-retina interface. A section shows the normal anatomical relationships of the macular choroid (CH) with blood vessels (BV), retinal pigment epithelium (RPE) and neural retina (R); the section passes directly through the fovea.

population, a number approaching 50,000,000 worldwide. Follow-up reports have since confirmed these findings in additional cohorts in the United States (213, 224), Iceland (225), the United Kingdom (226), and France (227). Interestingly, the major CFH risk haplotype in the Japanese population appears to be different than that reported in other populations, although the protective haplotype is the same (228).

In early 2006, a study showed that allelic variants in two other complement-related genes, Factor B (BF) and complement component C2, were linked to AMD (229). These are paralogous genes located 500bp apart on chromosome 6p21, and both reside in the major histocompatibility complex (MHC) class III region. BF is a component of the alternative pathway of complement, whereas C2 is a component of the classical pathway. Both

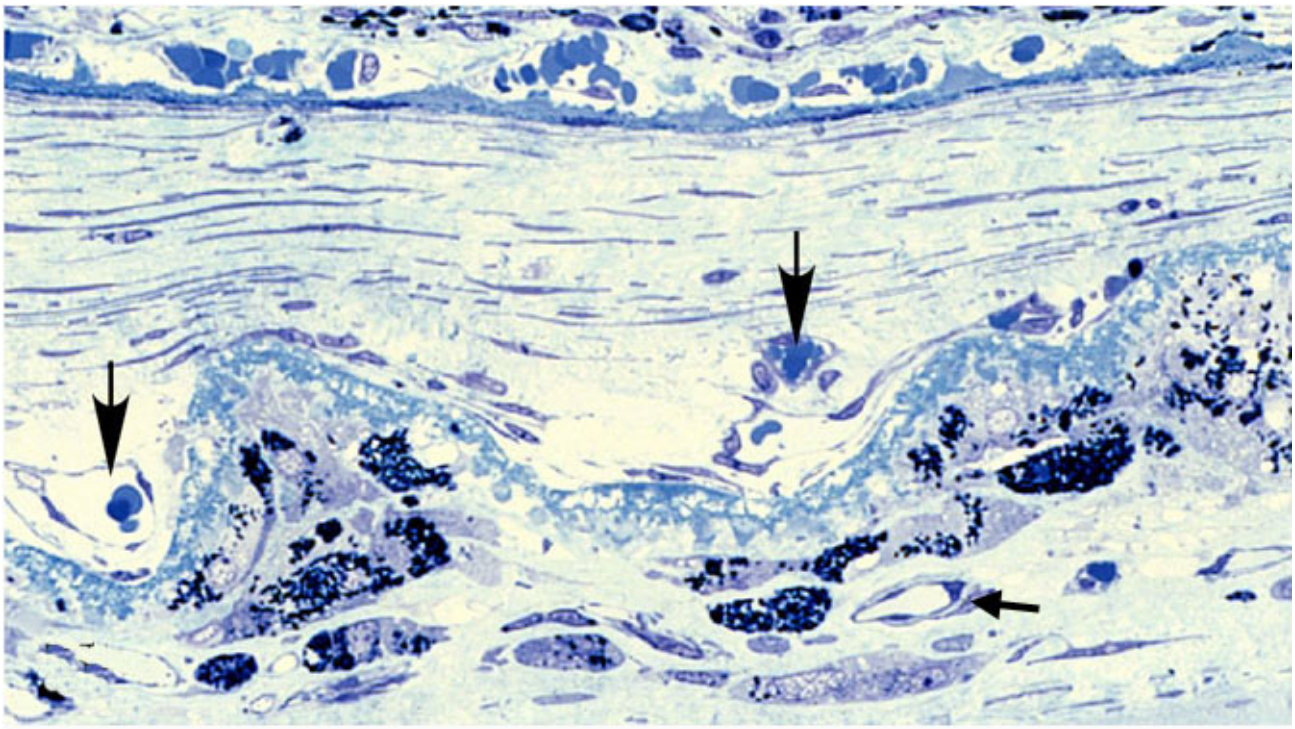

Figure 17. Light microscopic image depicting the choroid-RPE-retina interface. New choroidal blood vessels are located in both the sub-RPE and subretinal spaces (arrows).

variants together can account for nearly 74% of the risk of developing AMD. The protective haplotype for each of the three genes was completely absent in nearly 75% of all AMD cases; whereas 56% of controls possessed at least one copy of a protective CFH or BF haplotype. Approximately 60% of the risk in AMD cases, and 65% of the protection in controls, can be assigned to the CFH gene locus alone.

In addition to the 1q31 locus, a region on chromosome 10q26 has been identified in several recent studies of AMD (211) on a scale similar to that of the CFH Tyr402His variant. PLEKHA1 (pleckstrin homology domain-containing, family A, member 1) and a predicted LOC387715 gene were identified as the relevant candidate genes at that locus (231). A subsequent study concluded that SNP rs10490924 in LOC387715 was the most likely AMD-susceptibility allele (232). A third study identified a coding change in the LOC387715 gene as the significant allele that results in a non-synonymous substitution of alanine to serine at position 69 of the hypothetical protein. In addition, a significant statistical relationship between the LOC387715 variant and a history of cigarette smoking has been found (233). Thus far, there is no published evidence for expression of the LOC387715 gene product at either the RNA or protein levels; nor is there any indication of its likely functional properties.

Therapy for AMD

The molecular pathogenesis of AMD has only recently begun to be elucidated. So, it is not surprising that the therapeutic approaches for AMD have been of only limited benefit to most patients. Therapeutic interventions have focused almost exclusively upon the exudative "wet" form that comprises approximately 10% of the AMD patient population because it is the most debilitating and rapidly progressive form of the disease. Until recently, such therapies have resulted in a benefit to less than 50% of patients with "wet" AMD, and therefore less than 5% of all AMD patients. Developing therapeutics to delay onset or progression of "dry" AMD or the conversion from "dry" to "wet" AMD, have proven even more difficult. This due to the long study duration and large numbers of participants needed to achieve meaningful statistical results.

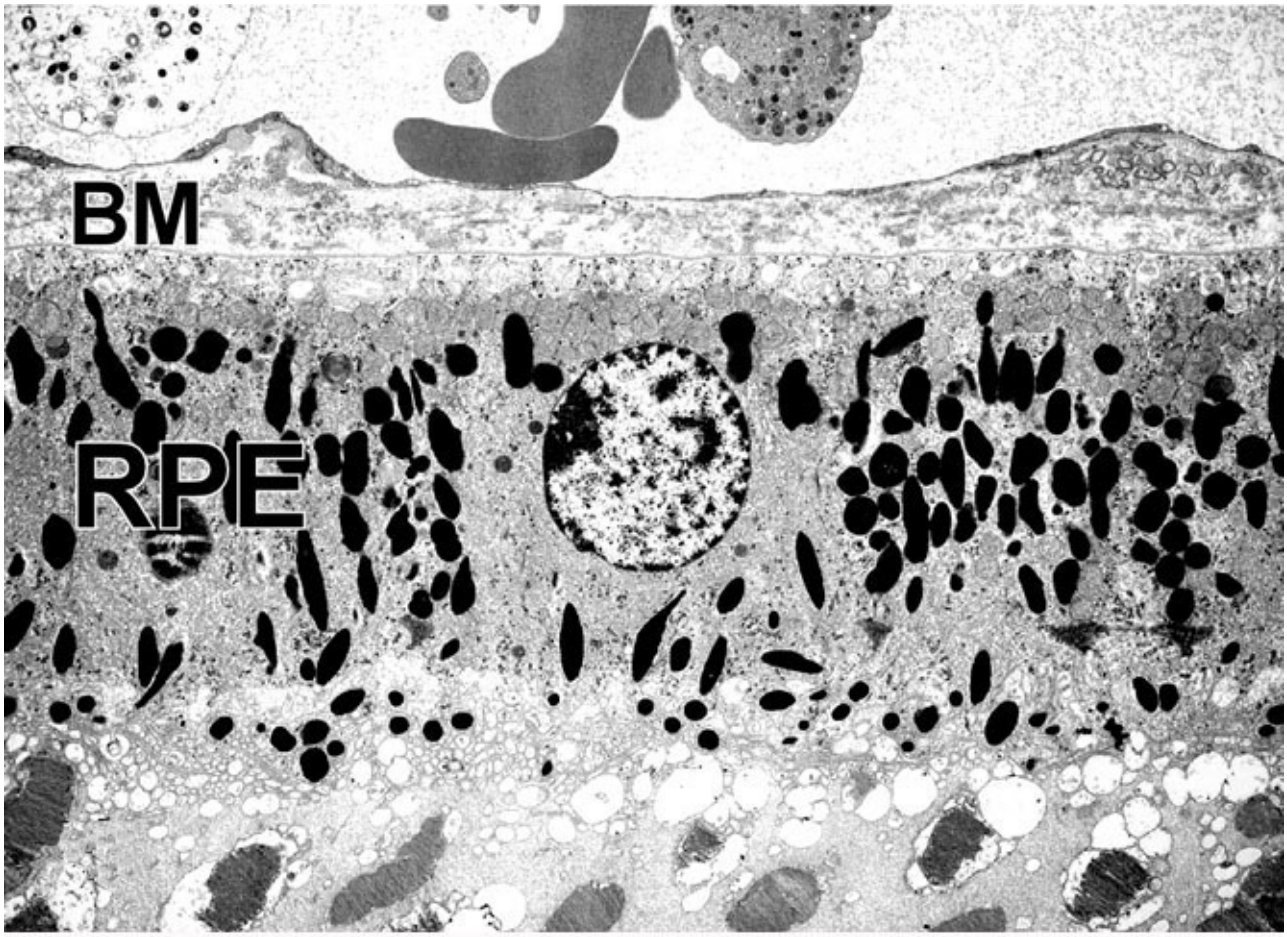

Figure 18. Transmission electron micrograph of the RPE-choroid interface in a normal human donor eye.

Over the last 30 years epidemiological studies have repeatedly identified four risk factors for AMD: age, cigarette smoking, increased body mass index, and inheritance (10, 31, 32). These same studies have produced conflicting information regarding the roles of dietary antioxidant supplementation and fat intake. In 1992 the Age-related Eye Disease Study (AREDS) group began enrolling subjects in a prospective, multicenter, randomized, controlled study (33). Patients enrolled in the AREDS had either mild, moderate, or severe dry AMD in both eyes, or exudative AMD in one eye only. The study tried to determine whether antioxidant therapy prevented vision loss, slowed the progression of dry AMD, or prevented conversion from dry to wet AMD. The results of 6.3 years of follow-up in the AREDS study were published in 2001 (33). The study results demonstrated that daily antioxidant therapy in the form of 15 mg beta carotene, 500 mg vitamin C, 50 mg vitamin E, 80 mg zinc (as zinc oxide), and 2mg copper (as cupric oxide) daily was superior to a placebo in delaying progression of advanced dry AMD, and in slowing conversion from dry to wet AMD. Specifically, the odds ratio of progression to advanced AMD was decreased to 0.72 in the group who took the above combination of antioxidants as compared to placebo. No benefit of antioxidant supplementation was demonstrated in the milder forms of AMD. However, because the early stages of AMD often persist for many years, it is quite possible that the study design was not long enough to demonstrate a benefit to patients with milder stages of AMD.

Another therapeutic intervention is laser therapy for eyes with drusen. Three prospective trials, the Choroidal Neovascularization Prevention Trial (CNVPT), Complications of AMD Prevention Trial (CAPT) and Prophylactic Treatment of Age-Related Macular Degeneration Trial (PTAMD) evaluated the efficacy and safety of light macular grid laser in reducing the risk of developing CNV in eyes with drusen. The CNVPT and CAPT used argon laser and the PTAMD used an 810 nm diode laser (34-36). In both the CNVPT and PTAMD studies,

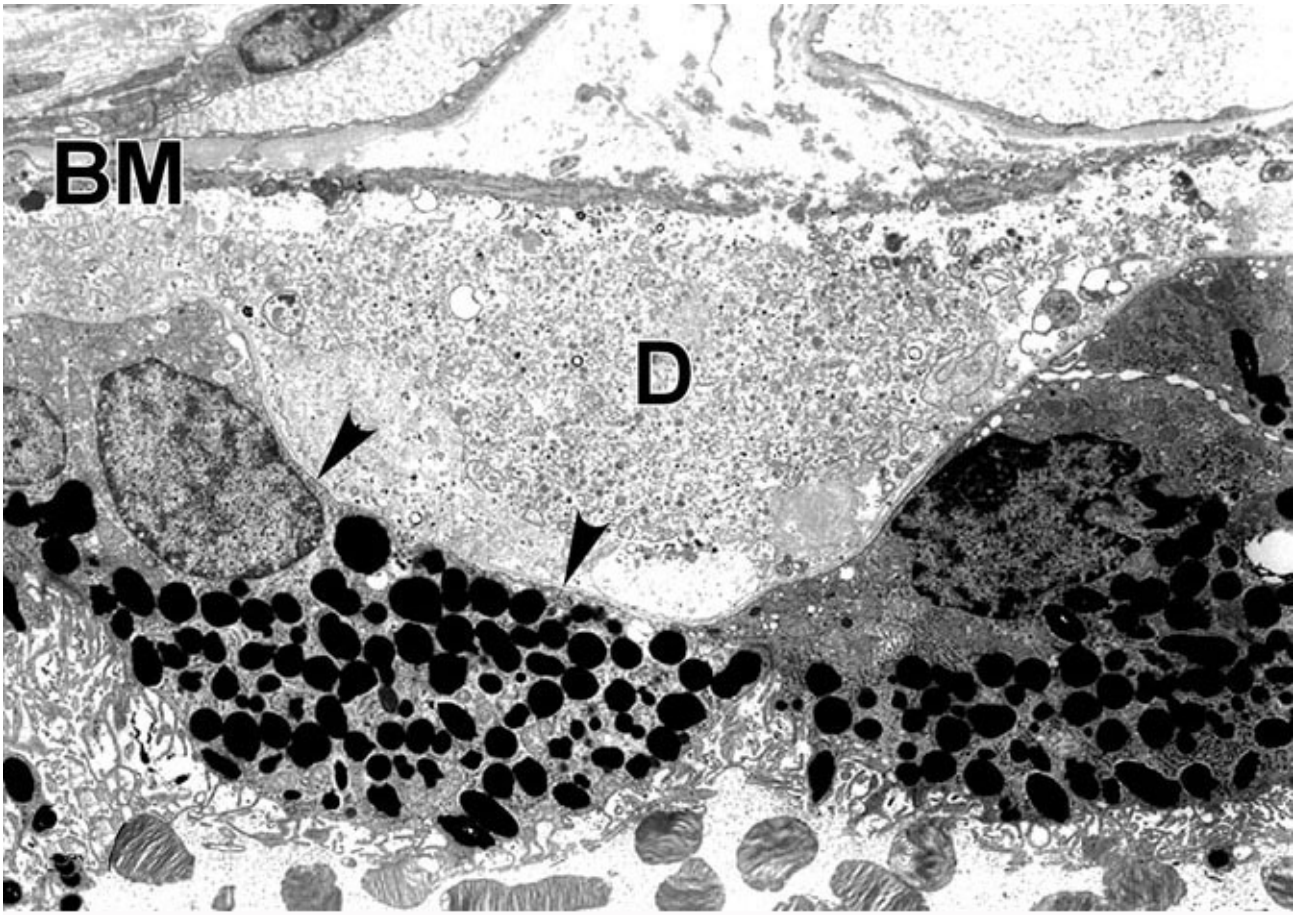

Figure 19. Transmission eectron micrograph of a donor eye with AMD. A single drusen (D) is shown to be located between the RPE basal lamina (arrowheads) and Bruch's membrane (BM).

grid laser treatment increased the risk of CNV. Therefore grid laser of eyes with drusen is not recommended if the fellow eye has CNV (36, 37). Recent results of the PTAMD bilateral drusen study reported no decrease in CNV development but a four-letter gain in visual acuity in treated versus control eyes after three years of follow-up (38). The larger CAPT study of treatment of one eye in the setting of bilateral drusen is ongoing but near completion of five years of follow-up. Until the results of the CAPT study are known, prophylactic laser of eyes with bilateral drusen is not a recommended therapy.

Therapy for exudative AMD has evolved from thermal laser photocoagulation in the early to mid 1980's, to photodynamic therapy for CNV beginning in 2000 and, most recently to inhibition of vascular growth factors. The three year results of the Macular Photocoagulation Studies (MPS) for AMD was published in 1986. It demonstrated a benefit for "extrafoveal" CNV located between 200 and 3,000 microns from the fovea (Fig. 24). Subsequent MPS studies for juxtafoveal (1 - 200 microns from the fovea) CNV and subfoveal CNV respectively, demonstrated a benefit for laser treatment versus no treatment (Fig. 24) (39-41).

However, visual loss was common even in those eyes with successful obliteration of CNV (42). Additionally, the closer the CNV was to the fovea, the poorer the visual outcome and the higher the rate of recurrence even in those who initially responded to treatment (43). In 1993, Freund and coworkers demonstrated that only 13% of new patients with exudative AMD (or approximately 1.3% of all AMD patients) met criteria for thermal laser treatment based on the MPS (Fig. 25) (44).

In the late 1980's to mid-1990's there was significant interest in vitreoretinal surgical approaches to exudative AMD. Vitrectomy surgery with evacuation of subretinal blood and neovascular membranes reported variable

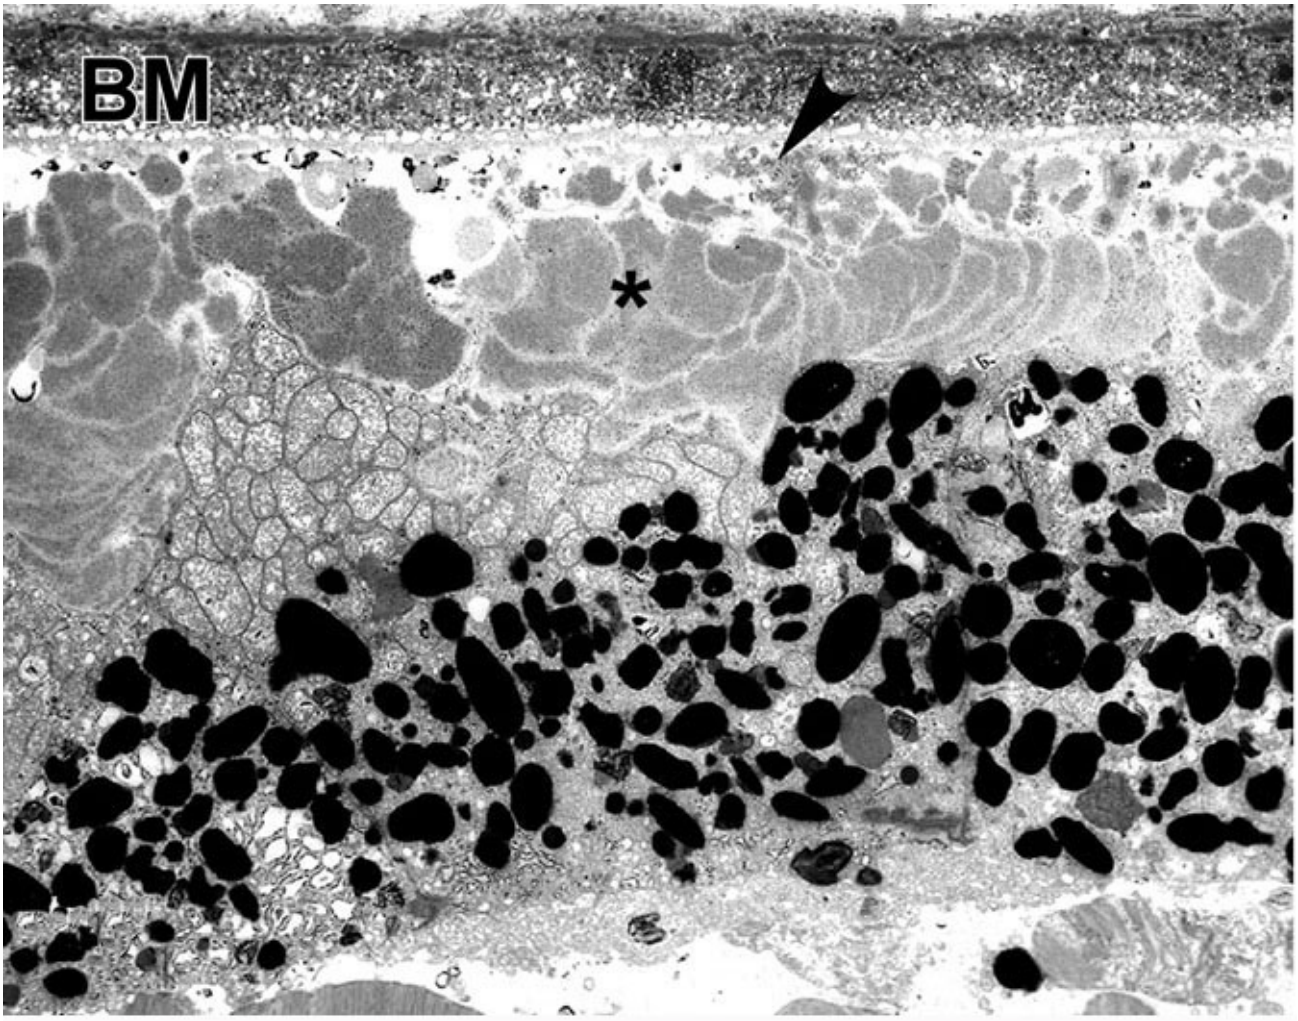

Figure 20. Electron micrograph shows BLamD (asterisk) accumulates between the basal surface of the RPE and its basal lamina (arrow), whereas BLinD is located within the innermost aspect of Bruch's membrane, in a case of AMD.

success rates. Trial designs were nonstandard, results were conflicting, and long-term follow-up in these pilot trials was lacking. Given the potential morbidity and expense of major eye surgery, the National Eye Institute sponsored the prospective, randomized, controlled Submacular Surgery Trials (SST). The results of the trial demonstrated that surgery did not increase the chance of stable or improved vision, and it prevented severe vision loss only in those eyes with large subretinal hemorrhages. Submacular surgery was also associated with some risk of rhegmatogenous retinal detachment. Given these results, and the advent of less-invasive therapy with anti VEGF agents (described below) submacular surgery is no longer recommended for exudative AMD except, perhaps, in select cases with large submacular hemorrhage (45, 46).

Other surgical approaches, which have been investigated in small pilot trials, are macular translocation (Machemer and Steinhorst, 47), and limited macular translocation developed later by deJuan (48). The former technique involves creation of a total retinal detachment, while the latter is limited to a partial retinal detachment. Both techniques involve displacement of the macular retina from an area of CNV to a location where the retinal pigment epithelium is thought to be healthier. While pilot trials have suggested a benefit from these therapies for a small subset of patients, the emergence of less invasive and more broadly applicable pharmacological therapies for exudative AMD have resulted in much less frequent application of macular translocation in recent years (Figs. 26-maculardegen.F2728).

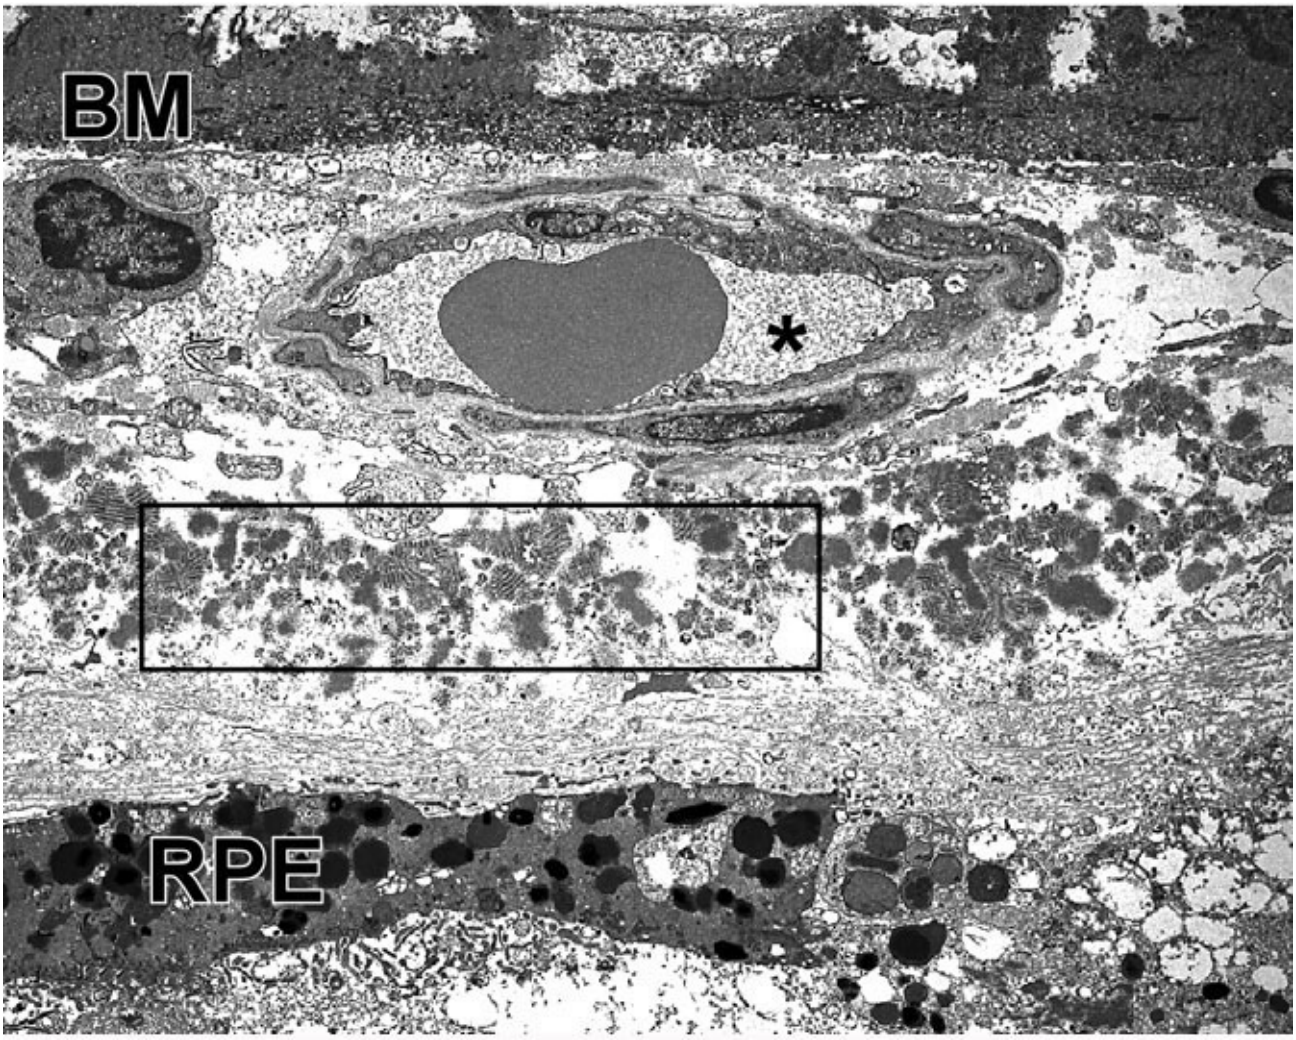

Figure 21. Electron micrograph shows a patent choroidal neovessel (asterisk), lying between BM and a layer of BLamD (rectangle) in a case of advanced AMD. RPE, retinal pigment epithelium; BM, Bruch's membrane.

In 2000, photodynamic therapy with Visudyne (tm) (verteporfin), a light-activated compound, was approved by the FDA for exudative AMD with predominately (>50%) classic, subfoveal CNV that was no larger than 5600 microns in diameter. FDA approval was based on the results of the Treatment of Age-Related Macular Degeneration with Photodynamic Therapy Investigation (TAP) study. In the TAP study, subfoveal CNV was divided into subgroups based on initial visual acuity, lesion size, and fluorescein leakage characteristics: enrolled subjects were randomized to Visudyne(tm) or placebo (49). Photodynamic therapy (PDT) involves intravenous administration of the photoactivatable compound, Visudyne (tm) followed 15 minutes later by irradiation of the CNV with a low energy, non-thermal laser. Activated Visudyne(tm) generates singlet oxygen that damages the CNV endothelium resulting in thrombosis (50). In the TAP study an average of 3.5 treatments spaced at three month intervals were required to ablate the CNV, so the process is a lengthy one. Visual results, though better than with any prior treatment, were less than optimal with only 67% of treated patients with predominately classic CNV losing fewer than three lines of visual acuity (as compared to 39% of placebo treated eyes). At 1 year, 16% of Visudyne treated patients gained one or more line of vision, and 15% of treated patients lost more than six lines of visual acuity. Over the course of the next several years, subgroup analysis of data from the TAP studies as well as additional trials with Visudyne(tm) treatment for lesions other than predominately classic CNV led to its application for other lesion types. However, the visual results for lesions that were predominantly occult CNV were less favorable than those with predominately classic CNV (51, 52).

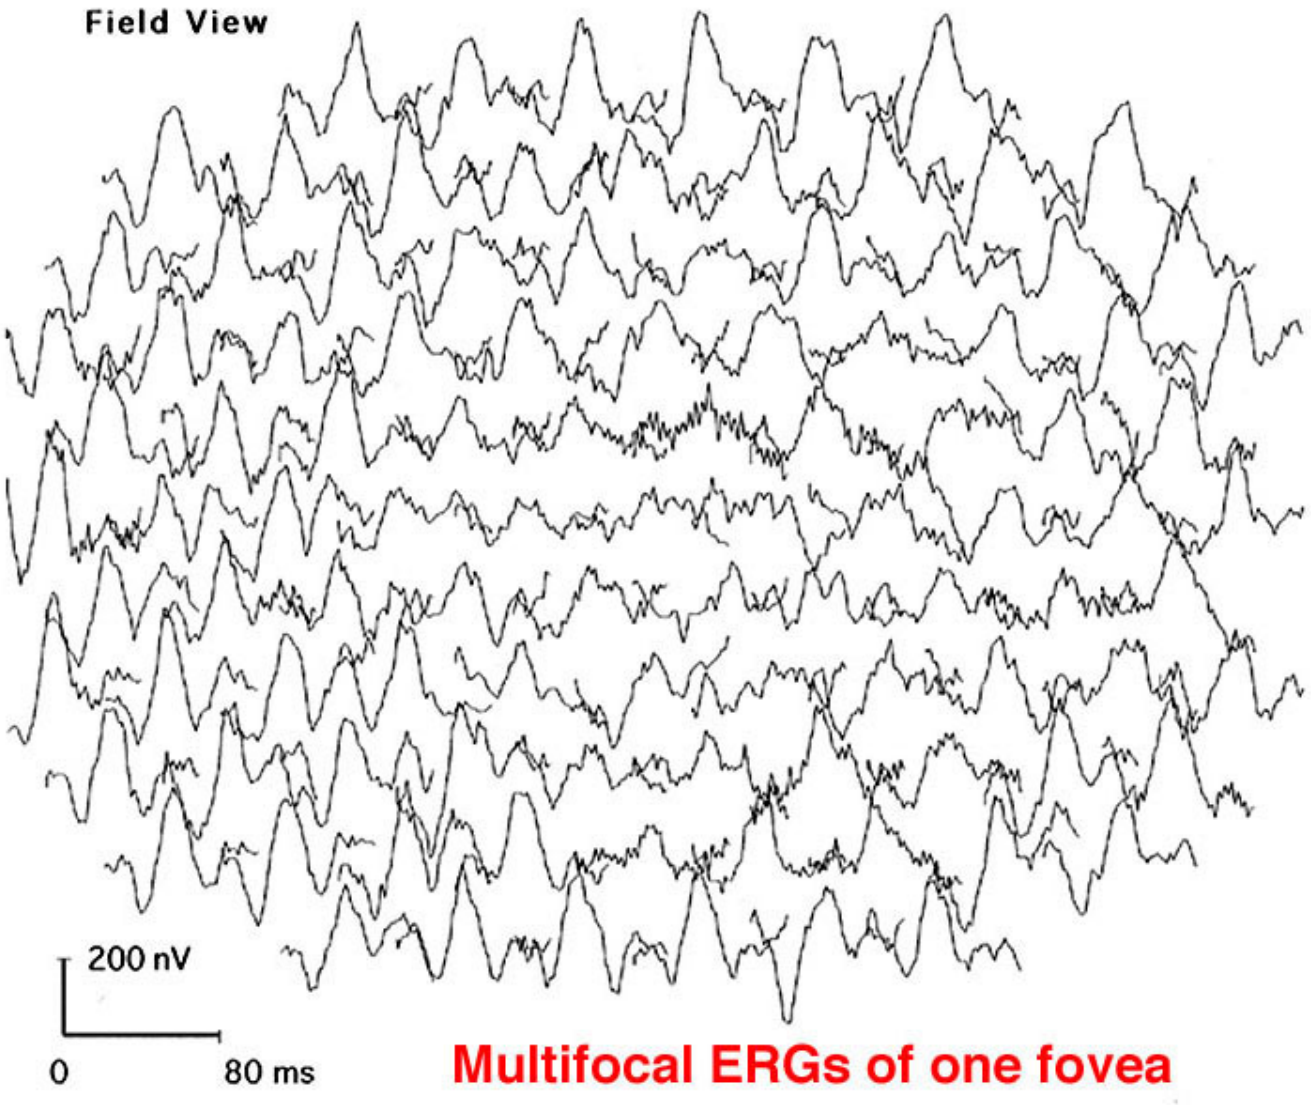

Figure 22. Multifocal ERG recordings in a patient with age related macular degeneration (AMD). Note the central resposes where the fovea is located are much reduced in amplitude.

Figs. 29-maculardegen.F30maculardegen.F3132 demonstrate a favorable response to PDT with Visudyne as seen in our clinic.

As noted above, however, not all eyes fare well with PDT therapy. Below is a photograph of an eye that did not demonstrate a significant benefit from PDT treatment with Visudyne (Fig. 33).

Other ablative treatments for CNV include transpupillary thermotherapy (TTT) and radiation therapy. TTT utilizes low energy diode laser (810 nm) applied to the CNV slowly over one minute. Small pilot trials of TTT for occult CNV initially showed promise but a randomized, prospective clinical trial (TTT4 CNV) demonstrated no significant benefit. Similarly, low dose radiation therapy for AMD was investigated in multiple small pilot trials with conflicting results (53-55). Although no definitive prospective clinical trial of radiation therapy for AMD has ever been conducted, the concept has become less popular in recent years, especially in light of the interest in pharmacological therapies for AMD.

The current era of therapy for exudative AMD utilizes administration of anti-neovascular agents periocularly or intraocularly. Studies implicating various cellular growth factors, including vascular endothelial growth factor

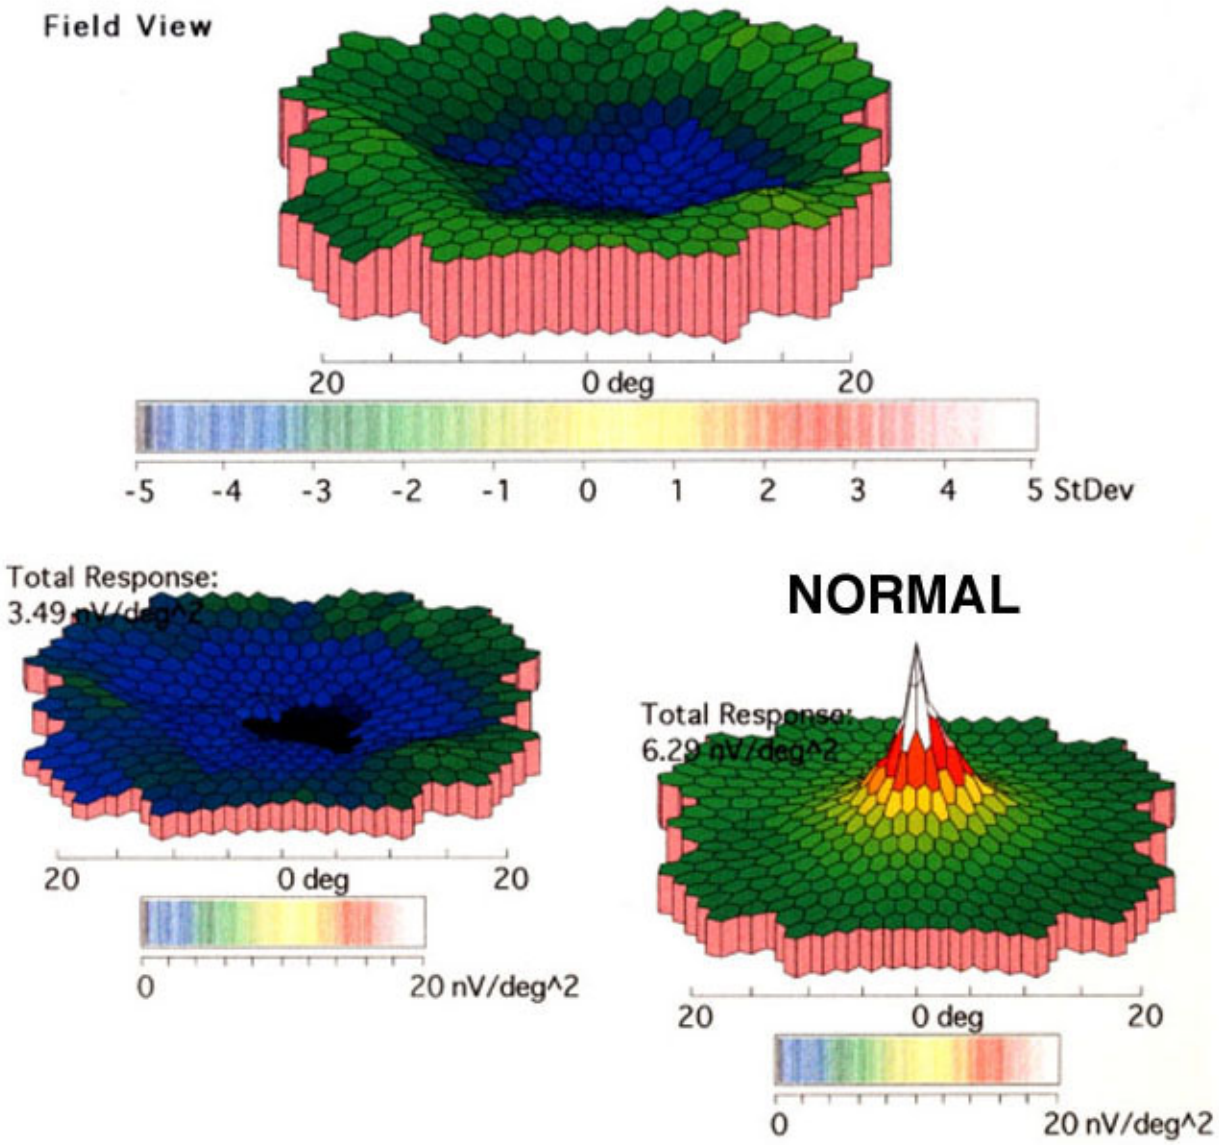

Figure 23. Multifocal ERG recordings transformed into 3-D maps of the macular area in a patient with AMD compared to a normal patient. The AMD patient has no responses in the fovea.

(VEGF) in a variety of ocular neovascular processes has led to the development of VEGF inhibitors, VEGF antibodies and other "broad-spectrum" antiangiogenic molecules that inhibit pro-angiogenic cytokines. In 2004, Macugen(tm) (Pegantanib Sodium) was the first of the VEGF inhibitors to be approved by the FDA for exudative AMD. Macugen is an aptamer which binds to the A isoform of VEGF-165 at its heparin binding site and prevents VEGF-165 from binding to its receptor on endothelial cells. Macugen is administered by intravitreal injection (i.e. injected into the vitreous cavity of the eye) every 6 weeks for up to a two-year course of therapy. Based on the Macugen (tm) study results of 1186 patients after one-year, 70% of subjects treated with 0.3 mg pegaptanib, 70% lost fewer than 3 lines of vision compared to 55% of controls. The risk of severe vision loss (> 6 lines of vision) was reduced from 22% in controls to 10% in treated subjects (56).

Another VEGF inhibitor undergoing clinical trials is ranibizumab or Lucentis(tm). Lucentis(tm) is derived from the Fab fragment of an antibody to isoform A of VEGF. The fragment blocks VEGF binding to its receptor on endothelial cells, thus inhibiting its biological activity. The ANCHOR trial was presented recently (57). The data demonstrated not only a preservation of vision in nearly 95% of patients treated with Lucentis(tm)

(ranibizumab) at year one but, for the first time, an improvement in vision in 30-38% of patients with exudative AMD. Another recently published trial comparing Lucentis alone to PDT alone demonstrated superior visual results with Lucentis. (ref: Anchor Trial). Lucentis(tm) was FDA approved for the treatment of exudative AMD in June 2006. Although the initial trials with Lucentis utilized monthly intravitreal injection with the drug, more recent studies indicate that some patients my respond favorably to a treatment regimen utilizing fewer than 24 injections over a 2 year period (Fung et al., 2007) (248). Currently, studies are underway to determine factors which might influence frequency and duration of treatment with Lucentis.

Avastin(tm) (beclumizabab), a VEGF antibody derived from the same parent antibody as Lucentis(tm), is approved by the FDA to treat colon cancer and is gaining popularity as an "off-label" intravitreal therapy for AMD. It is important to note that Avastin(tm) has not yet undergone the toxicity studies and controlled trials that are required by the FDA for ocular application (58, 59). Other anti-angiogenic therapies currently under study include anecortave acetate (Retane, an antiangiogenic steroid (60, 61)), squalene and triamcinolone (which carries a significant risk of causing cataract and steroid-induced glaucoma). Additional studies are underway to investigate the potential for a combination of Anti-VEGF therapy with Visudyne(tm) photodynamic therapy utilizing light doses lower than those applied in the TAP an VIP studies with Visudyne (62, 63, 249).

Figures 34 and 35 show results of pre (Fig. 34, Fig. 35) and post anti-VEGF treatment (Fig. 36).

As a result of the anti-VEGF treatment much improvement can be seen in the macular area along with good visual restoration. The OCT scans (Fig. 36) show filling in of the disrupted cell types in the retina (the holes of Fig 36a get occupied by cells) and glial cells react to restore damaged retina (Fig. 36b and Fig. 36c, green upward streaks).

One concern with all anti-angiogenic agents is their potential for systemic inhibition of VEGF that may produce cardiovascular or cerebrovascular complications, or inhibit wound healing. The immediate and long-term systemic effects of these drugs, especially those prescribed "off-label", are largely unknown and difficult to determine in an elderly population already prone to vascular events. Additional drawbacks to the intravitreally administered therapeutics include patient discomfort, intraocular infection (endophthalmitis), retinal tear or detachment, and lens damage in phakic patients (64). The incidence of endophthalmitis in published trials with Macugen and Lucentis were 0.16%/injection and 1.3% - 1.4% of patients respectively and the incidence of retinal tears and/or detachment in these studies were 0.08%/injection and 0% - 0.4% respectively. (see Macugen and Lucentis trials refs below) Risk of lens damage in phakic patients treated with intravitreal anti-VEGF therapy can be minimized by visualization of the needle tip with the indirect ophthalmoscope during injection and by proper patient preparation (anesthetic, education, and reassurance) during the injection process to minimize the risk of sudden patient movement. Some patients do quite well with topical anesthetic alone while others require subconjunctival anesthetic injection (249-251).

Recent discoveries of the role that inflammation plays in AMD pathogenesis (see above) has led to an interest in investigating the anti-inflammatory effects of statins on AMD. Several clinical population-based studies of the effects of statins on AMD development and progression have yielded conflicting results (65). Thus, more studies in this area will be required to assess efficacy.

In the near future, therapy for exudative AMD will likely involve multiple anti-neovascular agents, possibly coupled with less frequent application of photodynamic therapy, in order to maximize the beneficial effects of each and minimize the frequency of adverse side effects. Further on the horizon are anti-angiogenic agents in longer acting forms that require less frequent administration. The ultimate therapy for AMD, however, will lie in preclinical identification of those who are genetically "at risk" for the disease, coupled with preventative strategies that are designed to minimize or compensate for one's genetic predisposition.

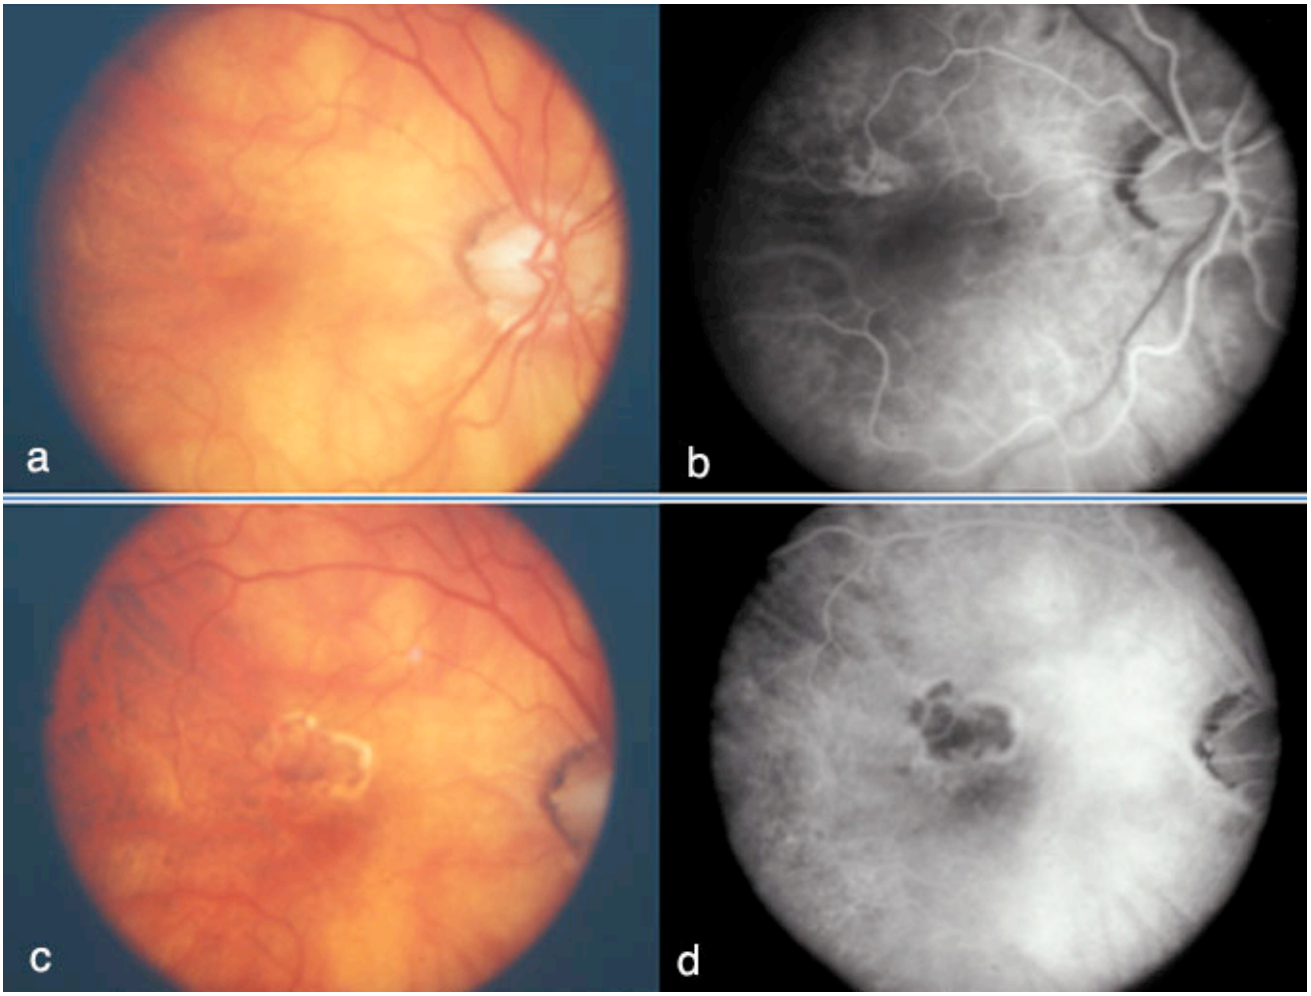

Figure 24. a) New extrafoveal CNVM. b) angiogram of extrafoveal CNVM (photos from KMG files). c) Laser scar after MPS-style laser for extrafoveal CNVM. d) Angiogram of laser scar after MPS- style laser for extrafoveal CNVM (photos from KMG files).

Conclusion

Complement Factor H is the first gene identified in multiple independent studies that confers a significant risk for the development of AMD. This finding, together with the subsequent identification of AMD-associated variants in the related complement genes BF and C2, provide compelling evidence that the innate immune system and, more specifically, uncontrolled regulation of the alternative pathway of complement, plays a central role in the pathobiology of AMD. At this point, the most likely scenario is that exposure to infection or some other triggering event in genetically susceptible individuals, coupled with impaired complement regulatory function leads to the sustained activation of complement cascade, drusen formation and, eventually, development of AMD.

The emergence of this new paradigm of AMD pathogenesis sets the stage for the rapid development of early diagnostics, novel bioassays, and new animal models that faithfully mimic aspects of the disease process. Furthermore, the way is now paved for development of novel therapeutic interventions aimed at modulating the alternative pathway of complement in "at risk" individuals prior to the onset of choroidal neovascularization or geographic atrophy.

Now that the genetic basis for a major proportion of AMD cases has been elucidated, what additional scientific progress may be anticipated, and what will be the significance of these new findings for the diagnosis and

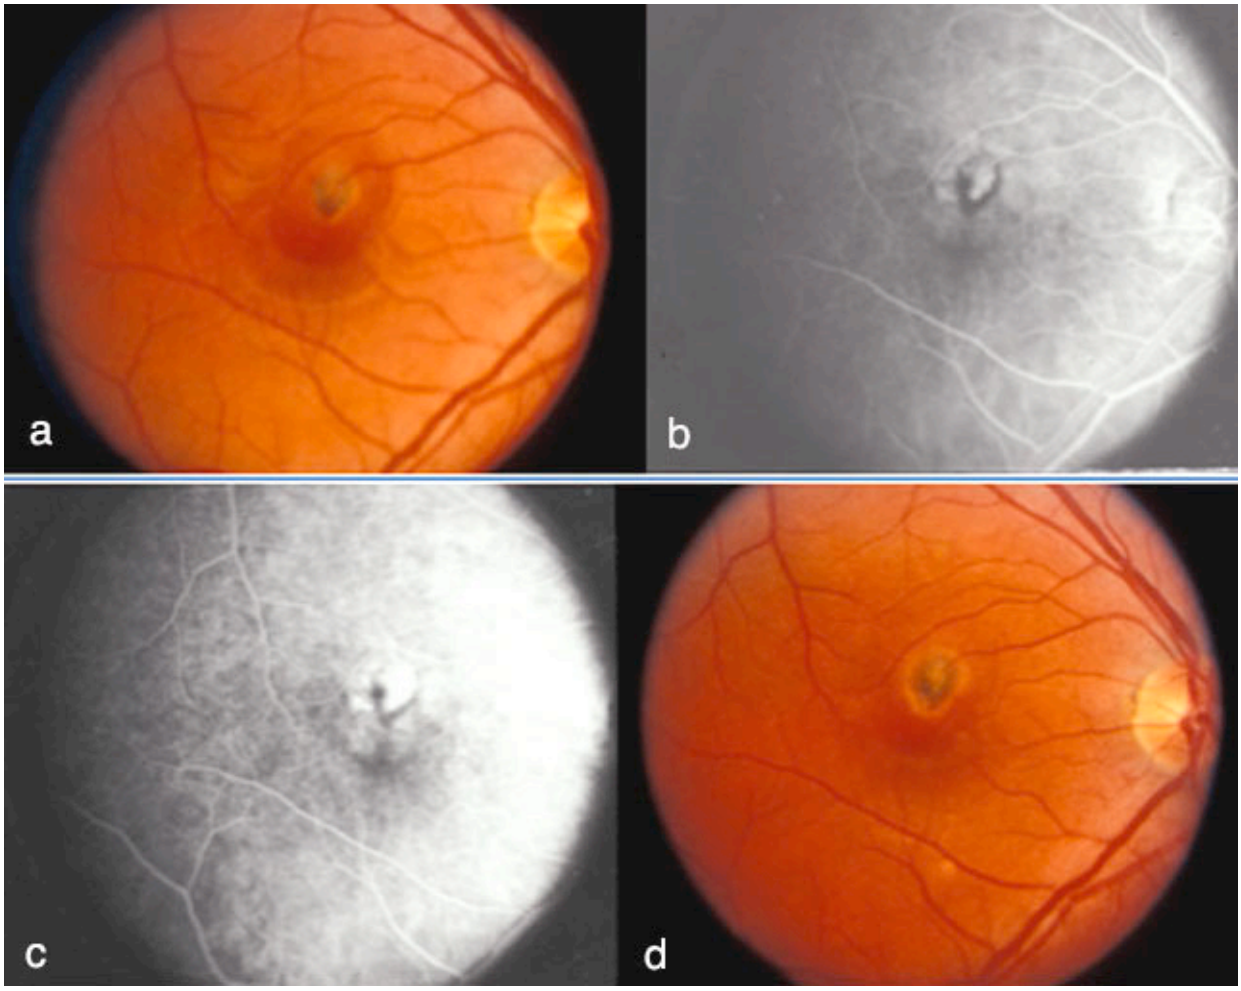

Figure 25. a) Subretinal hemorrhage and CNMV. b) Fluorescein angiogram demonstrates juxtafoveal CNVM in the transit phase. c) Fluorescein angiogram demonstrates late leakage from juxtafoveal CNVM. d) Dry laser scar 1 month after MPS style laser for juxtafoveal CNVM (photos from KMG files).

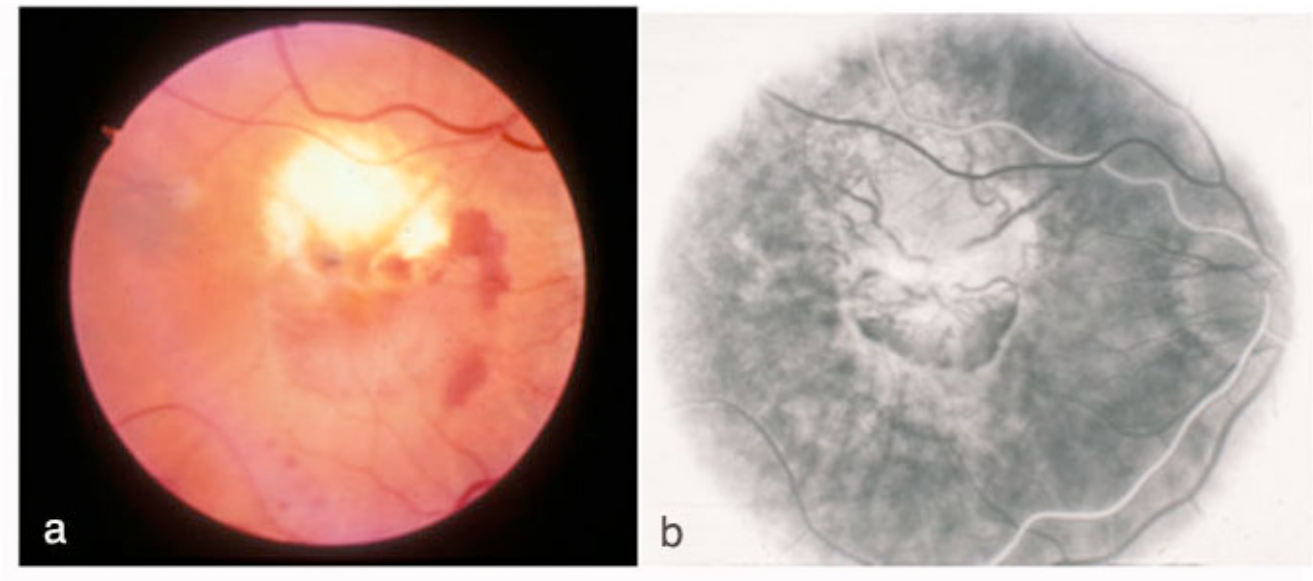

Figure 26. a) pre-operative color photo of subfoveal CNVM just inferior to prior laser scar. b) preoperative angiogram demonstrating a large, classic subfoveal CNVM (photos from KMG files).

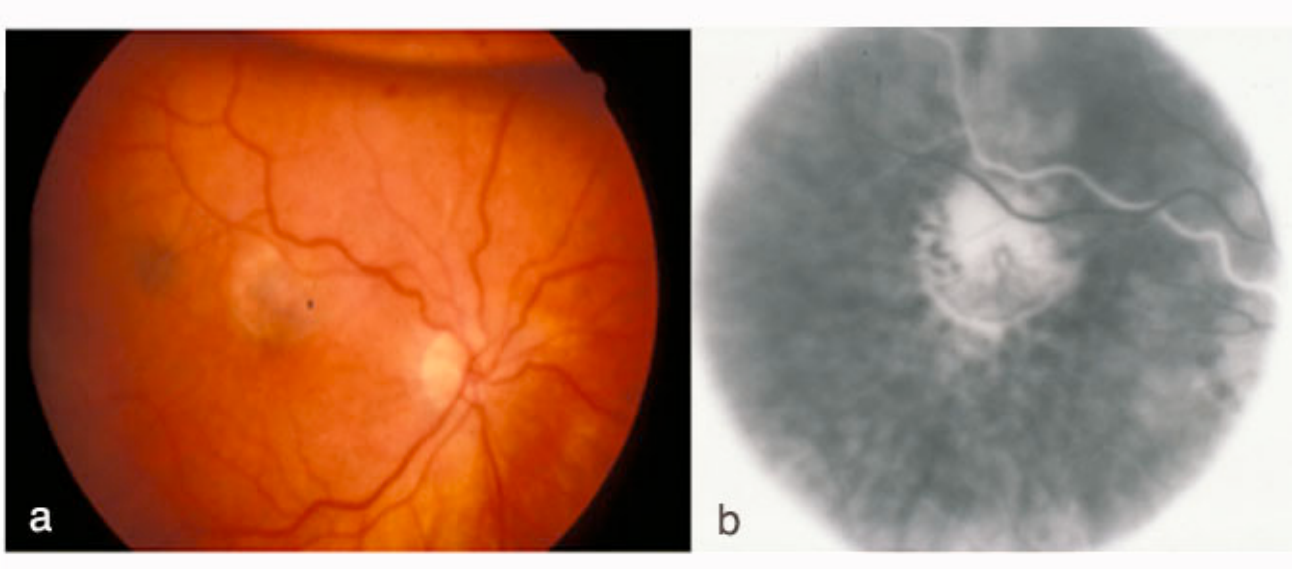

Figure 27. a) 4 day post-operative appearance after limited macular translocation (note air-bubble still present in the eye and superotemporal arcade has been displaced more superiorly than preoperatively). b) 4 day post-operative angiogram demonstrating previously subfoveal CNVM has been displaced superior to the fovea. (photos from KMG files).

Figure 28. Color photo 4 months after macular translocation and subsequent laser of CNVM. Vision improved from 20/80 preoperatively to 20/40. Unfortunately the CNVM recurred subfoveally with a chorioretinal anastamosis by 9 months post-operatively (photo from KMG files).

treatment of AMD? In the near term, a more comprehensive understanding of the genetic basis of AMD should rapidly emerge. It will not be surprising, for example, if genetic polymorphisms in additional complement components, complement regulators and, possibly, immune system effectors and inflammatory mediators are implicated in AMD. Secondly, it may be anticipated that the gene variants linked to AMD also contribute to other prevalent age-related diseases where chronic, local inflammatory processes are involved. For example, a significant statistical relationship between the CFH Tyr402His "risk" variant and the incidence of myocardial infarction has recently been reported (243, 245, 246). Based upon this new genetic information, it will be possible to devise genetic screening tests that will identify those individuals who are most at risk of developing AMD later in life. This will enable clinicians to monitor susceptible individuals from an early age, and to develop and test new preventive treatments in the early stages of the disease. Finally, the development of new diagnostic and pharmacological approaches will be hastened by the identification of the alternative pathway of complement as a prime therapeutic target. As our understanding of the pathogenesis of AMD continues to improve, so does the prospects for new diagnostic and therapeutic approaches. Hopefully, we will eventually eradicate AMD and dramatically improve the quality of life in our older generation.

Gregory S. Hageman, Ph.D., is a John A. Moran Presidential Professor of Ophthalmology and Visual Sciences, and Director of the Moran Center for Translational Medicine at the University of Utah. He is a graduate of the University of Southern California, where he conducted both his undergraduate and graduate studies in biology and marine biology. Most of his previous research career was at the Iowa Carver College of Medicine and his primary research interests have always been assessment of pathways involved in the etiology of age-related macular degeneration (AMD). Dr. Hageman is an active member of various professional and honorary organizations including the Macula Society and has also served on a number of national and international advisory boards, service panels and review committee. Moreover, he serves or has served as an advisor to Genentech, Alcon, Pfizer, OccuLogix, Novartis, Tanox and American Home Products. Dr. Hageman is an author or co-author of more than 100 refereed and invited publications, as well as multiple issued patents and pending patent applications. He was recently invited to present his research findings to Congress. He received the Trustee Award from Foundation Fighting Blindness, the Roger Johnson Prize for Macular Degeneration.

Diabetic retinopathy and a novel treatment based on the biophysics of rod photoreceptors and dark adaptation

Geoffrey B. Arden, MD, PhD[1,*] and David J. Ramsey, MD, PhD[2,†]

Created: July 14, 2015.

1. Introduction

There is a *pandemic* of diabetes. More than 350 million people are affected world-wide. In the UK more than 4.2 million people (6.3% of the population) are estimated to be living with diabetes, many without even knowing it (1). In the USA 29.1 million (9.3% of the population) have diabetes (2). Most individuals have type-2 diabetes, the onset of which is nearly universally attributed to the adoption of a "western diet", rich in calories from refined carbohydrates and saturated fat. But type 1 diabetes is also increasing. Furthermore, type 2 diabetes now appears at much earlier ages, even in children, and increasing numbers of people with type-2 are insulin dependent (3). Individuals are not only developing diabetes at earlier ages, but also living longer. There are now various ways of controlling diabetes, but sadly these are not as successful in treating the *complications* of diabetes that are related to the heart, major blood vessels, peripheral nerves, kidneys and the eye (4). With an estimated 150,000 people in the UK developing diabetes each year, the prevalence of very long standing diabetes is growing even more rapidly than the prevalence of diabetes itself. This sets up a 'perfect storm' for the complications of diabetes which develop after long periods.

2. Classification of diabetes

Diabetes literally means "a passer through; a siphon," so named because of the immoderate discharge of urine containing glucose which is a cardinal feature of the disease. The word comes to English by way of the Latin (diabetes) from the Ancient Greek (διαβήτης [diabêtês]). The earliest meaning of the noun "diabetes" was "compass" (5th cent. B.C.); it was not used in the sense of "siphon" (a passer through) until the 2nd or 1st cent. BC. Its first attestation as the name of a disease is in the 2nd century A.D. by Aretaeus, a Cappadocian (Greek) physician and medical writer (Figure 1), and by his contemporary Galen.

Aretæus of Cappadocia, writing in the 2nd century A.D., is the earliest physician whose account of this disease is extant: "Diabetes is a wonderful affection, not very frequent among men, being a melting down of the flesh and limbs into urine." (5)

The first occurrence in English may be in a 1425 translation into Middle English (*non vidi*) of Chauliac's seminal work on surgery, *Chirurgia magna*, which was finished in 1363. In seven volumes, the treatise covers anatomy, bloodletting, cauterization, drugs, anesthetics, wounds, fractures, ulcers, special diseases, and antidotes. The earliest attestation of "diabetes" in a primary English work comes from circa 1541, R. Copland's *Formularie of Helpes of Woundes & Sores in Guy de Chauliac's "Questyonary Cyrurgyens"* "Yiijv, Auycen Graunteth in diabete the water of the clere mylke of a shepe.", closely followed by an even clearer reference to the disease in Dean William Turner's book *Natures Bathes (1562)*: "It is good for the flixe to the chamber pot called of the beste Physicianes Diabetes, that is when a man maketh water oft and much."

* About the Authors

† About the Authors

Diabetes can further be broadly divided into two classes of disorders, diabetes mellitus and diabetes insipidus. Both share in common the production of copious quantities of urine, as well as an associated risk of dehydration and electrolyte imbalances; however, the two diseases originate from very different sources. When the term "diabetes" is used without qualification, it almost always refers to diabetes mellitus. Diabetes mellitus is a group of severe metabolic disorders marked by high levels of blood glucose resulting from defects in the production of insulin, resistance to that action of insulin, or a combination both. Greek physicians used to diagnose the condition by tasting the urine to detect saccharine matter. In 1675, the English epidemiologist Thomas Willis (1621–1675) rediscovered this phenomenon and appended the term "mellitus," meaning "honey-sweet," to the name diabetes (6). To some extent this diagnostic practice continued into the 20th century among physicians who were taught to use literally *all* of their senses in the art (and science) of diagnosis. Diabetes insipidus is a relatively rare disorder and glucose does not ordinarily spill into the urine of patients, hence the term "insipidus," Latin for "tasteless," appended to the name (6).

3. Types of diabetes mellitus

There are two main forms of diabetes mellitus: type 1 and type 2. In years gone by, these were sometimes referred to as 'Juvenile' versus 'Adult' or 'Insulin dependent' versus 'non-insulin dependent', but some type 1 cases develop in older age, and many type 2 cases are treated with insulin. Hyperglycemia is the hallmark of both forms of the disease, the result of a failure in insulin signaling. In type 1, diabetes results from diminished secretions of insulin because of a nearly complete loss of β cells of the islets of Langerhans due to autoimmune attack. In type 2 disease a number of defects conspire to reduce the effective secretion of insulin and its activity at its receptors in various tissues. Gestational diabetes mellitus (GDM) has been retained as a separate diagnosis category (7), and a new category called "other specific types" created to cover the growing number of cases where specific genetic defects, surgery, drugs, or other cause of hyperglycemia have been identified (8).

Type 1 diabetes

Type 1 diabetes results from the near complete loss of insulin secretion from the pancreas. Its onset is usually acute and associated with increased output of urine, associated thirst, tiredness and weight loss (the 'four T's' of toilet, thirst, tiredness, and thinner). For an unknown reason, autoantibodies are produced that destroy the insulin-producing β cells of the pancreatic islets. The loss of β cells may begin years before diabetes is detected, and in some cases children with type 1 disease have a short remission of symptoms during the early stages of the disorder; in rare instances a complete remission may even occur (9). There is a strong genetic risk for the disease associated with the major histocompatibility complex (MHC) genes, especially certain human leukocyte antigens (HLA) alleles, but genes outside of the MHC have also been associated with increased risk of the disease (10, 11). The mechanism by which heredity makes the β cells more susceptible to autoimmune attack remains obscure.

Type 1 diabetes only accounts for five to ten per cent of all diabetic patients, but is the most common form of diabetes in children and adolescents. The prevalence is approximately one out of every 500 children and adolescents in the United States (12, 13), having risen more than thirty per cent within the last decade. The mean age of onset of type 1 diabetes is approximately 9 years of age and has been reported to occur at a slightly earlier age in girls (8.7±3.8 years) than in boys (9.1±4.1 years) (14). Recently, the incidence of type 1 disease is increasing in many populations (by as much as three to four per cent a year), a fact that cannot be explained by genetics alone (10). Although epidemiological studies have failed to identify a specific causal entity (15), space-time clustering of cases suggests that an infectious etiology is possible (16). In certain instances, a virus, again most likely by initiating the development of autoantibodies, may also induce type 1 diabetes.

Figure 1: Aretæus of Cappadocia. Illustration depicting "Aretæus of Cappadocia," modified after a lithograph from Johannes Sambucus (1531-1584), *Icones Veterum aliquot ac Recentium Medicorum Philosophorumque* (Images of Some Ancient and Recent Physicians and Philosophers), 1901.

Type 2 diabetes

Type 2 diabetes is by far the more prevalent from of the disease, accounting for roughly ninety to ninety-five per cent of diabetic patients in the United States (17). The onset of type 2 diabetes is usually in adulthood and occurs decades after elements of the 'metabolic syndrome' appear. Type 2 diabetes usually has an insidious onset, and patients are for the most part unaware of the onset until they suffer from acute side effects of extreme hyperglycemia, or another illness which leads to its discovery (for example, repeated infections). Diabetes UK has estimated that up to 25% of patients who consult their general practitioners for other reasons may have undetected type 2 diabetes, and recommend that all patients have tests for glycosylated hemoglobin levels (Hb1Ac).

The hallmark of type 2 diabetes is insulin resistance, accompanied by variable defects in insulin secretion. In type 2 disease, insulin is usually present, but its activity is insufficient to meet the metabolic needs of the body. Initially, the β cells of the pancreas may be able to augment their secretion of insulin when faced with insulin

resistance, but over time β cell output fails. This may result from either increasing insulin resistance, β cell exhaustion (degeneration), or both. Insufficient insulin activity causes patients to become "glucose intolerant", i.e. experience abnormally elevated blood glucose levels following carbohydrate loads. Whereas nearly all patients with type 1 diabetes are aware that they have the disease because of the effects of severe insulin deficiency, roughly 6.2 million people in the United States with the type 2 disease are currently unaware that they have diabetes (3, 17). Often the onsets of symptoms are so gradual, or the effects of diabetes so mild or intermittent, that people with diabetes fail to recognize that they have a disorder of blood glucose regulation. However, if left untreated the consequences of diabetes are devastating. Together, these metabolic defects take their toll on the body, lead to a series of complications, and patients often succumb to an early death (15,18).

4. The effect of diabetes on the eye

Here we specifically concentrate on the damage that occurs at the level of the light-sensitive retina at the back of the eye. Already 240,000 people in the UK with diabetes have diabetic retinopathy. Visual impairment may occur from bleeding in the eye, often with accompanying abnormal proliferating blood vessels, retinal detachment from associated scar tissue, or even more commonly the leakage of fluid from damaged capillaries in the central part of the retina. This is called diabetic macular edema (DME). In the USA, DME is the leading cause of blindness in people of working age (3). In the UK although the prevalence is similar, there has been a recent increase in the incidence of hereditary retinal degeneration, so DME is now the second most common cause of registered blindness in the working age group (4).

5. Detection and screening

Once diabetes has damaged the retina, vision is often permanently lost. For this reason all efforts are being made to detect diabetic retinopathy (DR) as early as possible by taking photographs of the back of the eye (Figure 2) each year in every person who had diabetes. In the UK, for example, over 3 million people are examined in this way each year, and over 100,000 of these are referred to the eye departments of NHS Trusts, which are struggling to cope with these large numbers of patients. National eye screening programs using fundus photography and reading centers have been set up in many health care centers throughout the world.

Clinically, DR is divided into nonproliferative and proliferative disease, the latter of which is marked by evidence of new vessel formation. Non-proliferative diabetic retinopathy (NPDR) can further be divided into mild, moderate and severe, "pre-proliferative" diabetic retinopathy. The term "background retinopathy" is no longer used.

As patients with sight-threatening retinopathy may not have symptoms, life-long evaluation for retinopathy by annual screening is a valuable and necessary strategy. Pediatric patients with type 1 diabetes generally do not need to have a screening exam for retinopathy before age 9, or within 3 to 5 years of diagnosis, but should have them yearly thereafter (19). This is because DR generally does not start to develop until approximately five years after the onset of diabetes and is unusual before puberty; on average, only half of patients with type 1 diabetes develop retinopathy by eight to ten years after the onset of disease (20, 21). By contrast, because patients with type 2 disease may have had diabetes for ten or fifteen years prior to their diagnosis (22), it is essential that they are screened at baseline and yearly thereafter (23-25). Recent data from the Liverpool eye study suggest that a longer interval after an initial exam may be appropriate for type 2 patients. Type 2 patients without clinically detectible retinopathy at baseline remained free of sight-threatening DR for an average of 5.4 years (26). The complications develop insidiously often going unnoticed by patients until there is a sudden and dramatic loss of visual acuity caused for example by preretinal hemorrhages from new vessels or loss of central vision from retinal swelling. The fundus photographs (Figure 2) show small circular "dark lesions", which are microaneurysms or "dot and blot" hemorrhages, or lighter exudates. Swelling of the macular retina is also detectable (for more details see (27)). Microaneurysms are thought to be due in part to loss of pericytes (27). In

the resulting capillary dilatation, blood flow is sluggish and localised clotting may occur. In the end stages of this process the whole capillary is often obliterated. This can be seen histologically as 'ghost vessels' and on fluorescein angiography of the retinal circulation localized areas appear where the inner retinal capillary blood supply is lost. Dark-adapted thresholds are elevated early in diabetes (26, 28-31) and selective loss of blue–yellow colour contrast sensitivity occurs early in the disease (32-34). Clinical screening by slit lamp biomicroscopy and indirect ophthalmoscopy, complimented by fundus photography, and often optical coherence tomography (OCT) is necessary to monitor the disease in individuals. More recently, the advent of wide field and now ultra-wide field angiography have the potential to aid in the diagnosis and management of retinopathy (35, 36) but have not yet been incorporated into any screening programme.

In animals, results similar to those in man can be seen, but there are species differences. Rodents develop microaneurysms (37) but these changes are much less pronounced than in man (38) and proliferative retinopathy is not seen or the later hemorrhagic changes seen in man. These do appear in longer-lived species such as dogs. Swelling of the retina can be seen in mouse, but it is not clear how closely related this is to human DME.

The different stages of the disease are seen in the following series of retinal photographs. The progress of DR is most clearly seen in fluorescein angiographs where the damage to the retinal vessels and arterioles are more obvious than in the fundus photos. These studies also highlight regions of capillary dropout and other microvascular abnormalities.

6. Clinical grading of diabetic retinopathy and stage of disease

Nonproliferative retinopathy

In man the earliest stages of the disease, loss of retinal capillary pericytes, contributes to mechanical changes in the retinal blood vessels, altering their patency and permeability (39). These changes consist of microaneurysms (i.e. focal dilations) of retinal capillaries located in the inner nuclear layer that can be appreciated by the direct ophthalmoscope as tiny red dots about the size of a pinhead in the retina. (Isolated microaneurysms also appear in a number of other retinal diseases, including glaucoma, hypertensive retinopathy, and venous occlusal diseases like central retinal vein obstruction). These vascular changes often progress to yield hemorrhages within the retina. Hemorrhages in early DR usually appear as either "dot/blot" or "flame" hemorrhages, however, severe retinal bleeding can occur. Dot hemorrhages (tiny) and blot hemorrhages (larger) are the result of the rupture of weakened capillaries (i.e. aneurysms) within the neural retina. Flame hemorrhages are the result of the same underlying process, but occur in the superficial layers of the retina causing the blood to track along nerve fiber bundles. Hard exudates, appreciable as yellow-white spots in the peripheral retina or sometimes in a pattern of streaks around the macula, also tend to increase in number. These precipitates consist of lipoproteins and other proteins that have been extravasated from leaky retinal blood vessels as a result of the failure of the blood retinal barrier (40). Finally, microretinal infarcts often occur in the nerve fiber layer of the retina to give rise to patches of dead retinal tissue with vague borders known as "cotton wool" spots—transient findings that are no longer considered as predictive of high risk disease as many of the other vascular features discussed below.

The patient in Figure 3 has mild non-proliferative diabetic retinopathy (NDPR) and the fundus photograph at first blush looks almost normal. The changes clinically apparent are microaneurysms, some red spots of hemorrhage, and hard yellow exudates, and on close inspection early signs of ischemia. The damage to the retina in DR is most clearly seen in the angiographs where the damage to the retinal vessels and arterioles are more obvious than in the fundus photos. The fluorescein angiogram (right) shows the hemorrhages as dark spots. This photograph was taken as the dye began to fill the vessels, and a few bright spots indicate the presence of microaneurysms. In later frames of the angiogram (not shown) these cause leakage, which is one of the mechanisms by which retinal swelling is known to occur.

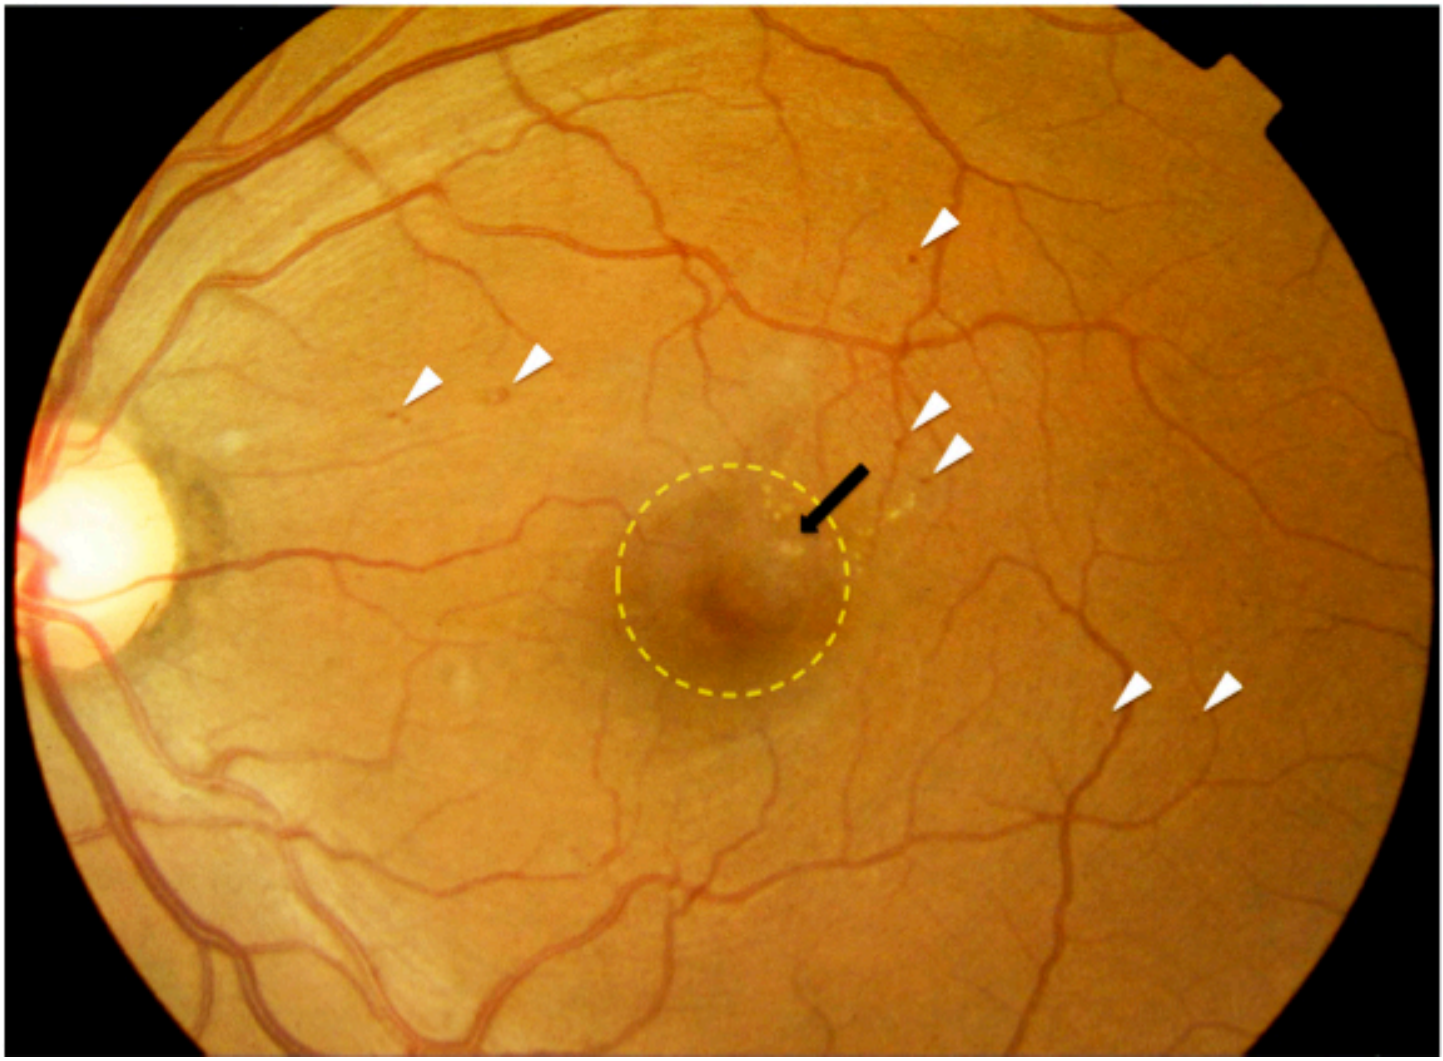

Figure 2: Fundus photograph of a person with mild (early) nonproliferative diabetic retinopathy with centre-involving diabetic macular edema (DME) in the left eye. The white arrow-heads highlight typical examples of small red "dot" (microaneurysms) and "blot" (hemorrhages). The black arrow points to retinal exudates several of which are within 500 microns of the centre of the fovea. The yellow circle delineates an area of central thickening of the retina (edema).

Pre-Proliferative diabetic retinopathy

Pre-proliferative retinopathy (PPDR) consists of a series of signs in the retinal vasculature that heralds the worsening retinal ischemia that can ultimately lead to formation of new vessels. Progression to the pre-proliferative stage of diabetic retinopathy is marked by 1: a rapid increase in the size and confluence of hemorrhages, 2: the appearance of >5 cotton-wool spots (ischemic nerve fiber layer infarcts), 3: venous dilation and beading (focal variation in the caliber of retina veins in response to ischemia), and 4: arterial abnormalities and remodeling of existing retinal capillary beds (causing intraretinal microvascular abnormalities that do *not* leak fluorescein). Of these clinical signs, venous beading is considered the most significant predictor of progression to proliferative diabetic retinopathy (PDR), whereas cotton-wool spots are the least significant (because they are so transient, lasting often only a few days to a couple of weeks). About half of eyes with these retinal characteristics progress to PDR within 12 to 24 months, indicating a strong need for careful monitoring at this stage. Unfortunately, no preventative or restorative treatment exists for PPDR, although anti-VEGF agents have shown some promise in clinical trials in patients with concurrent DME (41).

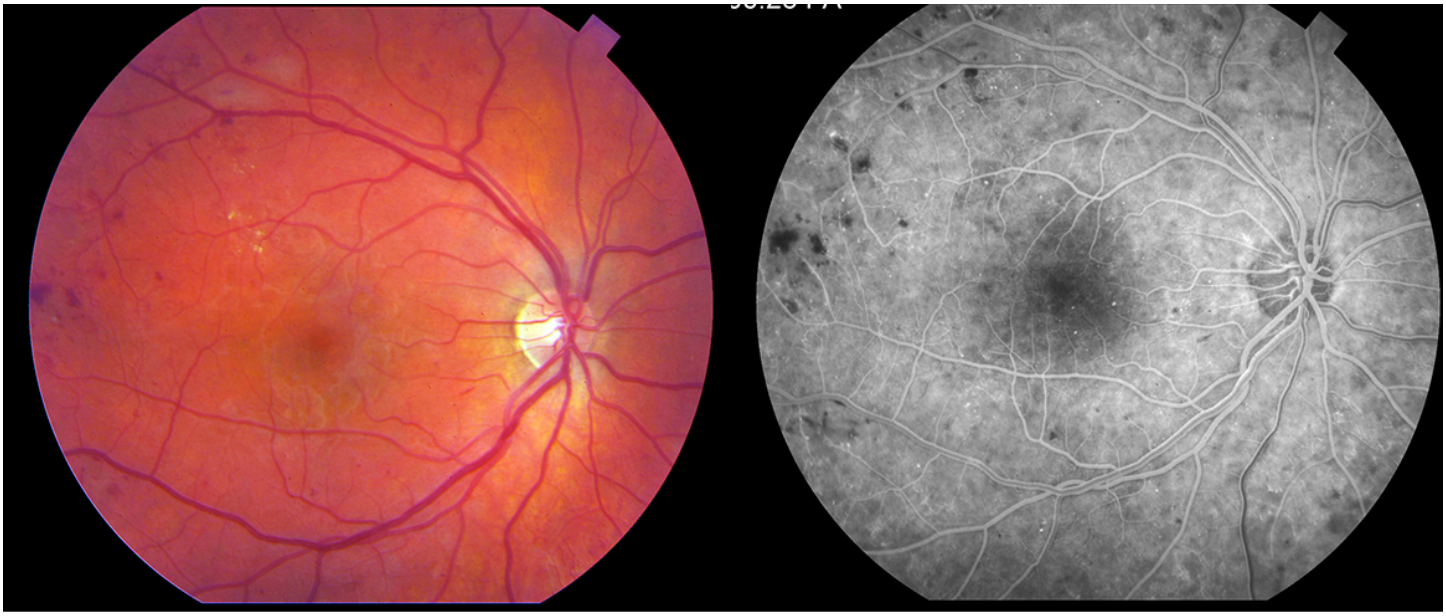

Figure 3: Fundus photograph and angiogram of patient with mild non-proliferative diabetic retinopathy (NDPR).

Proliferative retinopathy

The hallmark of proliferative diabetic retinopathy (PDR) is neovascularization of the retina at the edges of zones of capillary non-perfusion, most often near the optic disc or within three disc diameters of major retinal vessels (42). The new blood vessels that form around the optic nerve head are referred to as "new vessel disc" (NVD) and other vessels are clinically termed "new vessels elsewhere" (NVE). In some respects, the formation of new vessel can be viewed as an attempt by the retina to revascularize areas of capillary non-perfusion; however, this process does not occur in an orderly fashion and is largely unsuccessful at restoring any lost function. These new vessels penetrate the internal limiting membrane and form a dense capillary plexus between the inner surfaces of the retina or penetrate into the vitreous humor to grow along the outer surface of the vitreous body (46). The new vessels are also highly delicate and markedly permeable and may cause vision loss by intravitreal or pre-retinal (beneath the internal limiting membrane) hemorrhage. Early signs of changes in vasculature permeability can often be demonstrated by fluorescein angiography (FANG). In the late stages of the disease, these new vessels may regress, leaving only lattices of avascular fibrous tissue adhering to the retina and the posterior hyaloid membrane (42, 44). Fibroglial tissue may lead to mechanical deformation of the macula by putting traction on the retina as the vitreous body contracts, either with age or secondary to retinal ischemia (39). Retinal detachment may also occur, in some cases remaining stable for years, but other eyes rapidly progress to involve the macula and the rest of the retina, resulting in blindness if not rapidly reversed (42).

Historically, the incidence of proliferative diabetic retinopathy had been as high as 40-50% in some populations after 20-25 years of diabetes; however, the figure is now more commonly ten to fifteen per cent, nearly a four-fold decline due largely to tight glucose control that is the hallmark of modern diabetes care (43-45). However, the absolute number of new cases of blindness has not been decreasing as rapidly because of the ever expanding numbers of patients with diabetes and the earlier age of onset.

The patient whose imaging results are shown in Figure 4 illustrates many of the features of advanced PDR. There are blot and dot hemorrhages, flame hemorrhages (within the nerve fiber layer), cotton wool spots (infarcts in the nerve fiber layer), and neovascularization elsewhere (NVE) and of the disc (NVD). Inferiorly, there is a boat-shaped hemorrhage (in the lower portion of the image) that occurred some time ago. This eye has high risk features and requires treatment. The angiogram (Figure 4, right), taken at a later stage with dye filling both

arteries and the veins, demonstrates leakage from the areas of NVE and NVD, as well as many more microaneurysms. Dye has leaked from the capillaries into the extracellular compartment so there is a background glow. However in some areas the capillaries have been obliterated and these areas of ischemia appear dark in appearance and are essentially dead. There is also enlargement of the foveal avascular zone (FAZ) in the central macula, which may limit central vision due to damage to the fine capillary network that services this essential region. There is also significant ischemia in the periphery (not shown).

Figure 5 is from a patient with legal blindness from end stage diabetic retinopathy. This particular case is taken from a patient with type 1 diabetes who ran away from home at an early age. Living on the streets made it difficult if not impossible to handle her disease appropriately for many years. By the time she got treatment, in this case pan retinal laser photocoagulation (PRP) (seen as the scattered bright white spots in the color photography that act as window defects in the fluorescein due to the loss of pigment epithelium and overlying retina) the treatment was too late to arrest the progressive ischemic retinopathy. Ischemic maculopathy has developed, along with a central scar. Many of the larger retinal arteries and even some of the veins are no longer perfused, appearing as white ischemic vessels that remain unperfused on the FAZ. The optic disc is pale and yet new vessels emanate from the disc associated leakage seen in the FAZ. The patient unfortunately died from other complications from her diabetes in her late 20s. The progression of directly observable retinopathy often provides insight to the other complications of diabetes.

Diabetic macular edema

One of the most serious complications of diabetic retinopathy is diabetic macular edema (DME). Most of the early manifestations of diabetic retinopathy involve the peripheral retina, where changes in retinal function may be silent because of the ability of the CNS to ignore defects that develop in the peripheral visual field (46). However, as DR progresses, retinal vascular changes increase not only in number and severity, and tend to spread to the central retina where they can involve the macula, the region of the retina that underlies high acuity vision (Figure 6).

Anatomically, diabetic macular edema is the thickening of the center of the macula, i.e. fovea, due to the accumulation of fluid and plasma proteins as a result of leaky capillaries and a failure of the blood retinal barrier. Although the fovea is avascular, diabetes-induced damage to the fine capillary network that supports the function of this highly specialized region of the retina can lead to DME as the blood retinal barrier fails (40). Swelling that distorts the contour of the fovea (Figure 6), the neuroanatomical specialization at the center of the macula, can lead to a precipitous decline in visual acuity. DME usually presents as a progressive, painless loss of central vision. Patients usually report a decline in visual acuity that may develop suddenly or have a more gradual onset. DME requiring treatment may be present even when visual acuity is not yet significantly reduced (45, 46). The incidence of DME in the Wisconsin Epidemiologic Study of Diabetic Retinopathy (46-49) and the Early Treatment Diabetic Retinopathy Study (ETDRS) demonstrated that 6.4% of patients with DM develop permanent severe vision loss due to DME (44, 48-52). DME that occurs in the foveal center, if left untreated, can lead to permanent blindness (47-49). Extensive capillary closure, i.e. ischemic maculopathy, or scarring may also lead to vision loss (52). The development of optical coherence tomography (Figure 6), which uses timing or frequency differences in light reflected by different layers of the retina to examine the cross-section of the retina in real-time, has advanced our ability to diagnose and follow DME (53). Whereas “clinically significant” DME was originally based on biomicroscopic finding of macular thickening in ETDRS, many cases of DME where there are mild increases in retinal thickening sufficient to impact vision may be missed without that aid of an OCT scan (Figure 6) (54).

The standardised fundus photographs taken by screening centers (see Figure 2) have been used in attempts to grade the severity of a patient’s disease: The individual’s result is compared to a number of standardised views, by trained, registered observers whose estimates must agree. Either 2 or 7 standard areas of the retina are viewed and graded. This sort of quantitation has led to the Airlie House and the modified Airlie house grading (56, 57),

Figure 4: Fundus photograph and accompanying fluorescein angiogram in the early to mid-phase in a patient with more advanced (high risk) proliferative retinopathy.

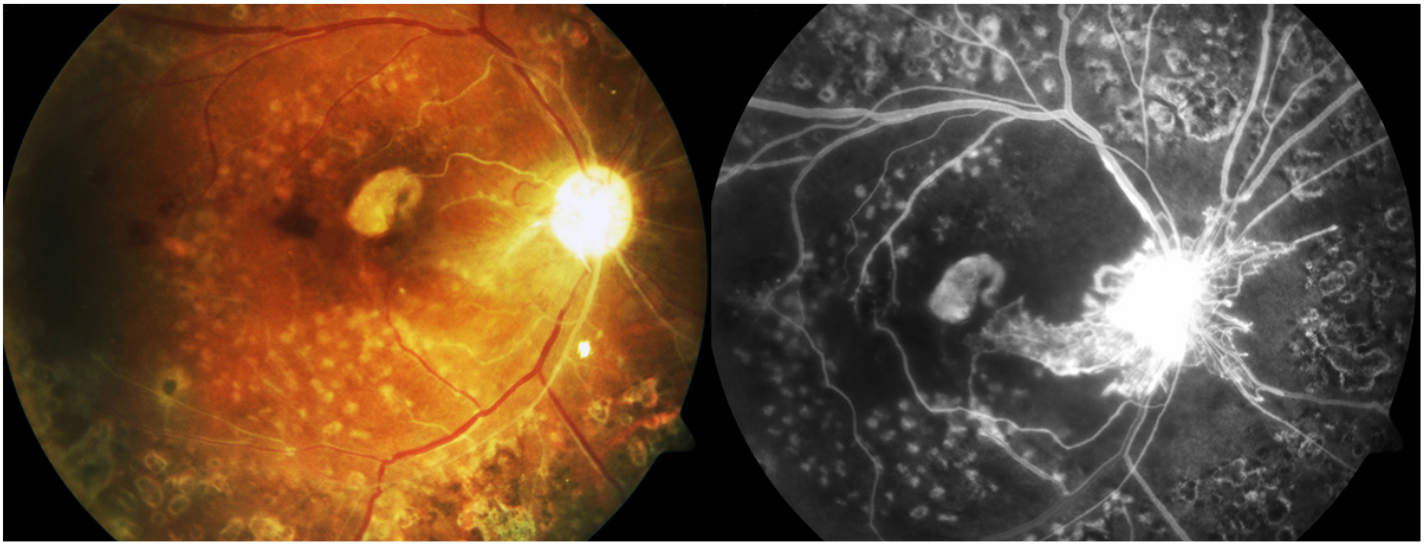

Figure 5: Advanced proliferative diabetic retinopathy with associated ischemic maculopathy. Note the laser scars form panretinal laser photocoagulation, including areas of focal grid laser treatment within the macula. The extensive capillary dropout represents end-stage diabetic retinopathy. Although additional laser may arrest the proliferative changes, very little vision remains secondary to the obliteration of the inner retinal vasculature.

which has proven value for research. The latest form of the grading appears in (27). The clinical usefulness of the classification has recently been questioned in view of the introduction of newer techniques like the OCT (55).

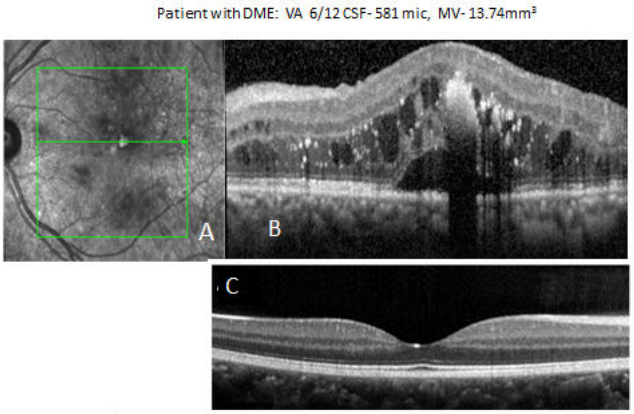

Figure 6: (A) Infrared image showing the location of the ocular coherence tomography (OCT) scan over laid on an infrared image of the fundus. The green box shows the border of the scans with the green arrow indicating the location of the scan shown in cross section in part B. (B) Cross sectional view through the fovea of a diabetic patient with severe clinically significant macular edema (CSME). The OCT can measure retinal thickness and volume can be extrapolated from a series of scans. Note the intraretinal cystoid fluid and highly reflective signals indicative of hemorrhages and/or exudates within the retina. (C) A representative OCT scan through the fovea of a normal eye (43).

7. Treatment of diabetic retinopathy

Laser panretinal photocoagulation (PRP)

Panretinal (scatter) laser photocoagulation (PRP) is effective in treating proliferative retinopathy, reducing the risk of severe visual loss by 50% (43). Figure 7 shows the end results of such treatment. The image is a collage of different areas of retina, photographed with the same equipment as the previous figures. Care is taken to avoid PRP in the central region or macula, as this would damage the central vision, although focal laser applications are sometimes used within macula to treat areas of leakage.

The white areas in Figure 7 are full thickness scars, in which the retina is dead. At first it was thought that the laser treatment prevented injurious substances leaking from those parts of the retina affected by diabetes (56, 57), but in fact, the burns can be placed anywhere in the peripheral retina and the treatment is successful in arresting progression of the disease as long as a sufficient area of the retina is treated. But the outcome is far from perfect. The treatment is often given after loss of visual acuity has already occurred, and it does not act to restore vision. Indeed after 5 years, slight further deterioration of acuity is the rule, although vision is conserved in patients who receive treatment compared to those who forgo PRP (58-60). Furthermore, the destruction of the peripheral retina has as an unavoidable side effect, loss of peripheral vision: and patients often complain of decreased night vision and reduced colour vision. Furthermore, the retinal nerve fiber layer in eyes that have been treated with PPR are thinner with abnormal cupping, but should not be mistaken for glaucomatous optic neuropathy (61).

2) Focal laser

The ETDRS demonstrated a 50% reduction in moderate visual loss (≥ 15 letters) in eyes with mild to moderate nonproliferative diabetic retinopathy and “clinically significant” DME (62). While a small percentage of eyes treated with laser photocoagulation had improvement in visual acuity, most did not and with time lesions often developed into focal areas of chorioretinal atrophy or scarring.

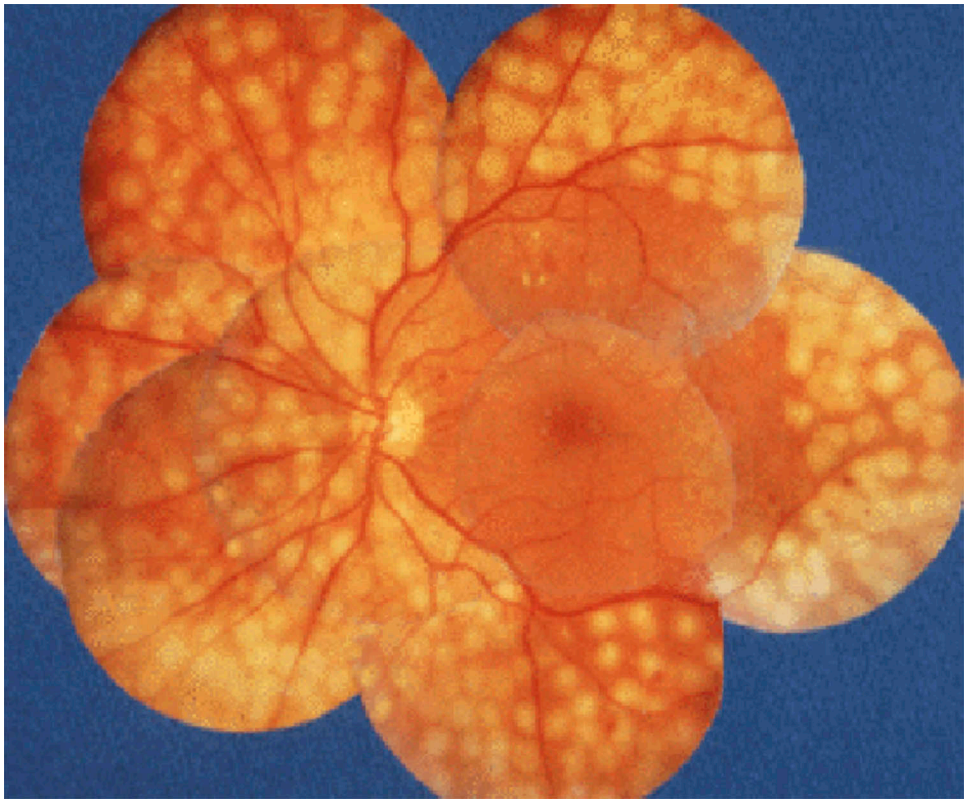

Figure 7: A montage of 7 fundus photographs from a patient who had undergone pan-retinal photocoagulation (PRP) some years previously. The optic nerve head is at the centre, and the blood vessels can be seen radiating from it. The white spots are scars left from the laser burns. Initially 400 μm across, they have enlarged with time. In these areas there is no retinal function.

The superiority of intravitreal treatment with anti-VEGF agents, specifically ranibizumab monotherapy over focal laser alone has been noted for DME (63). In the treatment of DME, laser photocoagulation may still be used as an additional, or "rescue", treatment. For example, in the case of the RISE and RIDE trials (identical, double-masked, sham-controlled, multicenter Phase III trials evaluating the impact of monthly ranibizumab injections on DME) laser was applied if it was found that central foveal thickness was >250 μm or if there was a 50-μm worsening from the prior month.

Recently, the development of subthreshold photocoagulation promises to greatly reduce the risk of structural and functional retinal damage from laser treatment, while retaining the therapeutic efficacy of conventional laser treatment (55, 56, 60 64, 65). The development of the diode laser with micropulsed emission with a longer wavelength in the near-infrared (810 nm) greatly reduces the thermal diffusion to the neurosensory retina and allows focal treatment without a visible burn endpoint (61). Although no retinal damage is detectable at the time of treatment, changes from the laser treatment, i.e. scarring, still develops albeit in a smaller proportion of patients compared to conventional green laser photocoagulation (64, 65, 66).

3) Intravitreal injection of medications

The situation has been transformed over the last decade with the introduction of intravitreal agents that target vascular endothelial growth factor (VEGF), one of the key cytokines whose abnormal expression has been strongly associated with the progression of diabetic eye disease. This discovery arose from an appreciation that angiogenesis of the retina of new-born animals was related to the development of local hypoxia in the retina driving the production of VEGF (67, 68). Soon after, increased VEGF expression was recognised in animal models of diabetes (69-71), as well as in samples of vitreous taken from patients operated upon for the complication of proliferative diabetic retinopathy (72). While awaiting FDA approval for ranibizumab

(Lucentis), a humanized small antibody fragment (Fab) with a high binding affinity for human VEGF, was specifically designed for intraocular use (73, 74). With a smaller size compared to its parent molecule bevacizumab (Avastin) (75, 76), ophthalmologists began treating neovascular AMD with off-label bevacizumab (76). This has since become a widely adopted as a lower-cost alternative to ranibizumab. A new drug, aflibercept (Eylea), which targets all VEGF isoforms and PEGF, has been recently approved for the treatment of DME (77, 78). Ongoing studies indicate that these and related compounds may actually slow the progression of diabetic retinopathy (79). Furthermore, they are highly effective therapies for DME, often resulting in an increase in visual acuity, although some patients do not respond and other have such extensive damage that vision is permanently lost (80-85). Unfortunately, the effects are also too often short lived and the effects of diabetes progressive, necessitating repeat injections of these very costly medications (86). Delivery methods for sustained release of anti-VEGF therapy are under development (87). DME may also be treated with intravitreal glucocorticoids, particularly triamcinolone acetonide, dexamethasone, and fluocinolone acetonide.

Beginning in the late 1990s, intraocular injection of triamcinolone acetonide was proposed as an adjunctive treatment of DME and numerous clinical trials for DME followed (88). In addition, in certain cases of DME that have proved refractory to anti-VEGF treatment, steroids may provide some benefit (89, 90). In addition, sustained release devices are available and approved from some ophthalmic indications, including diabetic macular edema (91). Although these medications can be effective, the risks associated with intravitreal administration of steroid medications, especially cataract formation and ocular hypertension or glaucoma, need to be taken into account.

So the list of available treatments is short, and the results and access to treatment are not particularly inspiring. But the important message of this paper is that it is almost certain that an entirely new method of treatment, which is not only non-invasive and without side effects, but is also so inexpensive, and simple you can 'do it yourself' has been discovered. Below the rationale and the supporting evidence is given.

8. Pathogenesis of diabetic retinopathy

Pathological features of diabetes can broadly be divided into acute metabolic problems and long-term complications stemming from hyperglycemia-induced dysfunction, broadly divided between those that affect the macrovasculature versus the microvasculature. The general metabolic problems associated with diabetes are largely due to: (1) decrease in the proper utilization of glucose, leading to high blood glucose levels that result in an osmotic diuresis as glucose spills into the urine; (2) abnormalities in lipid metabolism, leading to the deposition of cholesterol in arterial walls and atherosclerosis; and (3) increased ketone production, with the associated risks of diabetic ketoacidosis when insulin signaling is severely depressed for long periods of time.

The most pronounced and often-cited effect of diabetes is a chronic rise in blood glucose levels. However, it is very unlikely that elevated blood glucose plays a singular causative role in the development of diabetic complications; many other cellular metabolic parameters are no less seriously altered by a lack of insulin signaling.

9. Biochemistry of diabetic retinopathy

Investigations of hyperglycemia on cellular metabolism have demonstrated that cells and tissues cultured in added glucose, or animal models made hyperglycemic by the injection of streptozotocin, experience both active and passive damage to their biochemical machinery. Increased concentration of available glucose triggers abnormalities in a range of metabolic pathways that collectively leads to "oxidative stress" as the concentration of a group of energetic radicals increases (92-94). Another line of enquiry relates to the formation of advanced glycosylated end-products (AGEs), which are modifications of proteins or lipids that become non-enzymatically glycosylated when exposed to aldose sugars and oxidative stress (95, 96). The formation of AGEs degrade the function of cellular enzymes of metabolism, as well as those that serve antioxidant functions, further

contributing to oxidative stress. AGEs also contribute directly to the generation of reactive oxygen species (ROS) as a result of activating cellular mechanisms designed to rid the cell of damaged macromolecules.

Oxidative Stress

Oxidative stress occurs when the concentration of a group of energetic radicals increases (92-94). These are known collectively as ROS. ROS may include singlet or triplet oxygen, but the major contributor is the superoxide anion $O_2^{\bullet -}$. In addition, in the presence of nitric oxide (NO), the oxygen radicals can react to form nitroso-compounds, but although these have slightly differing properties, and engage in different chemical reactions to the superoxide (97) this is ignored in the treatment that follows. Active species have short lifetimes and the superoxide ion rapidly transmutes into hydrogen peroxide (H_2O_2). The lifetimes of all these molecules depend very greatly on the local reducing environment. In cells they are surrounded by compounds and enzymes that quench them very effectively so that a sustained rise in the concentration of ROS requires either an overproduction or a reduction in the rate of their destruction. This is the case with diabetes where the production of ROS increases simultaneously with a decrease in the ability of endogenous quenchers.

Mitochondria produce ROS

Of the ways in which ROS can be produced, the mitochondria are the most important (97, 98). ROS are produced by the normal operation of mitochondria producing ATP from oxygen and trioses derived from glucose (99-103) as part of the process of oxidative phosphorylation (Figure 8). In many types of cell increased blood sugar levels in diabetes lead to increased intracellular glucose, which enters via membrane glucose transporters (104, 105). Increased glucose concentrations drive mitochondrial oxidative phosphorylation, limited by the availability of oxygen, to produce ROS (92 99-103). Figure 8 diagrams the processes occurring in the mitochondrion. Because of the short half-life of ROS, it is common to measure their activity indirectly using reporter dyes, molecules that are chemically altered by oxidation (106, 107).

It is now possible to introduce fluorescent proteins into the mitochondrial genome and observe the process of ROS production in real time. Confocal microscopy of reporter proteins transfected into cells has demonstrated that ROS are produced in localised places on the mitochondria, where electrons leak from the electron transfer chain (ETC) in brief pulses (107). About 5% of the oxygen is diverted into this pathway and modern techniques have shown that they are emitted as discontinuous flashes (146).

The plasma membrane produces ROS

Another method of production of ROS is situated in the cell membrane and involves the enzyme NADPH oxidase (109) (Figure 9). Its activity is controlled by a complex regulatory system that involves the G protein Rac (109, 110). In resting cells, a membrane-embedded heterodimer of two polypeptides (p22phox and gp91phox)—which also contains two heme groups and copper as well as a flavine adenine dinucleotide (FAD) group—enables the transfer of electrons from cytosolic NADPH across the membrane to molecular oxygen without NADPH oxidase activity. It is believed that the charge compensation occurs when gp91phox polypeptide also acts as a proton pump. Upon stimulation, a number of polypeptides (p47phox, p67phox, and p40phox) translocate to the inner face of the plasma membrane to form a fully active enzyme complex that contains NADPH oxidase activity. The central polypeptide gp91phox also acts as a Ca^{2+} or H^+ channel, and the ROS produced appear to regulate signaling pathways (109, 110).

Targets of oxidative stress

Most ROS are formed in a highly reducing environment inside cells, and must pass through cell membranes into the extracellular environment (which also contains quenchers) before they can diffuse to other cells. Oxidative stress makes membranes more permeable (111, 112), and reduces the quencher concentrations. But initially, in the early stage of diabetes, ROS are unlikely to travel more than a few microns, lasting for very short periods,

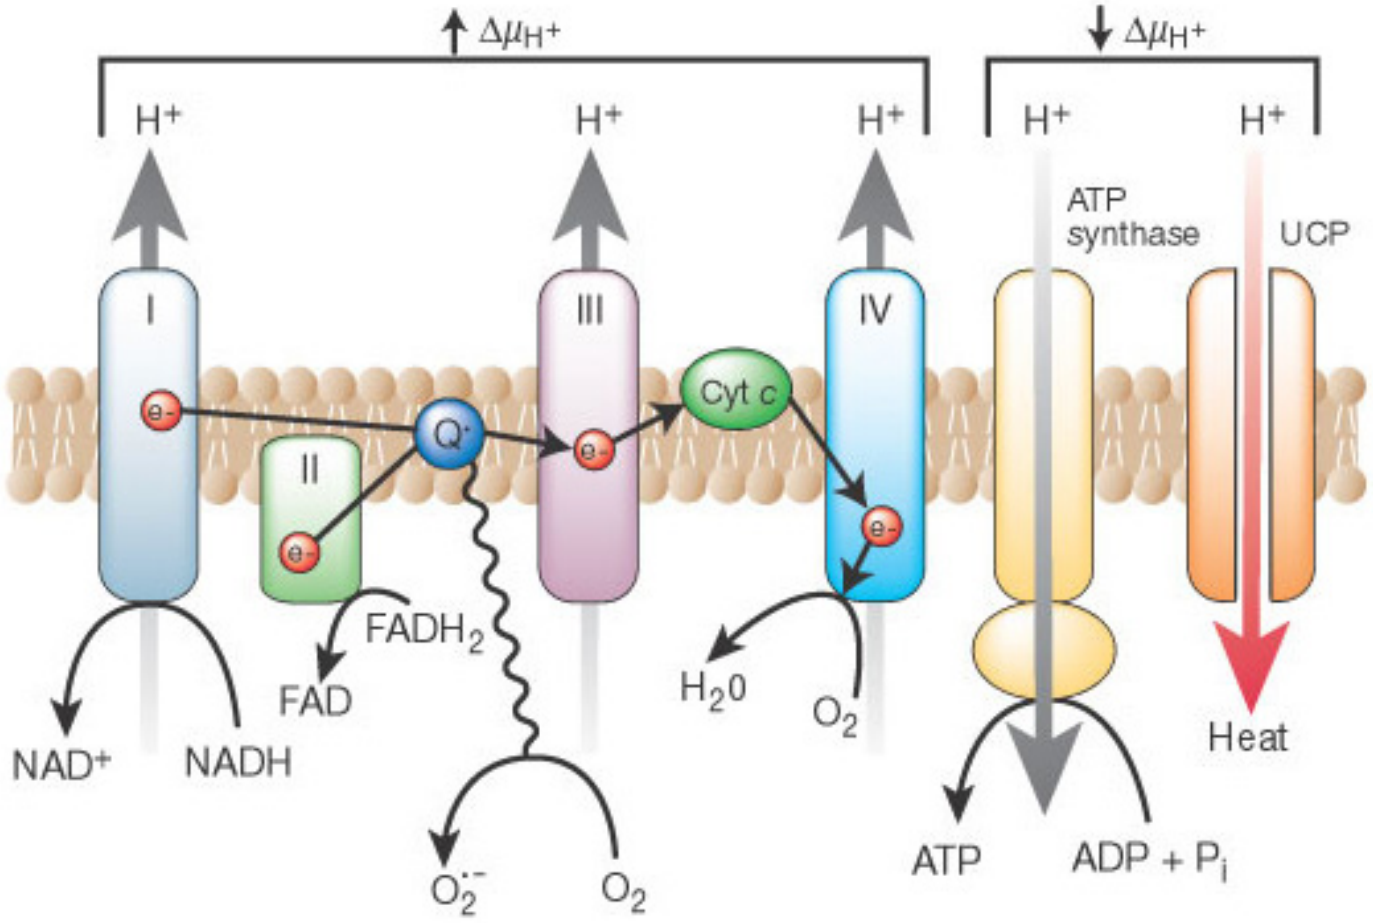

Figure 8: Diagram of the mitochondrial membrane showing the electron transfer chain (on the left) which results in the production of the superoxide anion, and a hydrogen ion gradient ($\Delta\mu H^+$) which when collapsed (on the right) produces ATP. From (102).

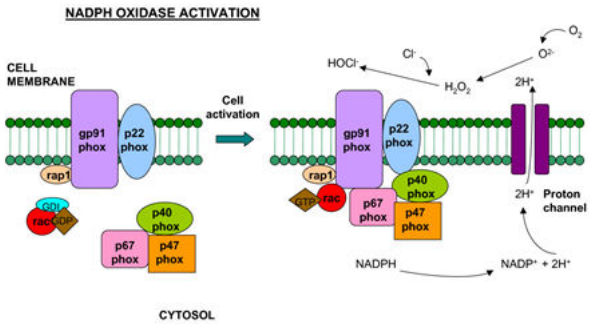

Figure 9: Production of superoxide ($O_2^{\bullet -}$) and hydrogen peroxide (H_2O_2) in the cell membrane. The 2 polypeptides gp91phox and p22phox together form flavocytochrome b_{558}, which is membrane-bound (upper diagram). When activated, the other polypeptides indicated in the diagram, which are usually free in the cytoplasm, bind to it and allow electrons to be transferred across the cell membrane (lower diagram). From (110). Image from (267). There are a number of different activating stimuli, including light. The difference spectrum, the change in absorbance from reduced to unreduced form as a function of wavelength, peaks at 640 nm (268).

before being captured and quenched, and therefore the earliest damaged in diabetic retinopathy occurs because of changes initiated intracellularly (113). Morphological evidence of intracellular oxidative stress is the swollen and disrupted cristae of mitochondria (114). Evidence of oxidative stress can be seen in many of the layers of the retina, for example the inner nerve fiber layer and ganglion cell layers, and this recently has been correlated with changes in the OCT (115). Localised oxidative stress in rodent retinal capillaries appears to develop rather late. Most of the ROS production however is in the photoreceptor layer (116). Although photoreceptor cells are major contributors to diabetes-induced oxidative stress and local inflammation, the functional disturbance to the phototransduction process is minimal, limited to the recovery rate after intense bleaching, and the responses to threshold stimulation (117-121).

Caveats to the oxidative stress theory

Despite this evidence, the precise mechanism by which hyperglycemia leads to the increased concentration of ROS is uncertain. In humans, there is no simple relationship between hyperglycemia and the development of retinopathy (122-124) (except for the very highest levels of hyperglycemia), so the determining factor may be when hyperglycemia reduces the capacity of antioxidant defences (125, 126). Experiments on tissues in raised glucose are usually confined to comparing the results in 5mM with 25 or 30mM glucose. In one case (studies implicating increased glucosamine with oxidative stress) (127), the threshold appears to be about 12mM. This corresponds to the highest levels of hyperglycemia found in normally functioning patients (122-124). At the glucose levels utilized in most biochemical investigations in excess of this level, patients would soon be severely ketotic or comatose with hyperosmolar non-ketotic decompensation syndrome, a condition that carries a mortality of 40% (128). It is therefore difficult to be sure that the 'downstream' abnormalities demonstrated in laboratory experimentation in "high" glucose have key roles to play in the development of retinal lesions, which develop in patients with relatively better controlled hyperglycemia. Rodents made diabetic with streptozotocin have body weights, which are up to 40% less than age-matched "controls", and results obtained under these conditions are possibly not directly applicable to clinical situations either. In fact, oscillating levels of elevated blood glucose levels appear to be more damaging than persistently elevated levels (129). Hyperglycemia can only have a direct effect if it results in higher intra-cellular glucose. While glucose can penetrate some cell membranes, in most it is ferried by glucose transporters (130), and either the number of portals increases or each turns over faster. It is of interest that in human retinal endothelial cells grown in monoculture, glucose transport does not increase under conditions of excess glucose, intracellular hyperglycemia does not occur, and the cells in culture do not show signs of oxidative stress (130, 131). This leads to the conclusion that the damage to capillaries by ROS (which are fundamental to the development of diabetic retinopathy) is due to a paracrine mechanism, i.e. they are secondary to some less direct effects caused by hyperglycemia.

Polyol pathways

Excess glucose not consumed by the tricarboxylic cycle may also be shunted to glycolytic pathways or enter the polyol (sorbitol) (133, 136) and hexosamine pathways leading to a build of up of metabolites that damages cellular function. Protein Kinase C (PKC) has also been found to be elevated in hyperglycemia. Increased glycolysis leads to the synthesis of diacylglycerol (DAG) which is a key activator of PKC. PKC in turn increases endothelial permeability, the production of VEGF, and leucostasis as well as endothelial cell proliferation (134, 135). Sorbital build up has been found in many cells (including retinal pericytes from diabetic animals). The reaction involves oxidation of glucose by NADPH, and this can cause a reduction of glutathione, one of the reducing agents that remove ROS (132), and increased accumulation of sorbitol is also thought to cause osmotic damage (133). Activation of these metabolic pathways leads to microvascular dysfunction, neuronal apoptosis, glial reactivity and inflammation (137, 138) (Figure 10).

Mitochondria also respond to hypoxia. The first effect is to reduce the formation and release of ROS (139, 140): However mitochondria and other cell-surface mechanisms, also initiate signaling cascades that increase ROS

(141-143, 144-152). The effect of alteration of the ROS output is however uncertain because change in pO_2 can also increase the output of quenchers, (148) at the same time as ROS are increased.

Advanced glycosylation end products

Hyperglycemia also results in the formation of complex molecules known as advanced glycosylation end products (AGEs) that affect the development of oxidative stress in several different ways (148) (Figure 11).

AGES contribute to the thickened basal membranes found in diabetes, which hinder diffusion of oxygen and nutrients both from blood to extracellular fluid and also within tissues. In additions, there are smaller molecule AGEs which interact with a receptor named RAGE, found on Müller and other cells, which, when satisfied, contribute directly to oxidative stress by directly affecting the NADPH oxidase system (149). RAGE also causes apoptopic cell death of retinal neurones by a mechanism involving the overproduction of nitric oxide (150). AGEs also directly affect retinal blood vessels causing leakage which is associated with increased VEGF and VEGF mRNA expression (95, 96, 150). The immediate effect of hypoxia is to reduce the production of ROS, as would be expected as the metabolism of the mitochondria slows (150). But part of the mechanism of production of ROS, the NAD/NADH ratio is changed by AGEs, producing "pseudo hypoxia", and this change increases oxidative stress (109, 144, 147).

The search for treatments

Many of the pathways involved in producing oxidative stress-induced cell death have been investigated by using selected animal models in which the activity of a particular pathway is increased. If the same experiments are carried out in animals in which quenchers are also increased, oxidative stress is reduced or may not appear (152, 153). If the stimulus driving oxidative stress is removed (e.g. hyperglycemia reduced) biochemical changes may not be restored to normal. It has been shown that ROS and reactive nitrogen species (RNS) activate a spectrum of transcription factors, including nuclear factor kappa B (NFκB), AP-1, p53, Ets transcriptional factor (Ets-1), hypoxia-inducible factor-1α (HIF-1α), and Nrf2. (154, 155) and following reversal of hyperglycemia to normoglycemia the transcription and regulation of proteins remains affected for months. This has been described as 'molecular memory' and due to changes in the nucleus. Damage to mitochondrial DNA also occurs(151, 155), and variations in mitochondrial DNA are associated with different probabilities of development of severe diabetic retinopathy (156) related, at least in part, to the expression levels of particular proteins. Amongst these is the expression of Vascular Endothelial Growth Factor (VEGF), interleukin 2 and transforming growth factor (TGF). All this experimental work has provided a number of blocking agents which can reduce the production of oxidative stress in laboratory conditions (157-171), but almost all have had inconclusive results in subsequent clinical trials (171-176). This has been explained (155) by the hypothesis that so many biochemical pathways contribute to and result from oxidative stress that blocking one is relatively ineffectual (108, 177).

Cytokines

The relatively spectacular improvement seen clinically with anti-VEGF drugs emphasises the importance of this cytokine as a final common pathway of damage to the retina and its vasculature. In turn the damage caused by excess VEGF prompts the production of abnormal concentrations of other related growth factors. Another observation quite unexplained, is the finding that in dogs, after 5 years of hyperglycemia, pericyte loss and capillary dropout occurs in retinal capillaries but not in brain (178): there appears to be a specific *retinal* cause for diabetic retinopathy, although the two tissues have the same neuroectodermal origin.

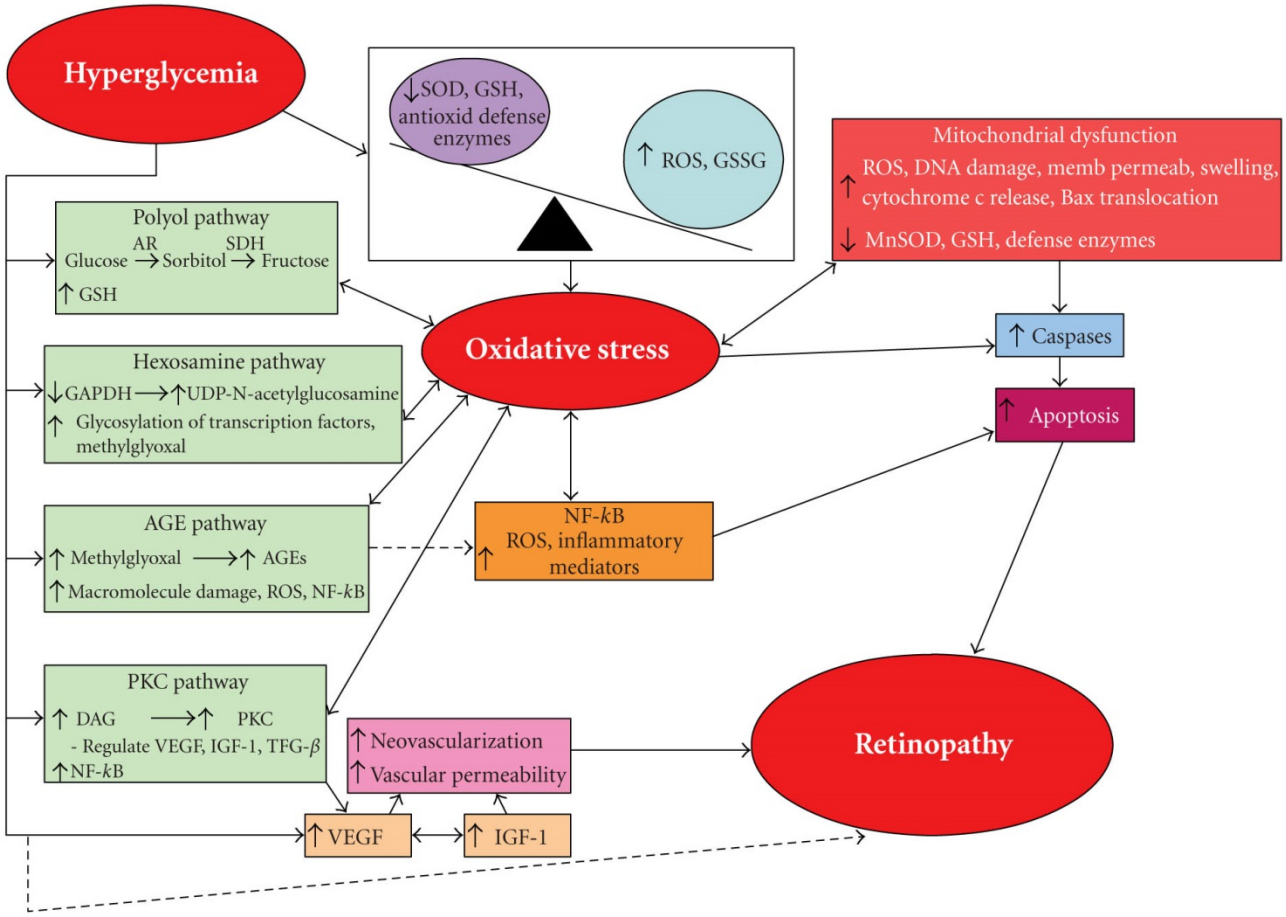

Figure 10: Summary of mechanisms by which oxidative stress in diabetes causes retinopathy. Four distinct glucose metabolic pathways are activated by hyperglycemia: Diacylglycerol (DAG)–protein kinase C (PKC) (137), advanced glycation end-products/receptor for advanced glycation end-products (AGE/RAGE), Polyol (sorbitol), and Hexosamine pathways.

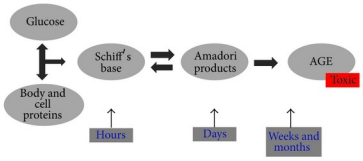

Figure 11. Mechanism of production of advanced glycation end-products (AGEs). From (136).

10. Neuronal abnormalities in early diabetes

In addition to the biochemical changes discussed above, which may cause the clinical vasculopathy, it has been known for many years that retinal neuronal damage occurs early in the condition (179). The examination of human post-mortem material (180) showed loss of tissue and excess TUNEL staining characteristic of apoptosis (181, 182). Thinning of the retina in living diabetic patients has been described (183). However the damage is selective: Ganglion cells and short wavelength cone receptors are preferentially damaged (184). Experiments on streptozotocin-induced diabetes in rodents (185) have led to similar claims. Thus more apopotosis has been claimed by some (186, 187), but has been reported absent by others (188). An example of damage to astrocytes and disappearance of connexin-43 normally seen in association with astrocytes is shown in Figure 12 (187).

Electrophysiological testing (189-191) both in man and rodents indicates inner retinal functions are disturbed much more than outer retinal function (31, 191). In psychophysical testing, losses in tritan colour vision, originally thought to be due to scattering changes, have been shown to be neural, to occur very early, and to be ameliorated by oxygen inhalation (192). Similar aberrations are seen with other psychophysical measures (189, 193-196).

There is some doubt about whether the neural changes precede the onset of the vasculopathy (197-198). Most biochemical experiments are studies after >4 week period of diabetes (216). Hypoxia and inner retinal neural changes have been reported at 2 weeks and the earliest vascular changes (leakage of fluid from retinal capillaries) can only be seen after 4 weeks. The early neuronal changes (187, 197, 198, 200) also occur in the absence of changes in the ERG which are dependent on the outer retina (201) (and see below). So it is possible that vascular and neuronal changes in the rodent retina are produced by different mechanisms, just as may be the case in man.

In superfused retinal slices, patch clamp recordings have demonstrated changes in glutamate release and activity in the rod pathway. These changes in spontaneous excitatory postsynaptic currents (spEPSCs) are an indicator of retinal neuronal activity and are controlled by hyper-glycemia. Thus excess activity in spEPSCs can be seen in the rod bipolar terminals recorded in slices from the retinas of rats made diabetic with streptozotocin (202). The activity returns to normal when the superfusing saline contains less glucose. The rod bipolar cell has a metabotropic glutamate receptor at its synapses with rod photoreceptors, and becomes depolarised on light stimulation. It releases glutamate at its axonal synapses with AII and A17 amacrine cells (see chapter in **Webvision** on Rod pathways through the retina). The glutamate release is increased in diabetics and returns to normal if the superfusing fluid does not contain extra glucose. The glutamate affects the α-amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid receptor (AMPAR) receptor in A17 cells. This, by affecting $[Ca^{2+}]_{in}$, reduces the inhibitory GABAc receptor activity at the rod bipolar cell and A17 synapse, and, in turn, still further increases the glutamate output by the rod bipolar cell (Figure 13) (202) (see chapter in **Webvision** on GABAc in the retina).

Thus not only does there appear to be a specific *retinal* cause for diabetic retinopathy (178), but also this cause is linked to hypoxia and metabolic overload, both in neuronal and vascular retinal elements. This was the trigger for the new hypothesis discussed below.

11. A new hypothesis based on rod photoreceptor biophysics

Hypoxia, driven by dark adaptation, accelerates the development of diabetic retinopathy (189, 203-205). There are several reasons why this occurs: Rod photoreceptors in the outer retina are ***maximally*** depolarized in the dark and continuously release large amounts of their neurotransmitter glutamate and this increases energy utilization and oxygen consumption (206-208) (Figure 14).

In darkness rods consume more oxygen than any other cell in the body (208-210) because the water and ions entering the rod outer segment need to be pumped out by pumps localized near the large mitochondria of the inner segment (Figure 14) (this pumping has similarities to a fireboat squirting out extreme amounts of water, Figure 15). Even though the choroidal blood supply is very profuse, the partial pressure of oxygen at the level of the inner segments of the photoreceptors is near zero in darkness compared with the 30 mm Hg common in most tissues. In animal experiments, the partial pressure of oxygen rises suddenly and briefly when the retina is stimulated by a flash of light (211). With normal oxygen concentrations, the rods receive sufficient oxygen, but if oxygen is reduced somehow, the rod sensitivity falls. This occurs with only a modest reduction of oxygen corresponding to a reduction in air pressure that occurs at an elevation of about 4000 ft. Thus, in commercial jet aircraft, which are pressurised to around 7000 ft., healthy normal observers have slightly reduced rod sensitivity and some individuals, particularly those with heart or lung disease, may experience symptoms of dimmed vision, fatigue, nausea, headaches, loss of consciousness, and (on extended flights) even pulmonary edema or death from altitude sickness (212). Consequently, if in retinal disease the availability of oxygen is reduced due to

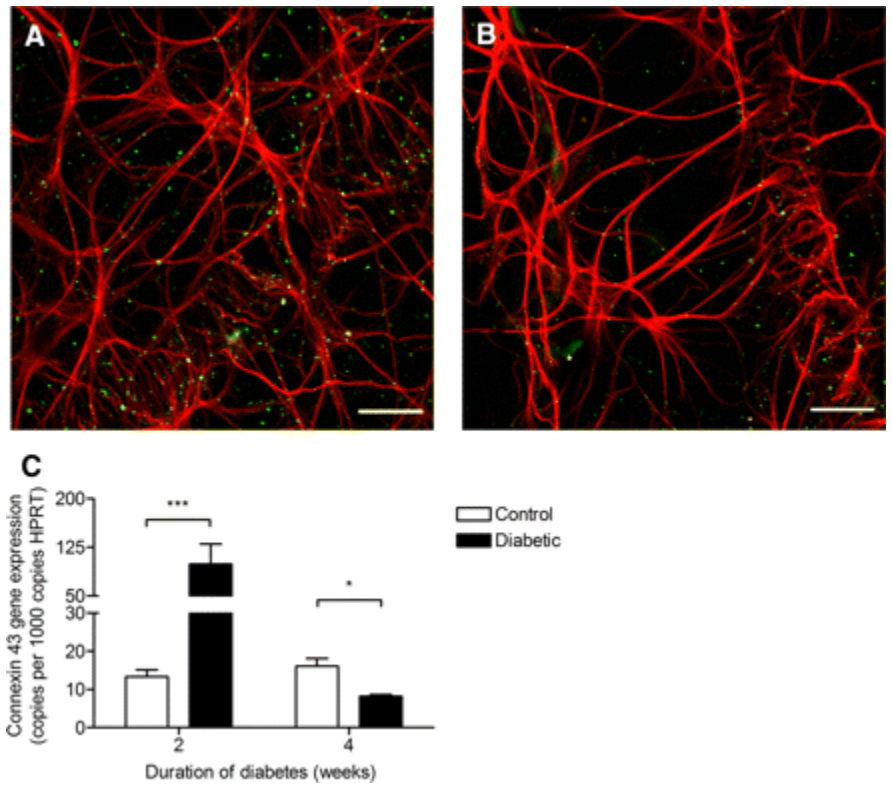

Figure 12: Changes in connexin-43 gene expression during early in diabetes. Control (A) and diabetic (B) rat retinas were immunolabeled with an antibody to connexin-43 (green) and the expression colocalized to astrocytes (GFAP, red). C) Connexin-43 gene expression was also quantified after 2 and 4 weeks diabetes using qPCR and the data are expressed relative to the housekeeping gene, HPRT. Connexin-43 gene expression is upregulated after only 2 weeks of diabetes, whereas its expression is decreased after 4 weeks. Data are expressed as mean ± SEM, ***P< 0.001, *P < 0.05, n > 9. Scale bar: 50 μm. Note the early and non-sustained expression of connexion in astroyctes, which contrasts with the more delayed and progressive changes in vascularity. From (187).

decreased function of the retinal circulation, or the relative demand for oxygen increases due to metabolic stress, there will be an imbalance which will lead to hypoxia in not only the outer retina (which is avascular) but also in the inner part, which is supplied primarily, but not completely, by the retinal arterial circulation. These processes are diagrammed in Figure 16.

Increased blood sugar levels in diabetics will lead to increased glucose transport through cell membranes in many cell types (but not apparently in rods due to their high affinity glucose transporters) (130, 131). On entering the tricarboxylic cycle, the excess sugars will lead to an increased demand for oxygen. This also results in the formation of advanced glycosylation end products (AGEs), which are modifications of proteins or lipids that become non-enzymatically glycosylated when exposed to aldose sugars and oxidative stress (213-215). Recent experimental evidence shows that rod photoreceptor cells are major contributors to diabetes-induced oxidative stress by producing reactive oxygen species and local inflammation in the retina (216).

These changes accumulate with time affecting both intracellular and extracellular function and by engaging the receptor for advanced glycation end products (RAGE). Activation of RAGE by AGEs causes upregulation of the transcription factor nuclear factor κ β (NFκβ) and its target genes. In Müller cells this promotes the expression of glial fibrillary acidic protein (GFAP) which is seen very early in diabetes, and the secretion of the cytokine, VEGF. As already alluded to above, VEGF causes changes to small vessels and makes them leaky (VEGF was initially identified as a vascular permeability factor [VPF] (217). Other AGEs contribute to the increase in basal membrane thickness which occurs in many tissues, including the capillaries of the retinal circulation (218-222). All these factors reduce oxygen transport into the retina. Additional biochemical alterations are known to occur in the diabetic retina, but once hypoxia is established, it will cause a cascade of effects that drive the production

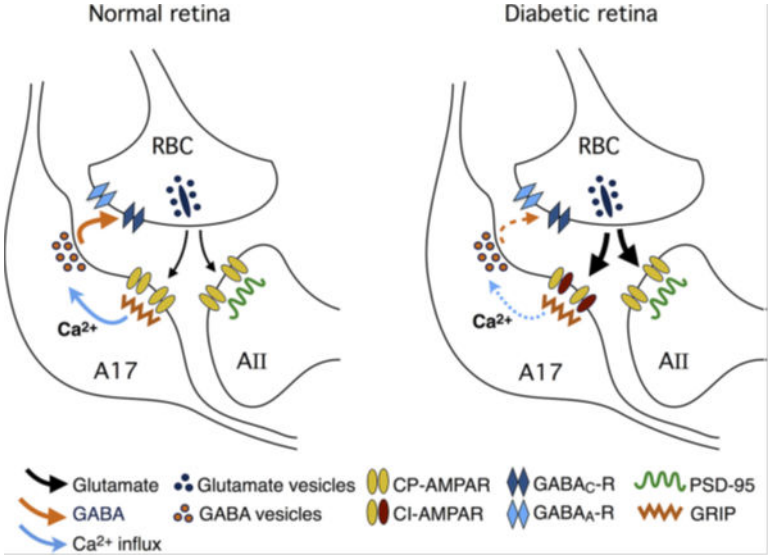

Figure 13: The rod bipolar- to-A17-amacrine feed-forward and feed-back interactions are affected by hyperglycemia. The rod bipolar cell (RBC) has postsynaptic metabotropic glutamate receptors, activated by rod signals. Its presynaptic surface is in a dyad into which the RBC releases glutamate. A17 amacrines and AII amacrines complete the dyad. Glutamate mobilizes calcium in the A17 and as a result, the amacrine releases GABA, an inhibitory feedback transmitter to the rod bipolar. This inhibition is weakened in high glucose, and consequently RBC output increases, as does AII output. (AII is the narrow field amacrine which connects to cone bipolar axons and ganglion cells). From (202). Of note, the sensitivity of the inhibitory GABAc receptor activity is increased in diabetic RBCs (269), most likely through its effect on the efficacy of gene transcription (201,270).

of VEGF (Figure 16) leading to further changes associated with diabetic retinopathy: and these changes in turn will exacerbate any underlying hypoxia.

Since a major cause of retinal hypoxia is the demand of the rods during periods of dark adaptation, reducing rod dark current should ameliorate diabetic changes. However, many other biochemical changes seen in diabetic retina have been connected to the overproduction of reactive oxygen species. (223). If these pathways are more important than the rod oxygen demand, increasing the retinal oxygen tension could either have little effect, or might even accelerate the progression of diabetic retinopathy. However, pan-retinal laser photocoagulation, the mainstay of treatment for proliferative diabetic retinopathy, has been shown to restore local oxygen levels to normal within weeks of its application (224). It is thought to work mainly by destroying large numbers of rods in the peripheral retina thereby increasing the oxygen supply to the remaining tissue (225). Furthermore, vascular responsiveness to oxygen inhalation also improves following photocoagulation (226-228).

12. Evidence for a new treatment based on the hypothesis that retinal hypoxia can be reduced by keeping rods light adapted at night

The success of panretinal photocoagulation is mainly because the treatment destroys rod photoreceptors, thereby reducing oxygen demand of the outer retina, particularly under dark adapted conditions. The remaining rods benefit, but even more importantly, there is improved ability of oxygen to reach the inner retina from the choroid because of the reduction in the number of rod photoreceptors with their oxygen-absorbing mitochondria. This may change the balance in the supply of oxygen to the inner retina, which already has a compromised retinal circulation.

The use of anti-VEGF drugs is now the most common initial treatment for diabetic eye disease, and hypoxia is the major determinant of VEGF production, but this is almost a circular argument. Direct measurement of

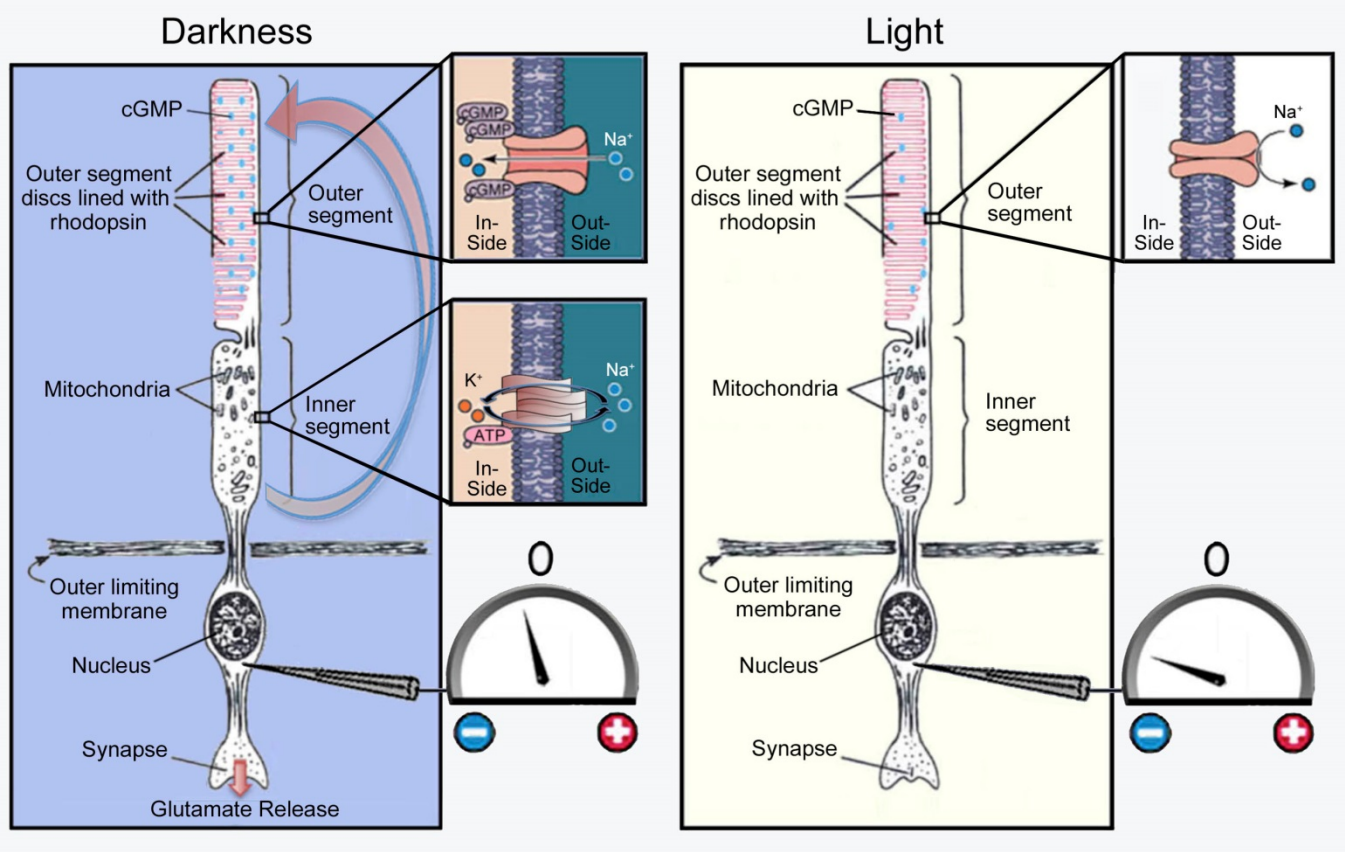

Figure 14: Mechanism of rod excitation. In darkness, non–specific cation channels in the outer segment membrane are open (as indicated by the left upper inset), and there is a net inward gradient of ions and water. This depolarizes the rod, as indicated in the diagram by the voltmeter recording from the nuclear region. In light, the ion channels close (upper inset right) and the rod repolarizes (hyperpolarizes). The water and ions entering the rod outer segment are pumped out by pumps localized in proximity to the large mitochondria of the inner segment. This causes a longitudinal current to flow from the inner to outer limb of the cell as indicated by the red arrow in darkness. In light this stops. The electrochemical changes that occur in response to an incremental change in light can also be measured electrophysiologically by the flash electroretinogram (ERG), recorded as a negative potential at the cornea known as the a-wave (not shown). Modified from (208).

oxygen tension in diabetic cat retina shows that the inner retina is more hypoxic than that of normal felines even in regions where there is no capillary dropout evident (229, 230) (Figure 17). The partial pressure of oxygen falls rapidly from the arterial level when the electrode moves from the RPE into the outer retina, and in darkness reaches a level of zero in the region of the rod inner limb mitochondria (229, 230). This rate of decline is the maximum theoretically possible if the choroid is an infinite source of oxygen, and the mitochondria, an infinite sink. As the electrode tip moves into the inner vascularized retina (see Figure 17A, top left tracing) the partial pressure increases again. Calculation shows that the rod mitochondria must also be absorbing oxygen from the retinal vessels. In light the oxygen tension is higher for all retinal locations, but especially at the level of the rod inner limbs, where it increases by about 30 mm Hg. (not illustrated). This shows how rapid the rate of respiration is, and how quickly it is affected by the processes of transduction. In addition in diabetic cat retina, even in regions in which there is no capillary dropout, the inner retinal oxygen tension is lower than in normal retina (Figure 17). There are also species differences in the oxygen tension profiles. In the miniature pig (224) and macaque (232), although the profiles resemble those shown in Figure 17A (from the cat (211)), the pO_2 at the level of the inner limbs does not fall to zero but about 5 mmHg. Nevertheless the outer retinal oxygen consumption greatly exceeds the inner retinal oxygen consumption. In guinea pigs (232) and rabbits (232, 235) animals with poorly developed retinal vessels, more of the inner retina's oxygen supply is provided by the choroid, but the same general relationships may be seen, and oxygen consumption and hypoxia of the outer

Figure 15: Allowing for the difference in volume, the rod in darkness pumps 10 times more than water from a fireboat! This produces heat, and demands a great deal of energy in the form of ATP, primarily produced by oxidative phosphorylation by the large mitochondria of the inner segment of the photoreceptor (of course the rod does not pump under pressure, like the fireboat!).

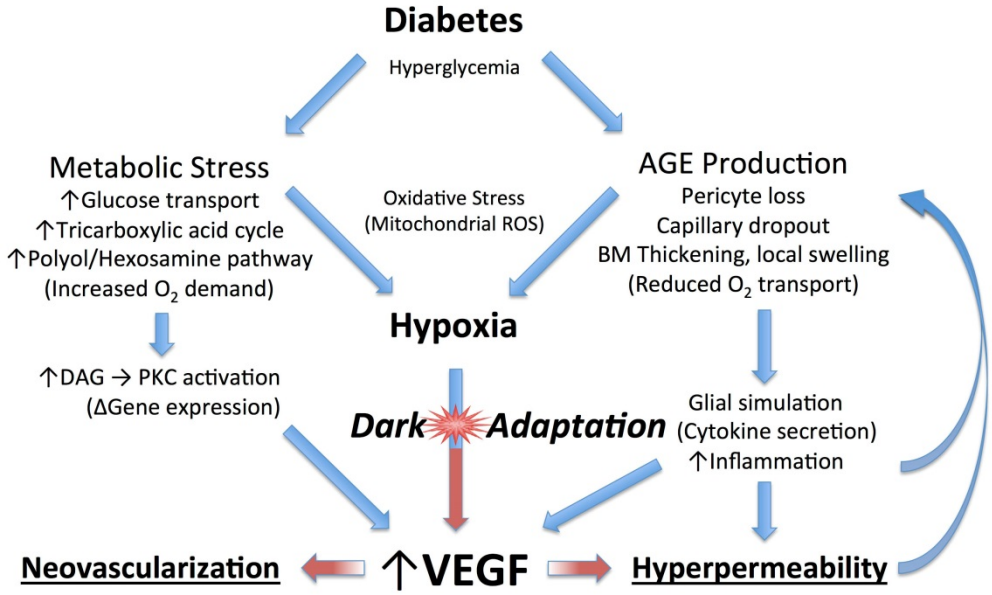

Figure 16: Diagram of how diabetes leads to vascular changes in the inner retina.

retina increases as the photoreceptors develop and their outer limbs lengthen. In the species studied in dark adaptation, diabetic animals have an inner retinal hypoxia more evident than in controls (224, 234). However, in the rat retina, the retinal profiles are different especially in the RCS rat (232), with the minimal pO_2 being found in the inner not the outer retina. Nevertheless the difference in oxygen consumption when in light or darkness is greatest in the outer retina, and corresponds to photoreceptor usage. This is supported by the change in profiles in the developing retina, and the change in profile when photoreceptor degenerations develop (233-235). So, in

rat (199), direct measurements of intraretinal pO_2 using oxygen microelectrodes have not shown hypoxia or change in diabetes. However, this last observation is difficult to reconcile with the other data measured in larger eyes, which are similar to human eye size (195, 235, 236) and to indirect evidences of rod-associated retinal hypoxia (237-239).

Human beings have many inherited diseases that selectively destroy rods, producing retinal dystrophies - Retinitis Pigmentosa is the most common of these conditions. Rod loss in many cases is slow, and diabetes can occur independently in conjunction with the slow loss of photoreceptors. However, in such patients, diabetic retinopathy-type changes rarely happen (Table 1) (240).

Another line of evidence comes from patients with maternally inherited diabetes and deafness (MIDD). These patients have mutation of mitochondrial DNA at position 3243 which manifests in a number of ways and can cause a type of retinal degeneration. This may or may not occur together with diabetes. If the retinal degeneration occurs together with the diabetes, the incidence of microaneurysms is less than if the diabetes occurs alone (241-243).

In some individuals, the efficiency of hypoxia in increasing VEGF and VEGF *RNA* levels is much reduced and can be seen by incubating white blood cells under normoxic and hypoxic conditions. Among this group, retinopathy does not appear in individuals who also have diabetes (243). In addition, breathing oxygen improves several visual functions in patients with diabetic retinopathy and DME (192, 193, 196, 189, 244, 245).

Finally, patients with diabetes who have sleep apnea, (defined as more than 5 periods, called *dips*, when oxyhemoglobin saturation falls below 90%), have more rapid development of diabetic eye complications than those who do not have sleep apnea. The increased risk is reduced in patients with sleep apnea who are treated with positive pressure ventilation (246-250). There are several recent reviews that include a more detailed discussion of the hypothesis that rod photoreceptor dark adaptation causes hypoxia and consequent damage to the retina in diabetic retinopathy (251, 252).

Given all the above evidence that hypoxia in the inner retina in diabetic patients causes the vascular damage of diabetic retinopathy, and evidence that rods are responsible for most of the oxygen consumption during their active metabolic time in darkness, it seems reasonable to suggest that curbing the rod activity at night would be beneficial. A simple treatment for impending diabetic retinopathy might be to prevent rod activity during darkness by the application of constant nocturnal light. This is the basis for the new treatment paradigm described below.

We have carried out clinical trials, in which patients wear "light masks" which provide retinal illumination through the closed eyelids during sleep. Sufficient light penetrates the lid to partially light adapt the rods. The light sources were either chemo-luminescent (glow-patches) or light-emitting diodes (LEDs). The green or blue-green light was used to selectively stimulate rods (95% of all photoreceptors are rods) rather than cones, because the sensations aroused by rod stimulation are less intrusive and tend to fade to insignificance as patients adapt to a low background luminance. In order to reduce inter-personal differences, the subjects wore masks which illuminated only one eye, with the other, in darkness being used as a control (253).

The results of a 6 month Phase I trial showed that no adverse reactions were encountered and patients accepted the idea of wearing a mask during sleep. However, unusual for a Phase 1 trial, the therapy caused a significant improvement in the 10 trial eyes relative to their controls. Figure 18 shows the results in one patient.

Fundus photographs such as shown in Figure 18 were examined under high magnification and the total areas of microaneurysms measured. The improvement in the condition (decrease in areas of affected central retina) was significant. A similar result was obtained when changes in tritan – blue-yellow - colour vision (known to be damaged early in diabetic retinopathy) was assessed (253) (not shown).

In a Phase II trial of 42 patients with non-center-involving DME, a similar benefit was shown. A high proportion of the treated eyes improved, while this did not occur in untreated eyes (Table 2). Much of this occurred during the first 3 months. Furthermore, whereas four of the patients recruited to the trial dropped out because the unilluminated fellow eyes received laser or intravitreal bevacizumab for DME during the study, none of the illuminated eyes required such treatment.

Ocular coherence tomography showed that cysts characteristic of DME disappeared, and significant reduction in thickness occurred (Figure 19) (254). The results of these changes in OCT measurements are shown in Table 3. The patients in this trial had very early DME, and in many patients the swelling did not involve the area within 300 μm of the fovea. Hence if there is a reduction observed in local swelling in one retinal region, might swelling simply be occurring in another region? In order to evaluate this, measurements were made in the Early Treatment Diabetic Retinopathy (ETDRS) zones, and the region with maximal swelling was compared to its opposite "mirror" zone. It can be seen that decrease in thickness occurs only in treated eyes (Figure 20). A small but significant improvement in visual acuity and contrast sensitivity also occurred among the light adapted eyes in this trial (table 4). It should be noted, that almost all the patients recruited were at an early stage of diabetic retinopathy with DME and had good visual acuity at baseline so a larger average increase in acuity would not be expected.

Such studies provide a "Proof of Principle" that retinal hypoxia in darkness must be an important driving force for diabetic retinopathy. However, further work is required to establish the role that 'light-at-night' may play in the treatment or prevention of the various complications of diabetic eye disease. Furthermore, we do not know how 'light at night' interacts with the other treatments for the condition. For this Phase III and IV clinical trials are required. This presents a difficulty, because for new pharmaceuticals, such trials are largely funded directly by the drug companies, while there is no such equivalent for medical devices. Small commercial companies have manufactured masks which can be used in such trials, and apparently in one trial carried out in the Department of Ophthalmology, Vinohrady, Prague, Czech Republic, produced encouraging results. These results have not been published in detail yet. Further trials are starting in London (255) Cardiff (UK) (256) and Boston (USA). There is a considerable need for this research because the cost of the present day "gold standard" treatment of repeated injections is becoming unsustainable (257). (Figure 21 refers of age related macular degeneration, but for diabetes the same economic criteria will apply).

Anti-VEGF drugs are expensive: Avastin costs about 1/40th of the price of Lucentis, but the cost of treatment by the two is not so different, in part because of the associated cost of administration (Figure 21). But only in the first world are incomes high enough for a significant proportion of the population with vision threatening diabetic eye disease to access treatment (257) and even then many individuals with vision threatened by complications from diabetes are not accessing available eye care (258). Worldwide there is not only a shortage of funding for available treatments, but a severe shortage of personnel trained to diagnose the condition and manage it appropriately (259). By contrast, the requirements of light-based treatment to interrupt nocturnal dark adaptation, for example through the use of a light masks, are relatively inexpensive, and so safe and easy to use that it could be made available with only basic instruction. This treatment may not replace medical intervention, but promises to complement or reduce the need for traditional therapies, thereby bringing down the cost of caring for patients with diabetic eye disease. We propose that more research and development be done so that light masks (or a similar device) may be manufactured on a scale that will reduce the cost to a level reaching the masses with diabetic eye disease.

It is possible that the evidence presented above concerning preventing dark adaptation in the diabetic retina, may also apply to other retinal conditions in which anti-VEGF drugs have been shown to be beneficial: Retinal diseases such as "wet" age related macular degeneration (257-265) (see chapter on age related macular degeneration (AMD) in **Webvision**) and retinopathy of prematurity (266) .

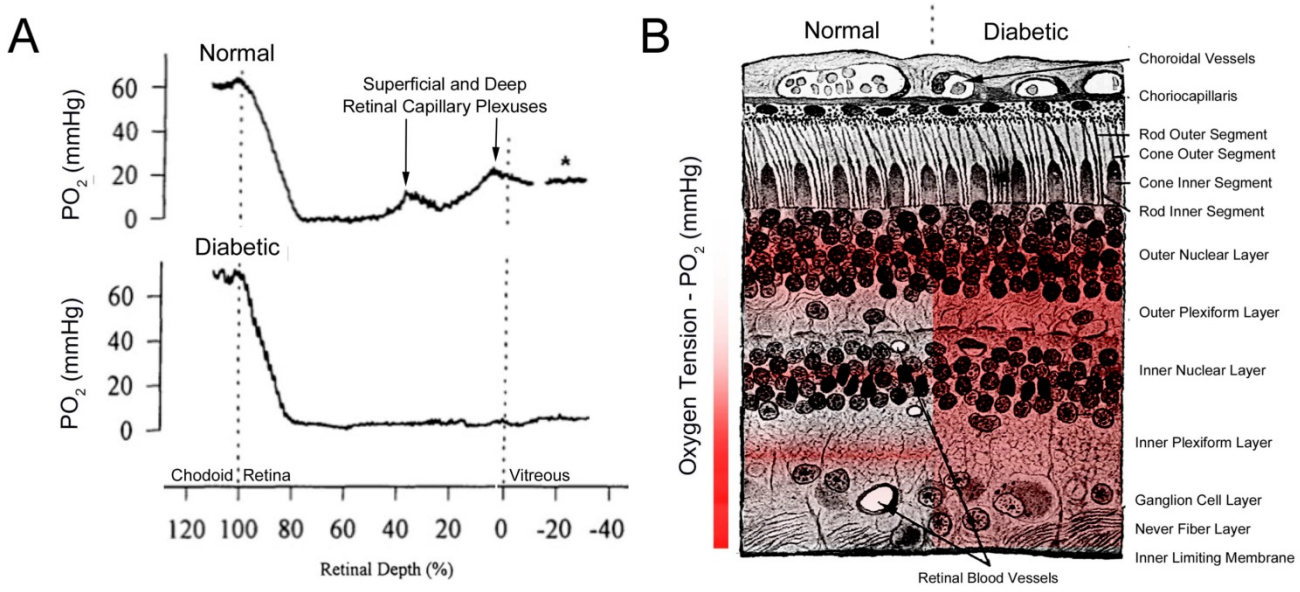

Figure 17: Retinal Oxygen Tension in Normal and Diabetic Cat. (A) Measurements (averaged) of oxygen partial pressure in retina, using O2 microelectrodes. The high tension in the choroid indicates blood with arterial saturation. A: upper part in normal animals, the rapid decrease as the electrode is withdrawn (proceeding from left to the right) is followed by an increase as the electrode passes through the deep and superficial capillary plexuses until the vitreous is reached (see * on trace). In the diabetic eye, (lower part) oxygen partial pressure is markedly lower in the inner retina. Modified after (230). (B) Cross section of the human retina with the gradient of oxygen partial pressure overlaid in red. The relative oxygen tensions are indicated by the depth of red shading, much reduced in diabetes. The left hand side of the retina illustrates the conditions present in the normal dark adapted retina (corresponding to the top trace in part A). There are regions in the outer retina and inner retina where oxygen tensions drop to very low levels (red shading). The right hand side illustrates what happens to oxygen tension in the diabetic state (corresponding to the bottom trace in part A). Modified after (231).

Interval between onset of night blindness and diabetes (years)	7.2 (n=10)	19.5 (n=24)
# of cases of diabetic retinopathy	0	0
# of cases of other major diabetic complications (non-ocular)	5 (n=11)	8 (n=18)

Table 1: Incidence of diabetic retinopathy in patients with both diabetes and rod degenerations (retinitis pigmentosa): None of the patients (discovered by a web-based search of patient-societies with surveys validated by attending ophthalmologists) has the characteristic changes, though many had severe vascular and other disease in other organs attributable to diabetes, adapted from (240).

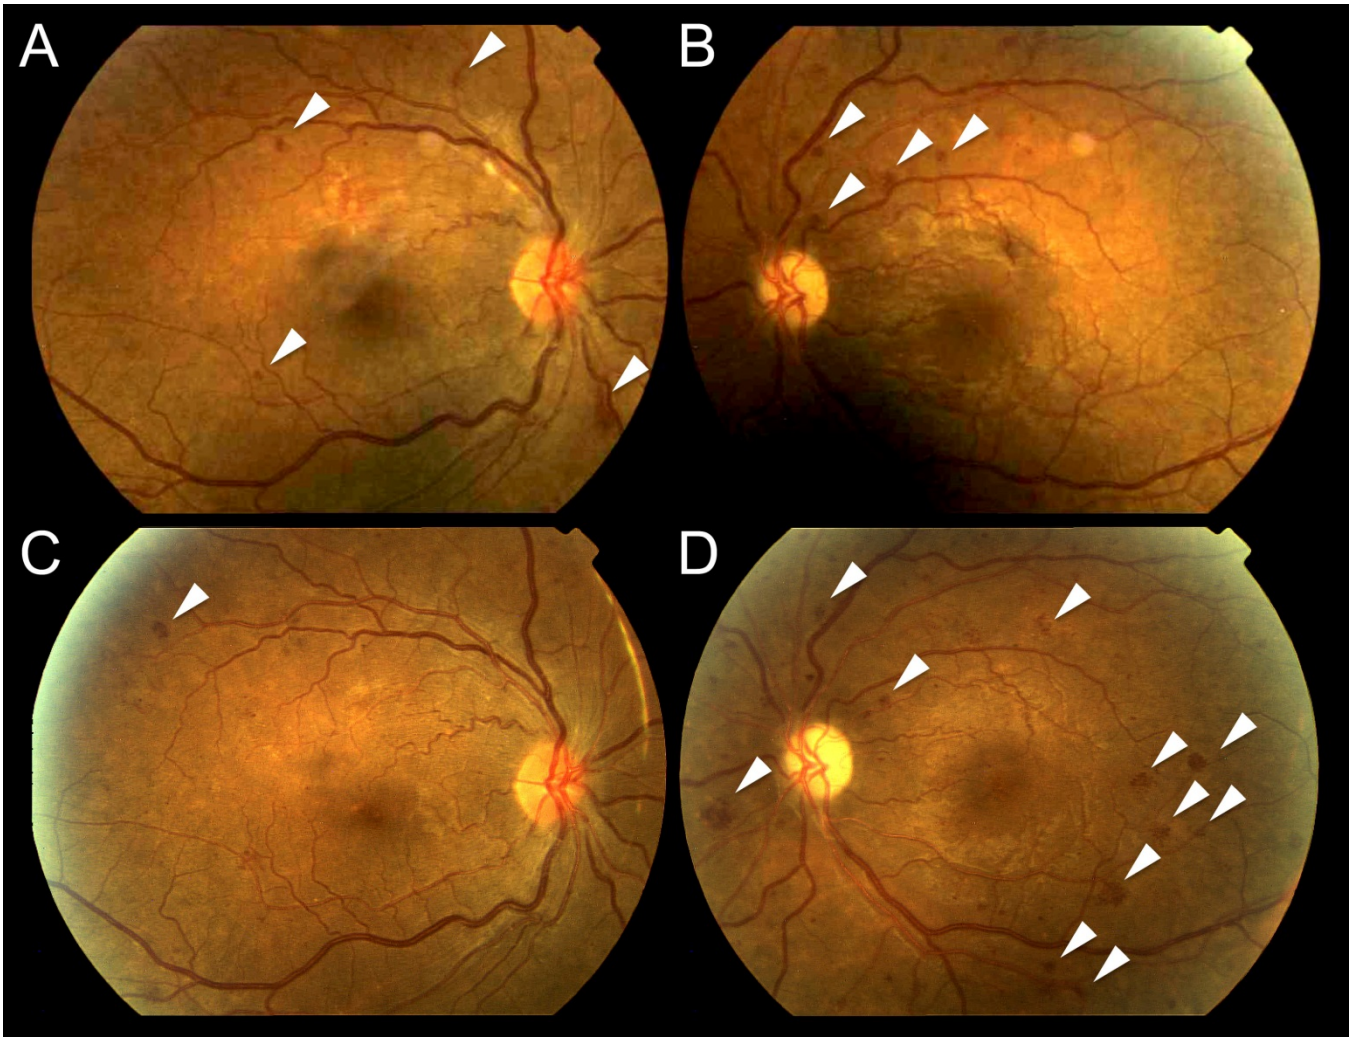

Figure 18: Representative fundus photographs from a patient with diabetic retinopathy. The upper row shows fundus photographs at baseline in the right (A) and left (B) eyes. The lower row shows the same patient following three months of light at night treatment of the right eye (C) with the left eye serving as a control (D). Note that in C the areas of hemorrhage (white arrows) have faded compared to A, consistent with an improvement in the clinical stage of retinopathy. In fact, in many light treated patients no new lesions developed. In contrast, the control eye (B and D) demonstrates many new and worsening hemorrhages at 3 months.

OCT macular fluid extent at 3 MONTHS

	Trial Eye	Control Eye	*P* value* (chi-squared)
Number improved	17	3	
Number unchanged	6	17	0.0003
Number worse	3	6	

Table 2: Change in DME at 3 months. Initial clinical results looking at change in macular thickness in a Phase II trial demonstrated that a majority of eyes treated with light at night improved, while untreated eyes in the fellow patient more often stayed the same or even worsened over the course of the trial (254).

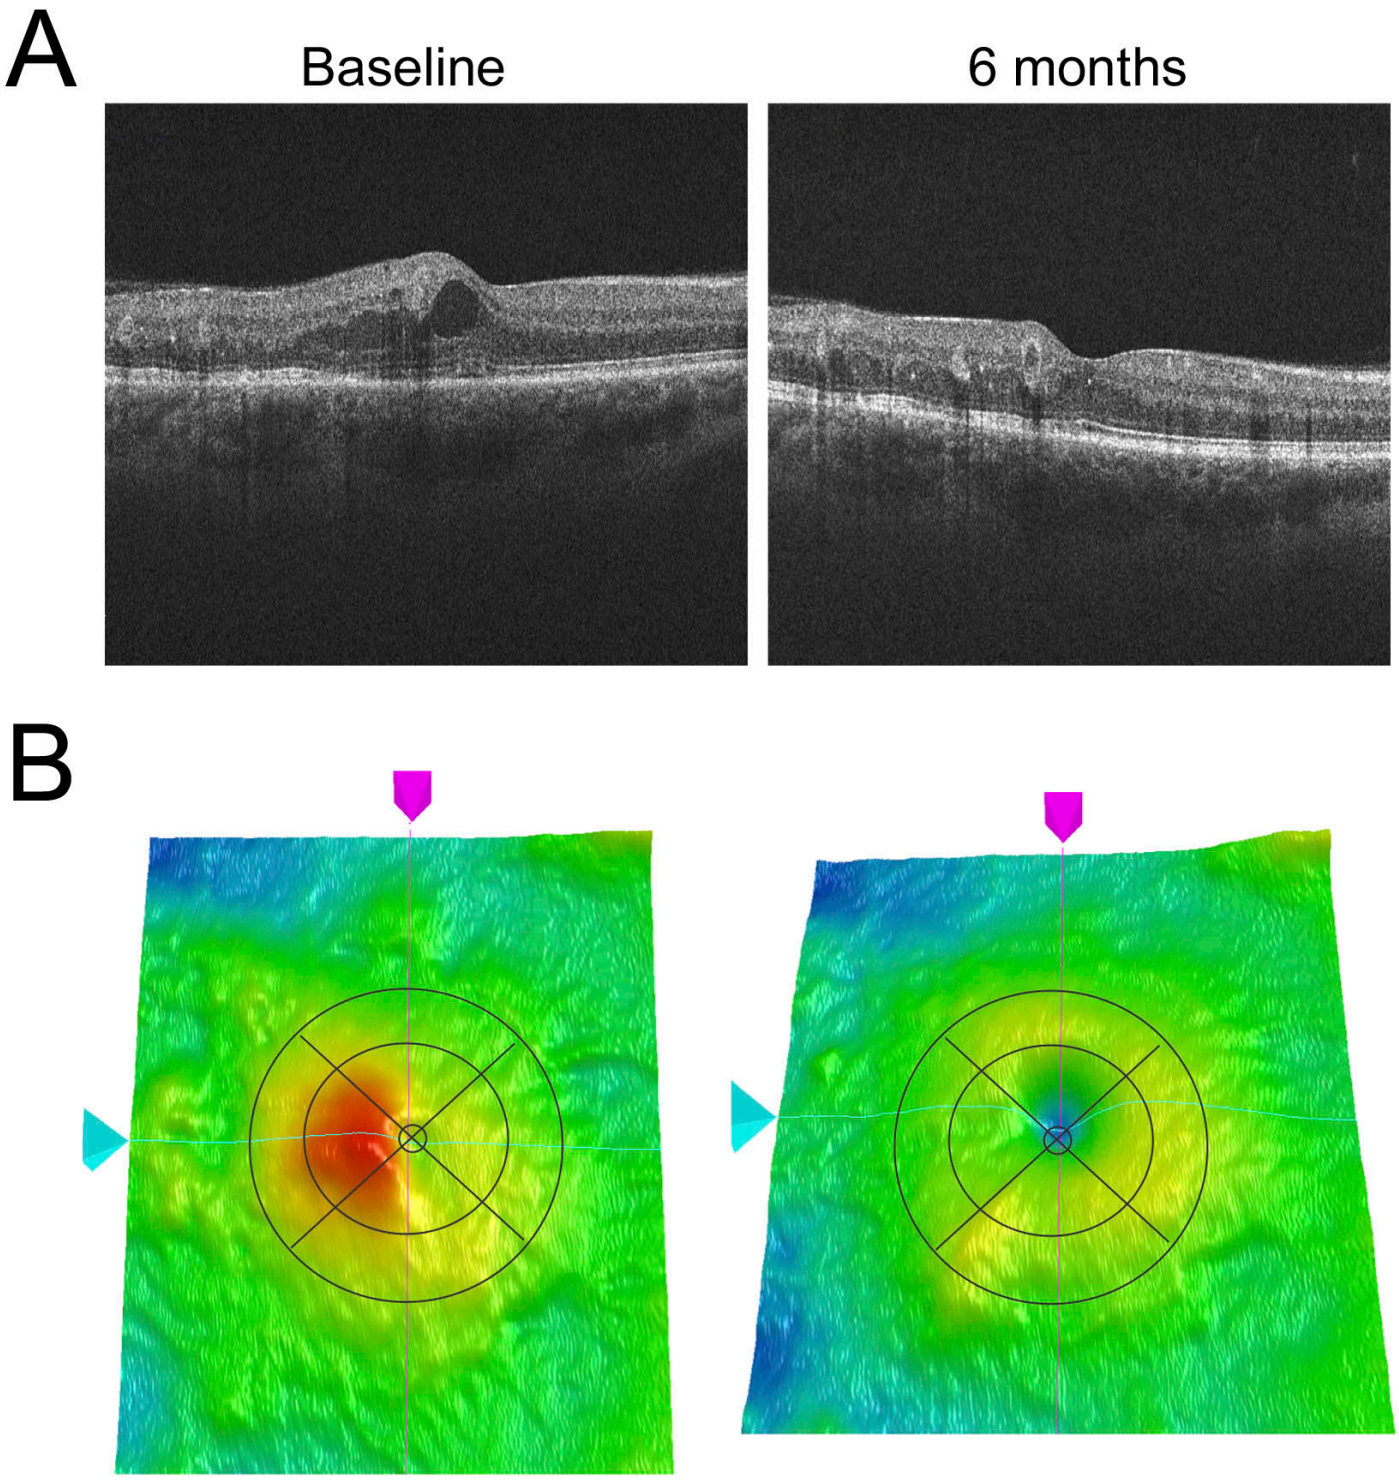

Figure 19: Illustrative OCT results on an eye before and after light treatment. (A) Cross- sectional views of the retina showing swelling and cyst at baseline, which has largely vanished at 6 months. (B) The False colour 3-dimensional OCT images from the same examinations. The overlay represents the ETDRS zones. The central small disc is zone 1 and contains the foveal pit. The area of maximal swelling (red) is in this case zone 2. The remaining zones of the inner ring, going clockwise are zones 3, 4 and 5, and the outer ring comprises zones 6, 7, 8, 9. The red-false colour in zone 2 indicates an abnormality. In the clinical trial the thickness of the maximally affected zone was compared to the relatively unaffected "mirror zone" 4 – or in other instances, if zone 3 was maximally affected, it was compared to zone 5. In this way it could be shown that the edema was reduced and had not merely moved to a different retinal locus (254).

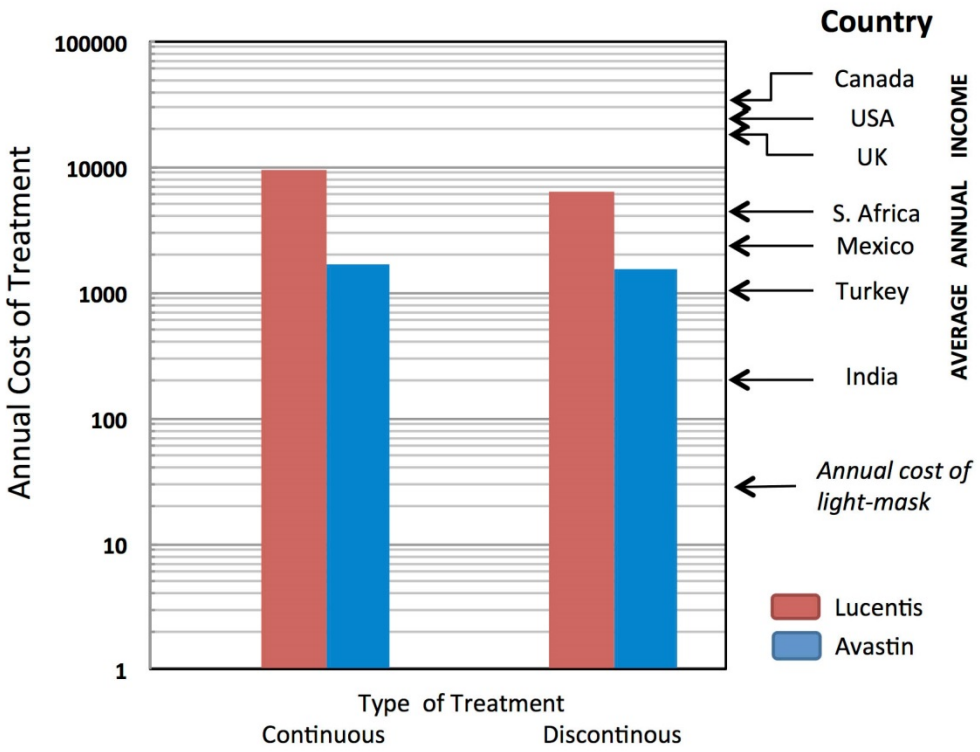

Figure 21: Health economics results of treatment of neovascular age related macular degeneration (AMD). Relative costs (£) of treatment by ranibizumab (Lucentis) and bevacizumab (Avastin) used at fixed intervals (continuous) or when required (discontinuous). Note the logarithmic ordinate. Lucentis is 40 times more costly to purchase than Avastin, but the difference in the total cost of treatment is much less. At the right, the median incomes in a number of different countries are indicated. Note only in the most affluent countries is the use of these drugs even possible for most of the population at risk. The cost estimate shown in this figure would be similar for DME. From (257).

About the Authors

Geoffrey Arden graduated in 1951 from University College London (UCL) and joined the MRC Vision Research Unit in the newly formed Institute of Ophthalmology. He obtained a Ph.D. in photochemistry under HJA Dartnall, and returned to UCL to complete a medical degree. After studying neurophysiological techniques with Ragnar Granit in Stockholm and KT Brown in San Francisco, he returned to the Institute of Ophthalmology. In the absence of any equipment except an ECG he devised the electro-oculogram (EOG) as a clinical test and

developed the first clinical electrophysiological department in the UK. He was appointed Professor, Honorary Consultant at Moorfields Eye Hospital and Director of the Electrodiagnostic department in 1968. He pioneered the use of cortical evoked potentials and the pattern ERG and devised clinical techniques for the measurement of achromatic and colour-contrast sensitivity. In an emeritus capacity he continues projects with investigators from Europe and the US and has turned his attention to the causes and treatment of diabetic retinopathy. He served a term as Chief Editor of the journal Vision Research.

Dr. David J. Ramsey received his M.D. and Ph.D. degrees from the University of Illinois at Chicago in 2008. He completed his residency in Ophthalmology at the Wilmer Eye Institute of the Johns Hopkins School of Medicine in 2012 followed by a combined medical/surgery fellowship in vitreoretinal diseases at the Massachusetts Eye and Ear Infirmary in 2014. Dr. Ramsey is currently a senior staff physician at the Lahey Clinic and sees patients in Burlington, MA. He also sees patients and performs surgery in Peabody, MA. His research focuses on the prevention of dark adaptation in patients with diabetes as a means to ameliorate diabetic changes in the retina. Future clinical trials will seek to determine whether this noninvasive, environmental intervention can limit the progression of diabetic retinopathy to PDR and/or reduce levels of sight-impairing macular edema.

The Science Behind Myopia

Brittany J. Carr, Ph.D.[1,*] and William K. Stell, M.D., Ph.D.[2,†]

Created: November 7, 2017.

Introduction

Myopia (near-sightedness) is the most common refractive vision disorder in children. It is characterized by blurring of objects viewed at a distance, and is commonly the result of abnormal elongation of the eyeball – which causes the refractive image formed by the cornea and the lens to fall in front of the photoreceptors of the retina (Figure 1).

The underlying biological cause of myopia is unknown, and there is no widely accepted means of prevention or cure. The optical error of myopia can be corrected only by using spectacle or contact lenses or corneal surgery. If left untreated, moderate myopia is one of the leading causes of visual impairment worldwide. The greater the degree of myopia, the greater the risk of complications such as macular degeneration, retinal detachment, cataracts, and glaucoma (1); the risk is especially great when the negative refractive error is more negative than -6.00 D (diopters), a condition called 'high myopia'. The prevalence of myopia varies greatly, depending on ethnicity, geographical location, and socioeconomic status, but is rising rapidly in most populations studied (2) (Figure 2). Myopia is a centuries-old problem, and although we have made great progress in scientific investigation of its underlying cause, we have been unsuccessful in preventing it from becoming named by the World Health Organization as an ever-increasing global health concern (3).

Clinical aspects & health care burden

There are two clinical designations for myopia: pathological degenerative myopia, and spontaneous-onset or school age myopia. Pathological myopia is characterized by rapid, extreme axial elongation of the globe, leading to a high refractive error (typically far more negative than -6.00D). This extreme stretching puts stress on the ocular structures (retina, choroid, and sclera), which can then result in degenerative changes in the eye (Figure 3), and irreversible vision loss. Fortunately, pathological myopia is relatively rare, affecting 0.9-3.1% of the population (4).

The most common form of myopia is school-age myopia; this is the form that will be discussed in this chapter, and it will be called simply "myopia" from this point on. It progresses slowly, and usually stabilizes by the age of 20. The retina looks normal. Recently, is has been projected that 2.5 billion people (1/3 of the world's population) will have some degree of myopia by 2030 (2).

Genes may play a role in development of myopia

Myopia prevalence varies greatly in different ethnic and geographical populations (1). Recent studies of American preschool children (aged 6–72 months) revealed a prevalence of 1.2% in non-Hispanic whites, 3.7% in Hispanics, 3.98% in Asians, and 6.6% in African Americans (5, 6). Among older children, the difference between Asian and Caucasian populations is obvious; a study of Australian adolescents reported prevalence of 42.7% in

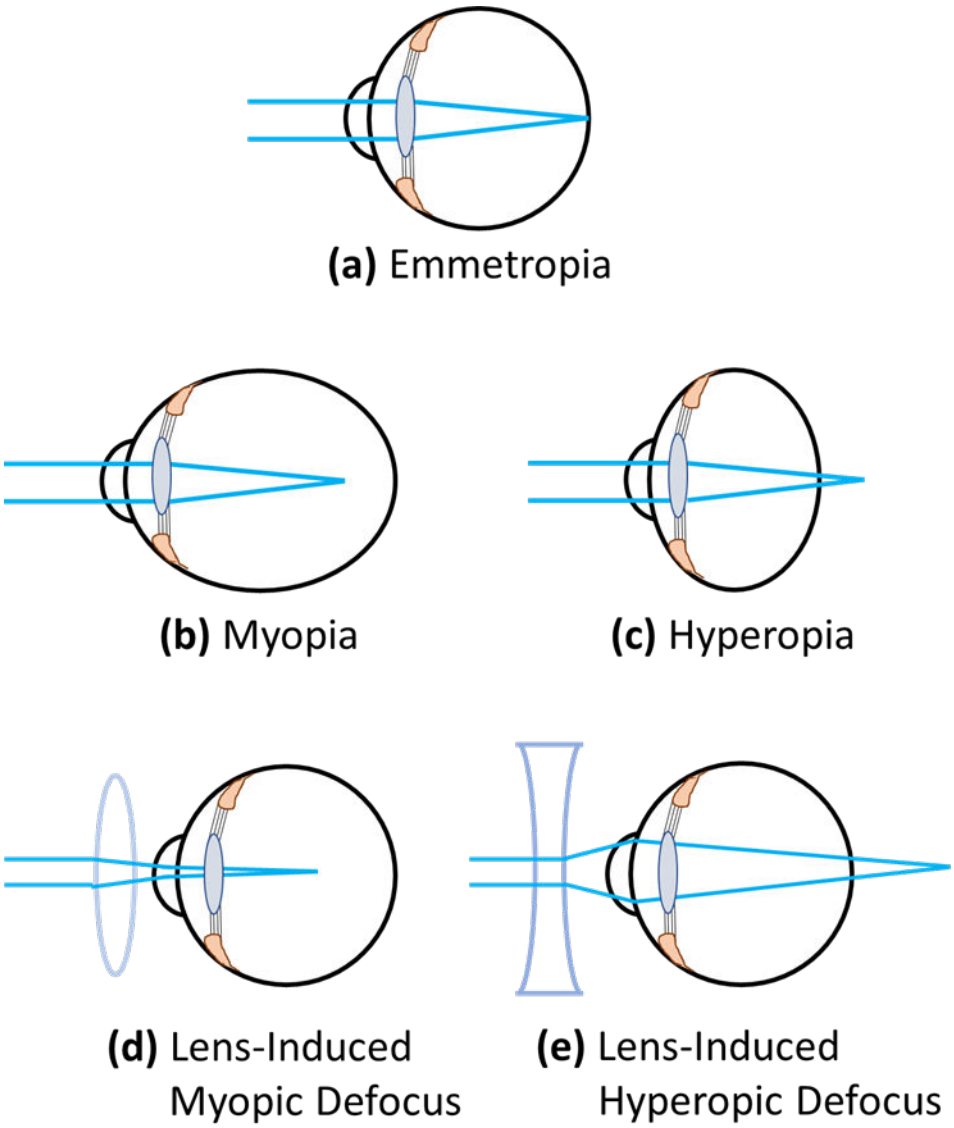

Figure 1. Exaggerated representation of simple refractive errors caused by abnormal eye growth. Emmetropia (normal vision) is the state of refraction in which light is focussed perfectly on retinal rod and cone photoreceptors (**a**). Myopia (near- or short-sightedness) occurs when the axial length of the eye is too long, and light is focussed in front of the photoreceptors (**b**). Hyperopia (far-sightedness) occurs when the axial length of the eye is too short, and light is focussed behind the photoreceptors (**c**). Refractive error can be modified using lenses: In an emmetropic eye, positive lenses impose myopic defocus (**d**), and negative lenses impose hyperopic defocus (**e**).

12 yr old and 59.1% in 17 yr old children of East Asian ethnicity, compared to 8.3% in 12 yr old and 17.7% in 17 yr old children of European Caucasian descent (7).

There have been attempts to identify genes that may be important in myopia development. "Genome-wide association studies" (GWAS), which examine genetic variations between individuals to determine whether certain variants are associated with a specific trait (in this case myopia), have identified correlations between variations in certain genes and an increased risk of myopia. The recently published Consortium for Refractive Error And Myopia (CREAM) study is the largest international genome-wide meta-analysis on myopia and refractive error ever conducted. It is based on data from 32 studies encompassing Europe, the United States, Australia and Asia (8). Twenty-four genomic variations were associated with up to a 10x increase in risk of myopia. These genetic variations are involved in many apparently unrelated ocular functions, instead of a single underlying system or structure. Thus, the CREAM study provided significant evidence that the risk of

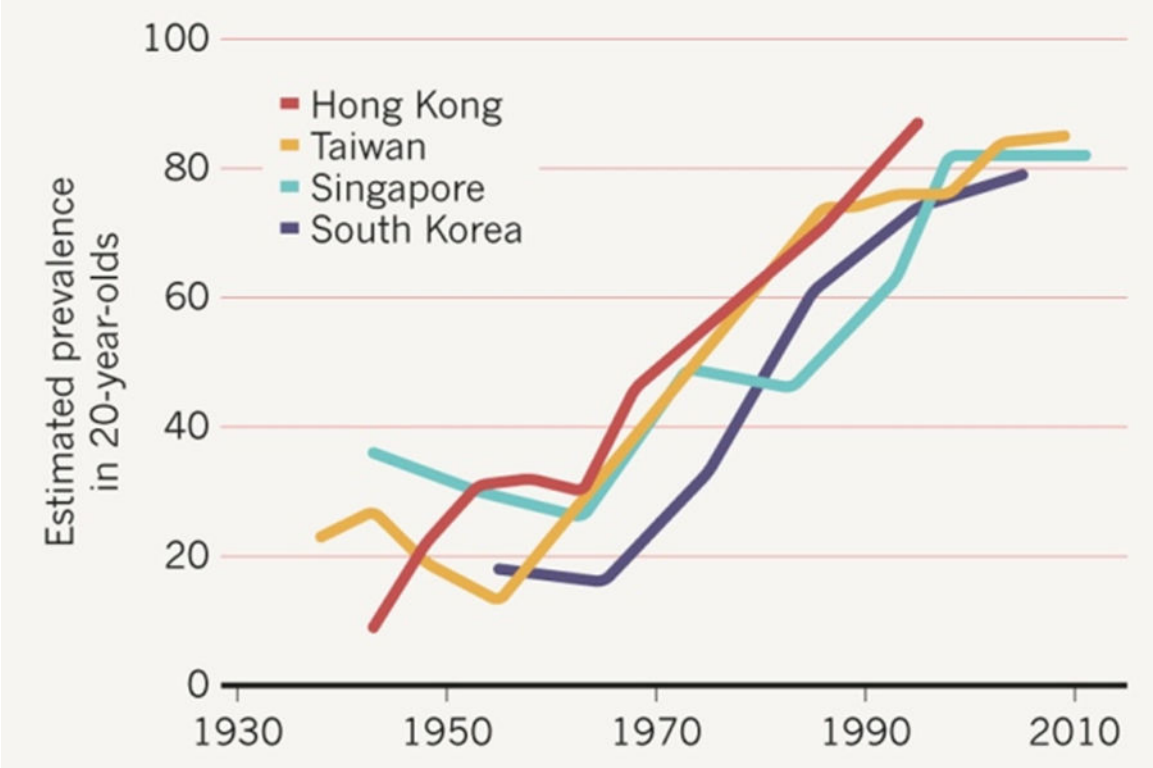

Figure 2. Myopia prevalence has been increasing steadily since the 1950's, especially in Southeast Asian countries. Reproduced with permission from Dolgin, E. (2015) (2). Figure source: Ian Morgan, Australian National University.

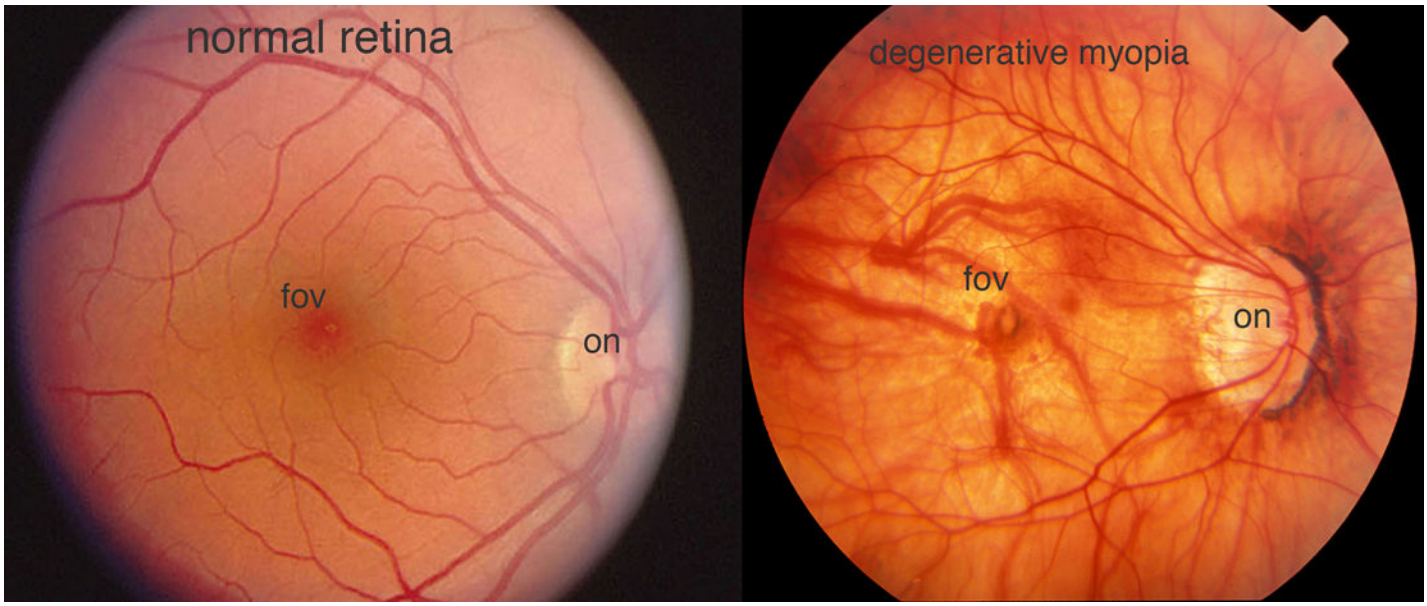

Figure 3. A fundus photograph of the retina of a person with degenerative myopia (right) is compared with that of a normal person's retina (left). The myope's retina is stretched and thinned, with thin blood vessels, a distorted optic nerve head (on), some folds in the thin retina, and pigmentation at the fovea (fov). Fundus photos provided by James Gilman and the Moran Eye Center ophthalmic photography department.

developing myopia may be affected by many unrelated genetic abnormalities, instead of a single underlying cause (Figure 4).

Twin studies and parental myopia studies have also been conducted to try to assess the role of genetics in development of myopia (9). Twin studies have reported that the correlation of prevalence of myopia was significantly higher in identical twins than fraternal twins (9-11). Age, and the methods used to gather and analyze the data, are important, however, as myopia correlations determined by such studies can range from r = 0.11 (low correlation) to r = 0.94 (high correlation) (10). There is strong evidence to suggest that increased risk of myopia is highly correlated with the number of myopic parents (12-16), and that this risk is independent of environmental factors (13, 15). One problem with twin and familial studies, however, is that few of them bothered to control for environmental factors that would be likely be shared among family members – for example, the likelihood that identical twins engage in the same activities in a much higher frequency than fraternal twins or non-twin siblings.

It is reasonable to assume that genes play a part in myopia risk, but they alone cannot account for the rapid changes in myopia prevalence that are being observed all over the world, nor for the dramatic differences in myopia prevalence within the same ethnic populations – in urban vs. rural environments, for example (2, 17). Thus, the underlying cause of spontaneous-onset myopia is most likely to be a combination of genes and environmental triggers. Most of the identified risk factors for myopia are correlated with environmental influences, such as an increased socioeconomic status, residing in an urban environment, higher education and IQ, increased time spent performing near work, and increased time spent indoors (1, 18). These risk factors are based on observations of human populations over many decades, but they do not provide a mechanistic explanation as to why they are associated with an increased risk of myopia.

To understand the roles of environmental risk factors for the cause of myopia (which are difficult to study in human subjects under stringently controlled conditions), scientists have turned to animal models. The results have demonstrated clearly that, while genetics may determine myopia susceptibility (e.g.: age of onset, rate of progression, ultimate refractive error), environmental factors are powerful modifiers of eye growth, and they may override genetic predispositions. For a comprehensive review on the biological basis and mechanisms of the eye's self-regulation of growth see, "Homeostasis of eye growth and the question of myopia", by Wallman & Winawer (19).

Animal models of myopia: What we see controls how the eye grows

The first reported case of myopia in experimental animals was observed serendipitously in non-human primates, during investigations into the cortical effects of monocular visual deprivation in young macaques. In these animals, sewing the eyelids shut for many months resulted in high levels of myopia (20); the longer the period of visual deprivation, the greater the resultant refractive error (21). The establishment of this "form-deprivation" model of myopia in primates led to parallel studies of experimentally-induced myopia in young tree shrews (22) and chickens (23). Instead of sewing the eyelids shut, scientists now use frosted plastic goggles to induce deprivation myopia, or lenses with a strong negative power to cause "lens-induced myopia" (24) (Figure 5). Today, the most commonly-used myopia model animals are chicks and guinea pigs, but tree shrews, non-human primates, and mice are also studied (25).

That we can experimentally-induce myopia in young, rapidly growing animals tells us that the visual environment plays an important role in regulation of eye growth. Applying goggles over the eye works even when the optic nerve has been cut, which tells us that the eye alone – or more specifically, a specialized sensorineural tissue in the eye called the retina – can discriminate whether the image is well focussed or not, and act locally to mediate optically-induced changes in eye growth (19, 26, 27). Affixing a frosted goggle or negative lens over the eye causes excessive axial elongation of the eye, and myopia, but affixing a positive lens over the eye causes inhibition of axial elongation, and far-sightedness (hyperopia) (Figure 6). The complementary effects of positive and negative defocus reveal that the eye – most probably the retina itself – can discriminate between

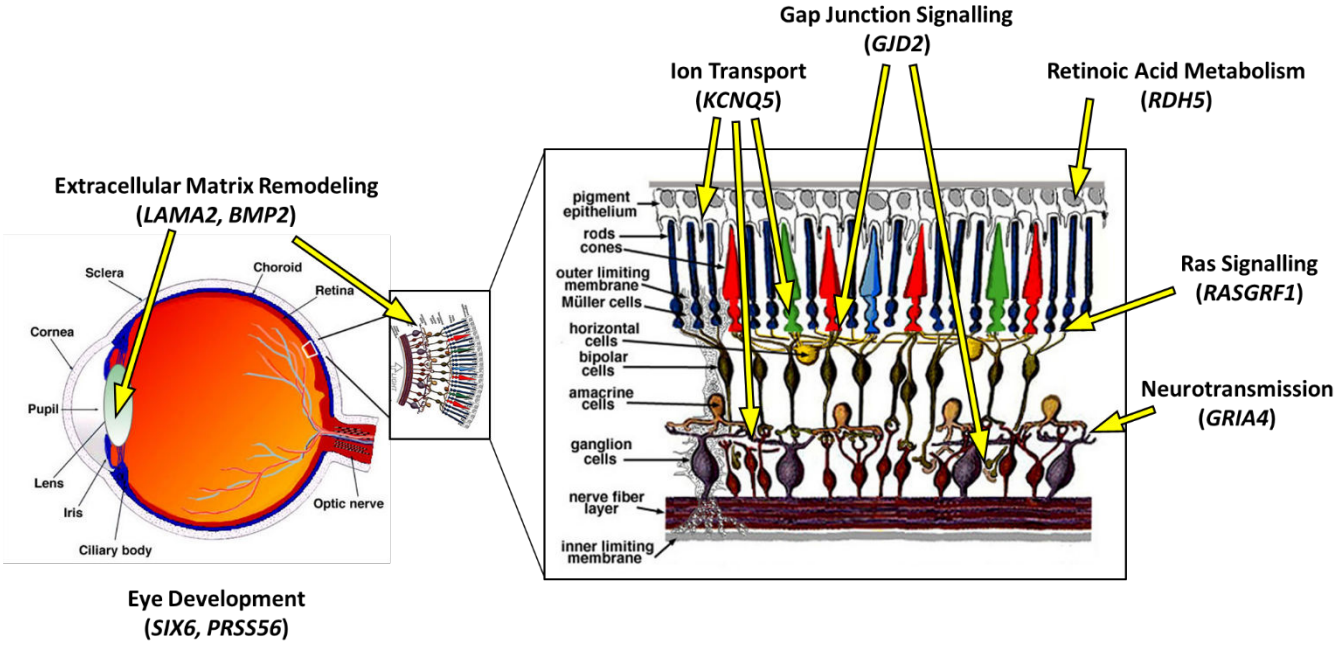

Figure 4. Localization and functions of a few genes identified by the CREAM study (8) in the eye and retinal tissues. Some of the genes identified are functionally involved in processes that facilitate communication between cells in the retina (*KCNQ5, GJD2, RASGFR1, GRIA4*) or control the ability of photoreceptors to respond to light (*RDH5*). Some others are involved in pre-natal eye growth and development (*LAMA2, BMP2, SIX6, PRSS56*).

positive and negative defocus, as well as between unfocussed blur (form-deprivation) and blur due to negative lens treatment, even though the static images produced by the two different treatments appear very similar (Figure 5, b vs. c). We do not know whether eye growth is controlled by two different signals, one "start" and one "stop", operating in push-pull fashion (like turning the steering of an automobile to left or right) – or by a single signal that increases elongation ("grow" or "on") or decreases it ("stop" or "off") (like increasing or decreasing pressure on the accelerator pedal of an automobile). We also do not know the identities of these hypothetical "start" or "stop" growth signals, but a number of signalling substances have been identified that are very strong candidates for "eye growth regulators" (discussed in greater detail below).

Myopia-inducing stimuli require prolonged exposures (days-weeks) for a significant effect. In the chick, however, it takes only ≥2 hrs per day of unobstructed viewing of a richly textured visual environment to completely block the development of form-deprivation myopia (28), and positive-lens wear for only 2 min, four times per day, is enough to block lens-induced myopia (29). In addition, the eye can "recover" from experimentally induced myopia and return to an emmetropic refractive state, if the animal (or human) is young enough. Once an organism has reached adulthood, however, there is no known way to decrease the size of the globe, without surgical intervention.

Inhibiting accommodation does not prevent myopia

Perhaps you are familiar with the old wives' tale, "Don't sit too close to the TV, or you'll ruin your eyes!". This is likely because the most common and longstanding hypothesis about the cause of myopia development was that excessive near work results in accommodative fatigue, which then causes myopia. Accommodative fatigue occurs when the ciliary muscle weakens due to overexertion – as arm or leg muscles would – in response to an entire day of heavy lifting. Weakening of the ciliary muscle would result in loss of the focussing power of the lens, leading to hyperopic defocus when objects are viewed up close (Figure 7). As discussed previously in the

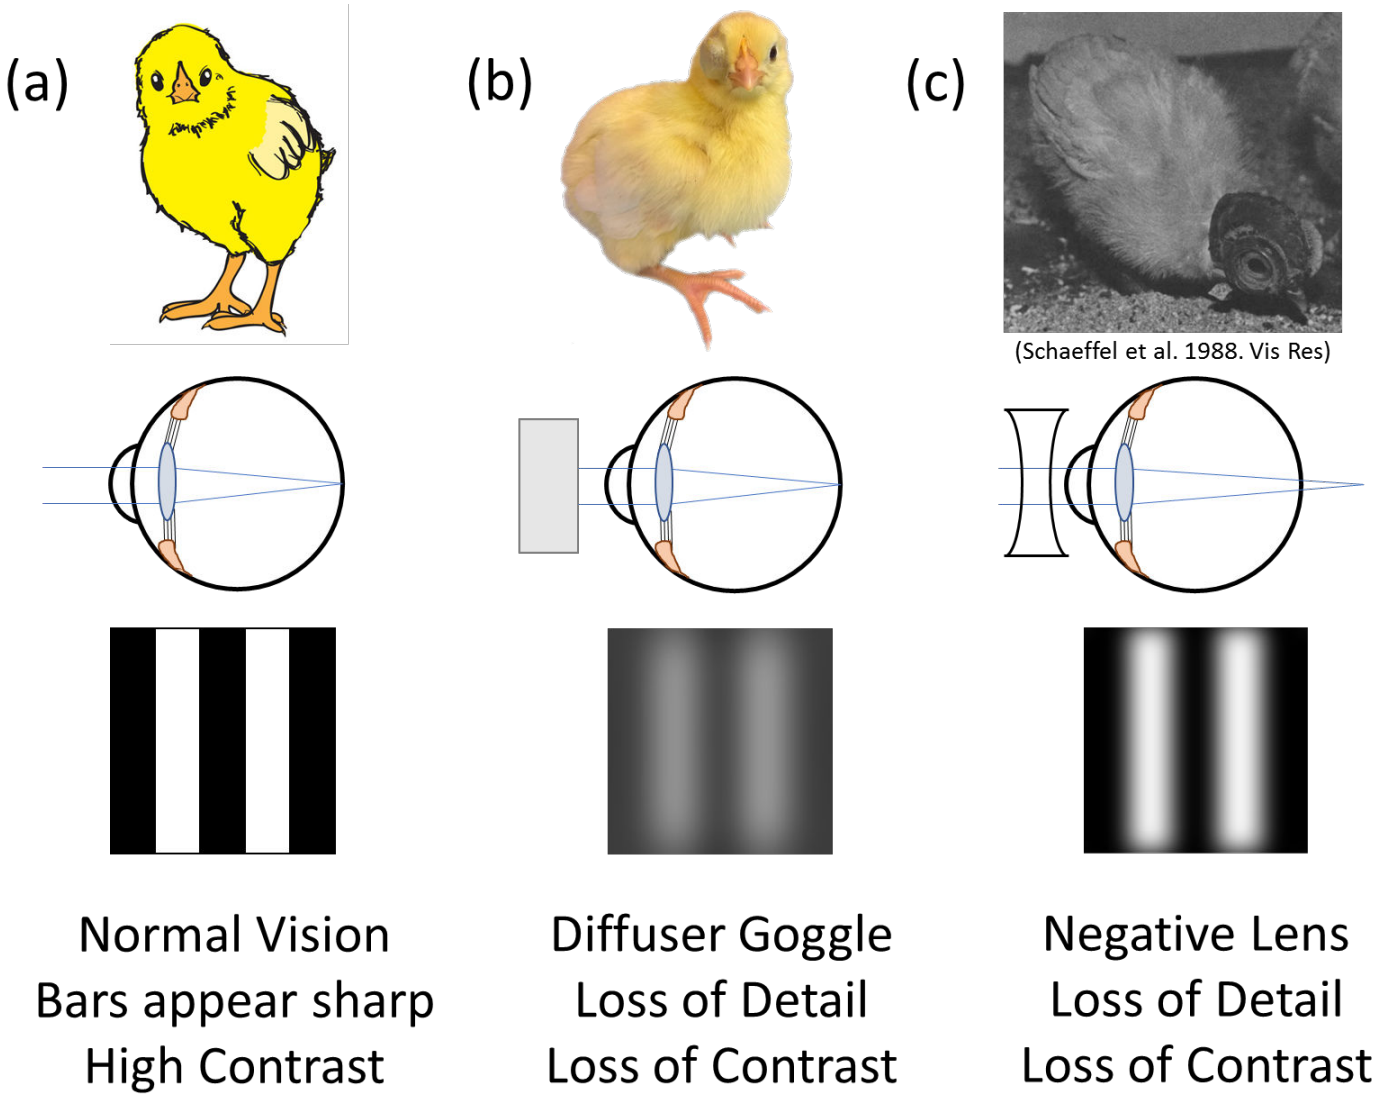

Figure 5. The effects of goggles on the initially focused image of a square-wave grating. When no goggle is applied, the grating image appears as sharply defined black and white lines (**a**). Myopia can be induced by manipulating retinal images optically, in animal models such as the chick, by application of a frosted diffuser goggle (**b**) or a negative-powered lens (**c**). Both treatments reduce spatial contrast of the image (difference between white and black), especially at higher spatial frequencies (the sharpness of the line borders).

section about animal models of myopia, hyperopic defocus (pushing the plane of focus behind the photoreceptors) can be a stimulus for eye growth.

To investigate whether reducing the need for accommodation in children would be preventative against myopia, scientists have utilized progressive-addition lenses (PALs). In principle, the use of PALs should allow accommodation (contraction of the ciliary muscle) to relax, while keeping a blur-free image on the retina (30) (Figure 8).

"The Correction Of Myopia Evaluation Trial" (COMET) was the largest and most significant human clinical trial ever conducted to test whether relaxation of accommodation through the use of PALs could help to inhibit the progression of myopia in children. It was a multicenter, randomized, double-masked, controlled clinical trial that took place over a period of three years (n = 469 children). At the end of the study, a statistically significant 3-year mean difference was found in children who wore PALs versus single vision lenses (SVL) (refractive error progression: PAL: −1.28 ± 0.06 D *vs.* SVL: −1.48 ± 0.06 D, p = 0.004; axial length elongation: PAL: 0.64 ± 0.02

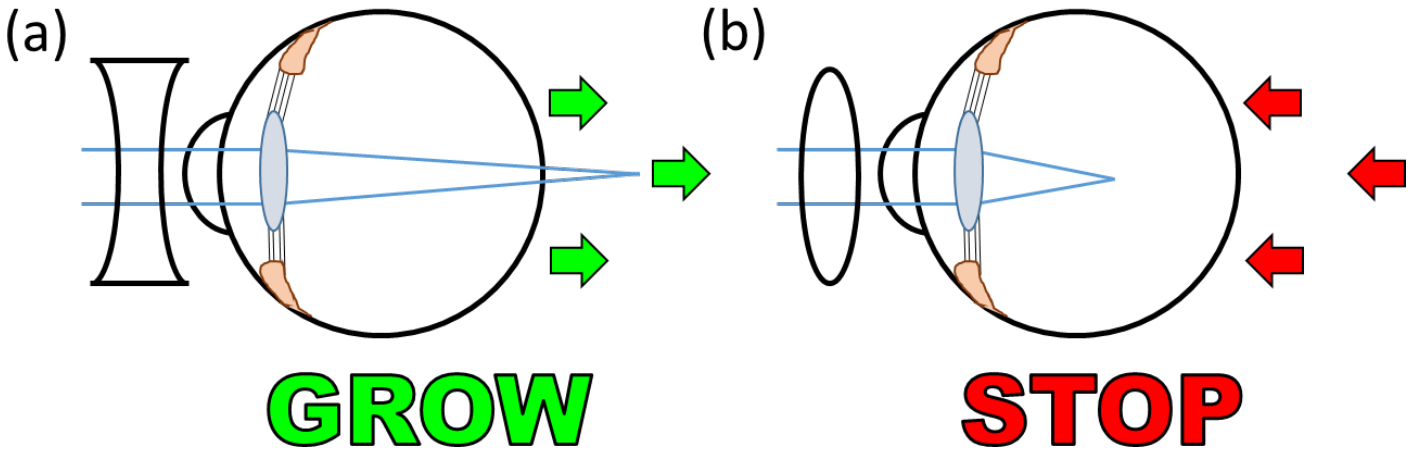

Figure 6. Affixing a negative (concave or diverging) lens over the eye pushes the focal plane of the visual image behind the retina, inducing an increase in axial elongation and a more myopic refraction (**a**). Conversely, affixing a positive (convex or converging) lens over the eye pushes the focal plane of the visual image in front of the retina, inducing a decrease in axial elongation and a more hyperopic refraction (**b**).

mm *vs.* SVL: 0.75 ± 0.02 mm, p = 0.0002). These data supported the hypothesis that changes in accommodation can affect myopia progression. Unfortunately, this effect was too small to be considered clinically significant, although one subset of children – those who had high accommodative lag – seemed to benefit significantly from PAL wear (Figure 9). Subsequent studies have confirmed these findings (31), reporting a statistically significant, but small, reduction in myopia progression in children wearing PALs versus SVLs; these effects were not dependent on accommodative lag, as high-lag children had similar results as others. The accumulation of experimental evidence from animal models and further human trials, however, does not support a significant role of accommodation in myopia development (32). It remains possible that most PAL-wearers in the COMET study did not use the lenses properly, but tolerated the blur that resulted from accommodative fatigue and continued near-work without adjusting viewing angle for better focus.

A second hypothesis is that accelerated eye growth can occur because of over-correction of myopic refractive error (similar to lens-induced myopia). To test this hypothesis, children were under-corrected by +0.5 to +0.75 D. This trial therapy was largely unsuccessful; myopia progressed more rapidly in under-corrected children than in fully-corrected controls (33, 34). Interestingly, a recently published study (35) reported that myopia and axial elongation progressed more rapidly in fully under-corrected than in fully corrected myopic children. This held true even when controls were applied for other risk variables, such as baseline refractive error and axial length, number of myopic parents, age at myopia onset, and time spent doing near work and outdoors (35). Thus, there is still no consensus on whether under-correction may be an effective anti-myopia therapy.

Intense outdoor light protects against myopia

In recent years, spending time outdoors has been reported to reduce the risk of developing myopia, and this effect does not seem to be dependent on the amount of physical activity (7, 36). We do not yet know the mechanisms through which outdoor light might protect against myopia, but some ideas are that it might (a) stimulate intensity- or wavelength-dependent anti-myopia systems in the retina, (b) cause sustained pupillary constriction via the melanopsin system – thus improving retinal image quality by reducing longitudinal aberrations, (c) increase the production of vitamin D in the skin, (d) increase the average viewing distance of objects outdoors compared to indoors, thereby reducing accommodative fatigue, or (e) increase the activation of spatiotemporal image-response mechanisms in the retina, which inhibit myopia development. For a recent review on the roles each of these factors may play in myopia, please refer to "The role of luminance and

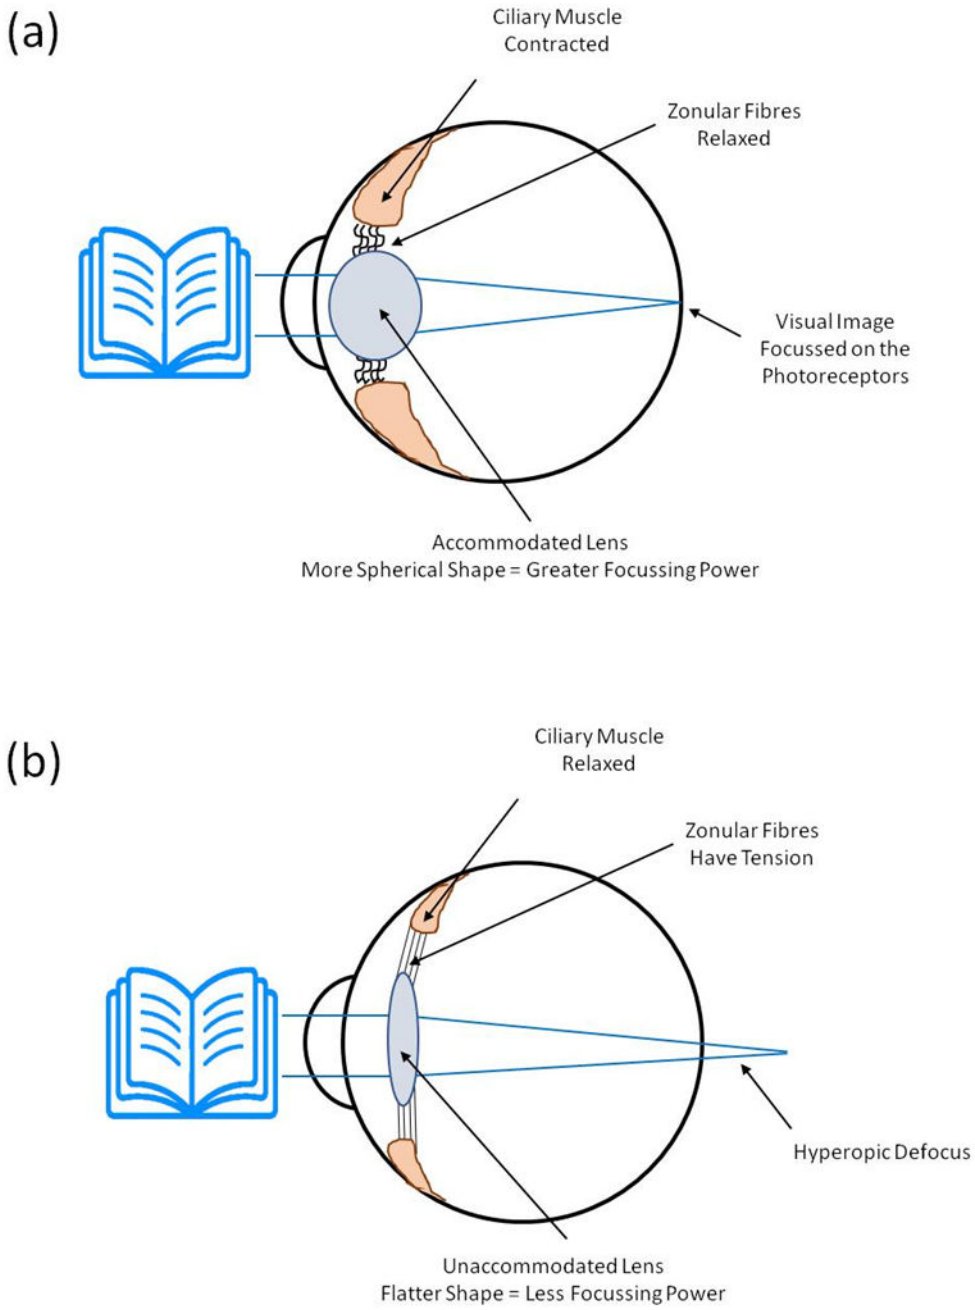

Figure 7. The effect of ciliary muscle contraction or relaxation on the focussing power of the lens. When the ciliary muscle is contracted, the lens becomes more spherical – and has increased focussing power – due to a lessening of tension on the zonular fibres (**a**). When the ciliary muscles relax, these fibres become taut – pulling the lens out into a flatter shape, which has less focussing power (**b**). Accommodative fatigue, the decrease in focussing power while continuing near-work, results in hyperopic defocus, which, in principle, might act as a stimulus for eye growth.

chromatic cues in emmetropization" by Frances Rucker (37). For more information about the melanopsin system, refer to the Webvision chapter "Melanopsin-expressing, Intrinsically Photosensitive Retinal Ganglion Cells (ipRGCs)" by Dustin M. Graham and Kwoon Y. Wong.

High-intensity illumination

When Rose et al. studied the effects of time spent outdoors on the development of myopia in Australian children, they found that children who spent more time outdoors had lower associated myopic refractive errors

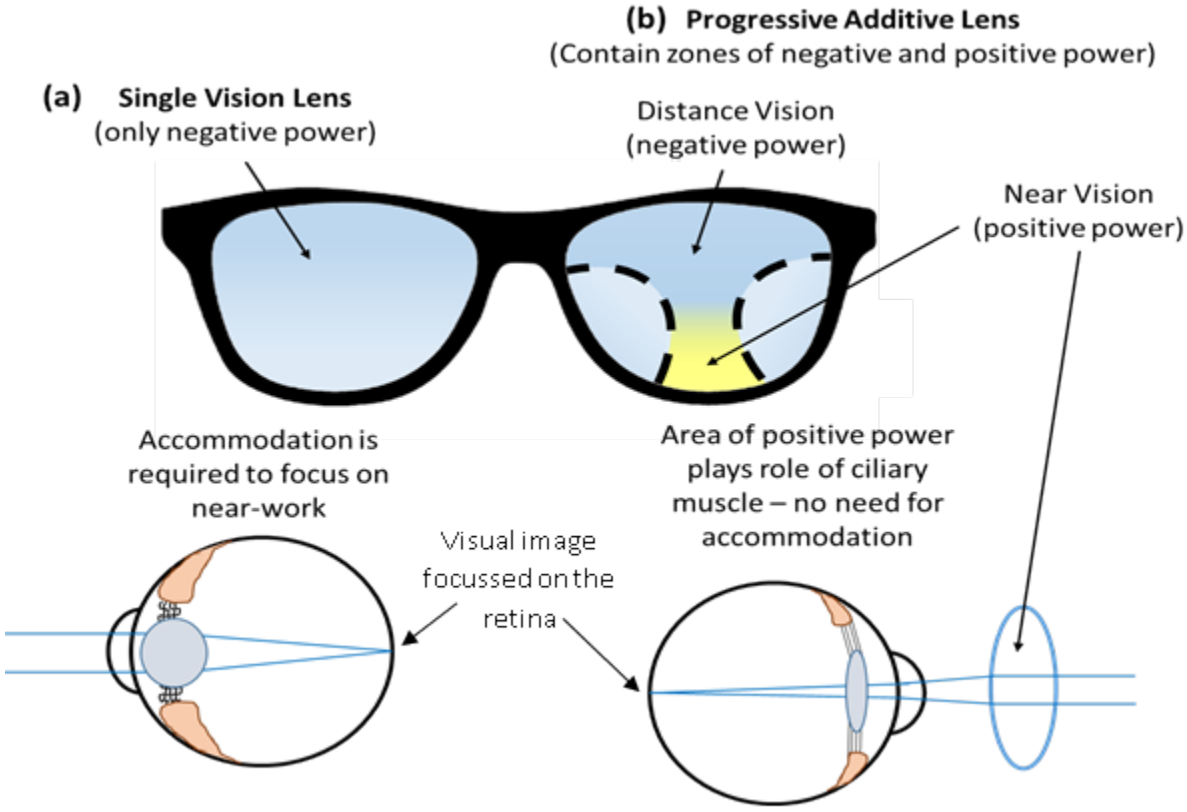

Figure 8. The two types of lenses used in the COMET study. Single vision lenses (a), which have only one power across their entire area, are the most common for correction of myopia. Progressive addition lenses (b) have multiple lens powers distributed across specific areas of the lens. This allows the wearer to focus at a distance (by looking through the top of the lens) or near (by looking through the bottom of the lens). In theory, the positive power in the bottom of the lens should have allowed children wearing PALs to perform near-work without the risk of accommodative fatigue.

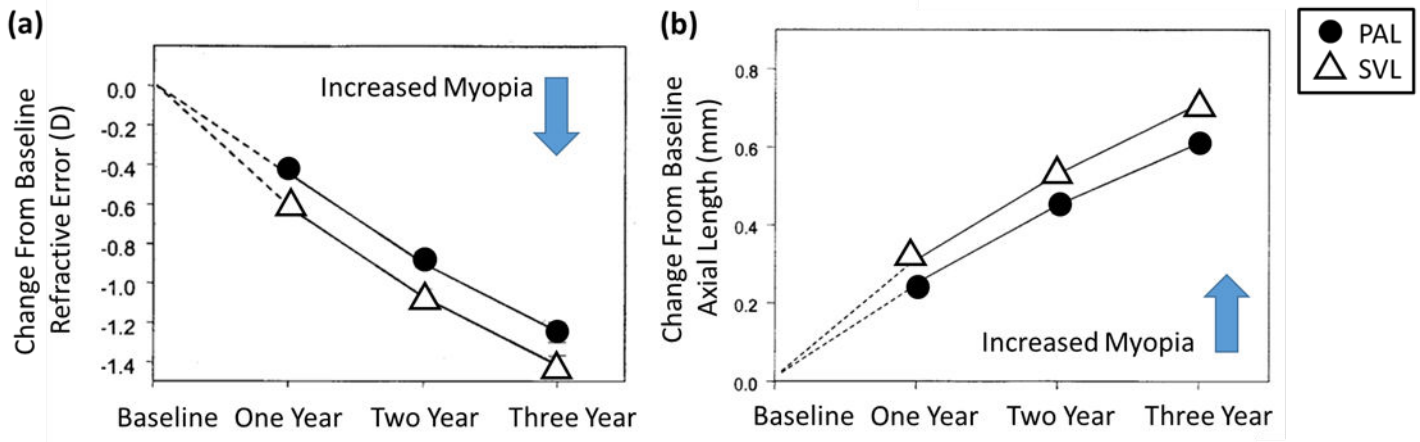

Figure 9. Example data from the COMET studies. A small, but clinically insignificant anti-myopia effect was gained by children wearing the progressive additive lenses (PAL; black circles) as evidenced by slightly less negative refractive error (**a**) and slightly decreased axial length (**b**) compared to children wearing single vision lenses (SVL; open triangles). Reproduced and modified from Gwiazda, J. *et al.* (2003) (30).

than children who spent most of their time indoors, even after adjusting for near-work, parental myopia, and ethnicity (38). Exercise versus leisure did not affect associated levels of myopia (Figure 10).

Therefore, it was proposed that the higher mean illuminance (light intensity) outdoors – which can be as much as 100,000 lux in Sydney AU, compared to typical indoor values of 350-500 lux – was responsible for the protective effect of outdoor activity against myopia progression. Human pilot studies to test this hypothesis have been successful in inhibiting myopia, in a small cohort of Chinese schoolchildren (39) and in a larger cohort of Australian schoolchildren (36). High-intensity light is also protective against experimentally-induced myopia in monkeys (40, 41) and chicks (42, 43). The mechanism through which intense light may prevent myopia is unknown, but we can use animal models to investigate the signalling molecules that may be involved. There are substantial links to the up-regulation of neuromodulators such as dopamine (44) and nitric oxide (45). These neurotransmitters are strongly correlated with myopia-inhibition on their own (46, 47), and they may also work together in the same myopia-inhibiting pathway (48).

Wavelength

During emmetropization, the eye needs some sort of visual cue to determine the direction of blur (29), and chromatic aberrations have been suggested as a possible cue (37). The most common chromatic aberration is longitudinal chromatic aberration (LCA), in which different wavelengths of light are focussed at different distances along the same axis (Figure 11).

In humans, the fovea is most densely populated with medium- and long-wavelength-sensitive cones. One idea is that the eye should be guided to grow to a size at which middle wavelengths in the visible spectrum (yellow-green, 550-570nm) will be the most sharply focussed, with the highest contrast, to attain the highest possible spatial acuity. If this were the case, the in-focus image of an eye that is too small will be blue-shifted, with high contrast at short-wavelengths (450-470 nm), whereas the in-focus image of an eye that is too large will be red-shifted with high contrast at long-wavelengths (610-630 nm) (Figure 12).

The results of research on the effects of LCA on emmetropization in the eye show that it is sufficient to detect the direction of retinal blur (49), but it does not seem to be necessary for emmetropization (49-51). Despite this, many studies have demonstrated clearly that the chromaticity (spectral composition) of light can be an important modulator of eye growth, although its effects do not seem to be the same in all animal models. In chickens raised *without* goggles or lenses, short-wavelength (blue) light retards eye growth, whereas long-wavelength (red) light promotes it; white light (which contains all spectral wavelengths) has no effect (52). In chicks wearing monocular diffusers, long-wavelength illumination (achieved using filters) is myopia-promoting, while short-wavelength illumination is myopia-inhibiting (Ghodsi & Stell (53), and Nguyen & Stell unpublished studies; Figure 13). Form-deprivation myopia in guinea pigs also responds to narrow-band long- or short-wavelength exposure in the same way as chicks (54-56). In contrast, long-wavelength light is growth-inhibiting and short-wavelength light is growth-promoting in rhesus monkey (57) and tree shrew (58). Thus, further investigations are needed to explore the effects of light spectrum on myopia development and to identify the underlying retinal mechanisms, in various animal models.

Retinal circuitry and ocular pathways of myopia

Emmetropization is an active-feedback process, guided by visual cues. It aims to match the axial length and resting focal power of the eye in such a way that images of objects viewed at any distance, can be focussed onto the retinal photoreceptors without accommodation (59).

Past studies indicate that the retina is the primary source of signals that regulate eye growth (19), while pathways involving transmission between retina and brain, via the optic nerve, may play roles in focal refinement of the visual image (60).

The retina is a highly specialized neural tissue that lies at the back of the eye (Figure 14), and although evidence suggests that the retina is the source of ocular growth-regulating signals (19), we do not know the specific cell

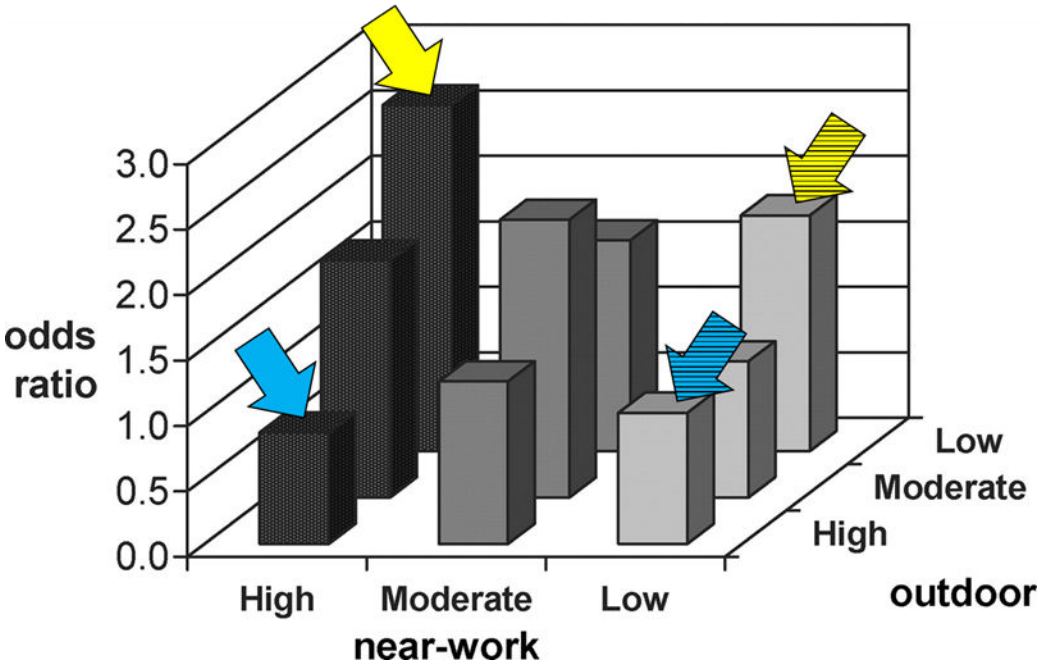

Figure 10. Multivariable-adjusted odds ratios (adjusted for gender, ethnicity, parental myopia, parental employment, and education) for myopia development by reported average daily hours spent on near-work versus outdoor activities in 12-year-olds. Activities were divided into columns of high, moderate, and low levels. The group with high levels of outdoor activity and low levels of near work (striped blue arrow) is the reference group. The blue arrow denotes the group with high levels of near work and high levels of outdoors activity. Yellow and yellow-striped arrows denote high near work and low outdoors activity, and low near work and low outdoors activity, respectively. Reproduced and modified from Rose, K. A. et al. (2008) (38).

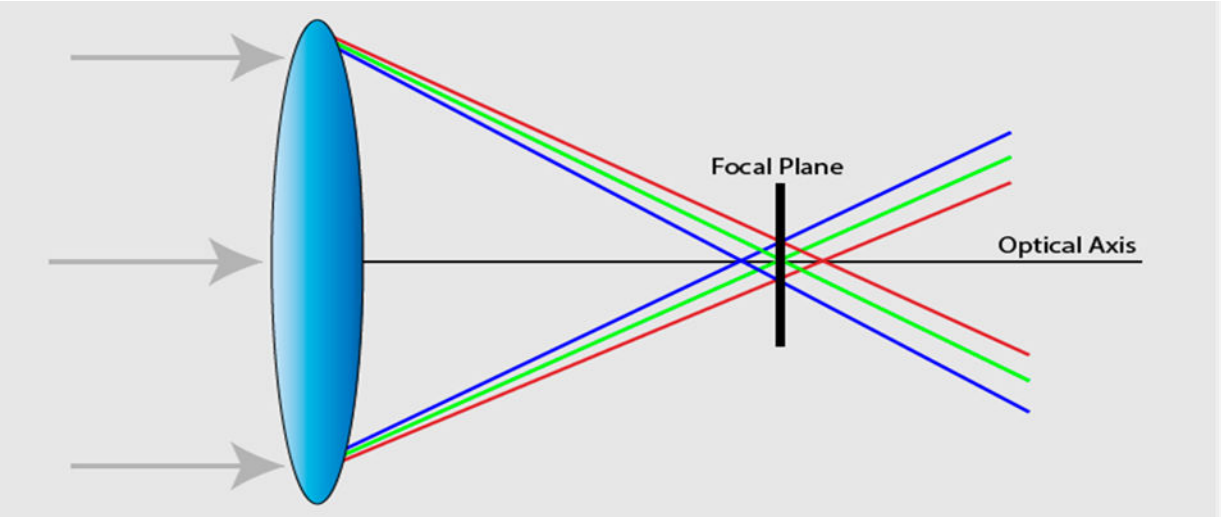

Figure 11. Longitudinal chromatic aberration is due to wavelength-dependent differences in refraction of light by the same lens. Light of shorter wavelengths, which appears violet to blue-green, is refracted more strongly than light of longer wavelength, such as that which appears yellow-green or red, and consequently is focused closer to the lens. From Photography Element .

types involved in emmetropization. There is no evidence for the direct involvement of horizontal cells, but destruction of photoreceptors (PRs) and/or amacrine cells (ACs) in the chick retina has been associated with increased axial growth of the eye (61, 62). Given the broad-spectrum action of toxins on retinal neurons, the relative roles of PRs and ACs in myopia-control in these types of studies are not well-defined, and molecular tools which would disrupt function of retinal cell types more specifically than toxins are not as widely-

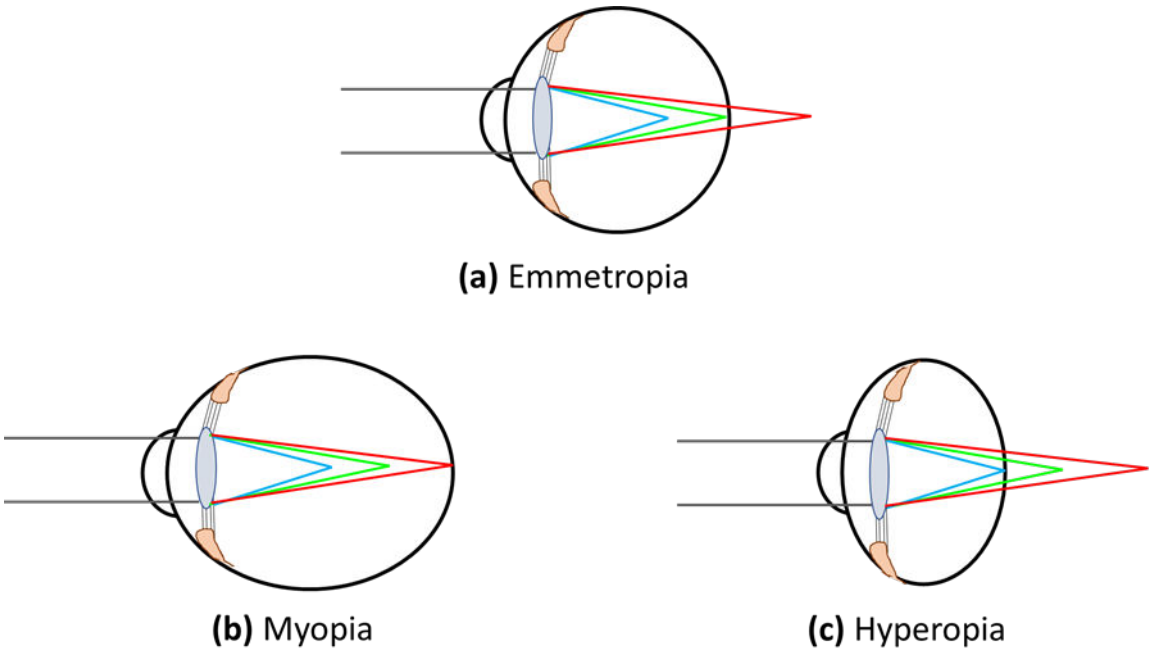

Figure 12. One hypothesis about the effect of LCA on defocus and contrast. In an emmetropic eye (a), the green region of the spectrum (middle-wavelengths) would be the most in-focus and have the highest contrast. If the eye is too short (b), the blue region of the spectrum (short-wavelengths) will be the most in-focus and have the highest contrast. If the eye is too long (c), the red region spectrum (long-wavelengths) will be most in-focus and have the highest contrast.

researched or available in chicks, the most common myopia model organism. Animals in which molecular tools are currently available – such as mice – are less suitable for studies of eye growth because their eyes are extremely small. This makes it very difficult to measure accurately any changes in axial growth or refractive error. This drawback of the chick model may change with a new genome-editing technology called CRISPR (63, 64), which is an exciting development that could be applied to the myopia-research field. Delivery of gene-silencing agents constructed from older technologies to cells in the retina of hatched chicks presents challenges that we have still not overcome (65).

That is not to say that myopia experiments in mice have not been performed. Genetic "knockout" mice models – in which their genome has been edited to "remove" certain retinal cell types or visual processing mechanisms by causing mutations – were used to determine the contributions of rods, cones, and retinal ON-pathways (some bipolar cells) to emmetropization (66). Eyes of mice with mutations causing severe degeneration of rods and cones (*rd1*$^{-/-}$ & *rd10*$^{-/-}$) were more susceptible to form-deprivation myopia than those of their wild-type (unmanipulated) counterparts (67) (Figure 15), while the eyes of rod-specific knockout *Gnat1*$^{-/-}$ mice, which exhibit little retinal damage, were unresponsive to form-deprivation (68). Eyes of mice with a mutation in nyctalopin (*Nyx*$^{nob/nob}$) – a protein important in ON-bipolar cell signalling – exhibited an increased susceptibility to form-deprivation myopia (69).

This led the authors to conclude that perhaps rod-mediated signalling in the retina is more important for emmetropization than cone-mediated signalling. This revolutionary concept is supported further by the fact that rod photoreceptors signal primarily through ON-bipolar cells, which likely mediate the effects of the injected glutamate analog, L-APB, on eye growth in chicks (70). Furthermore, rods vastly outnumber cones in most mammalian retinas, including those of mice and humans; and vision with high spatial resolution, which is not mediated by rods, is not necessarily required for the retina to successfully detect blur (19, 71). It is possible that the transgenic ablation of rod-ON-BCs could have damaged the inner-retinal circuitry that produces myopia-

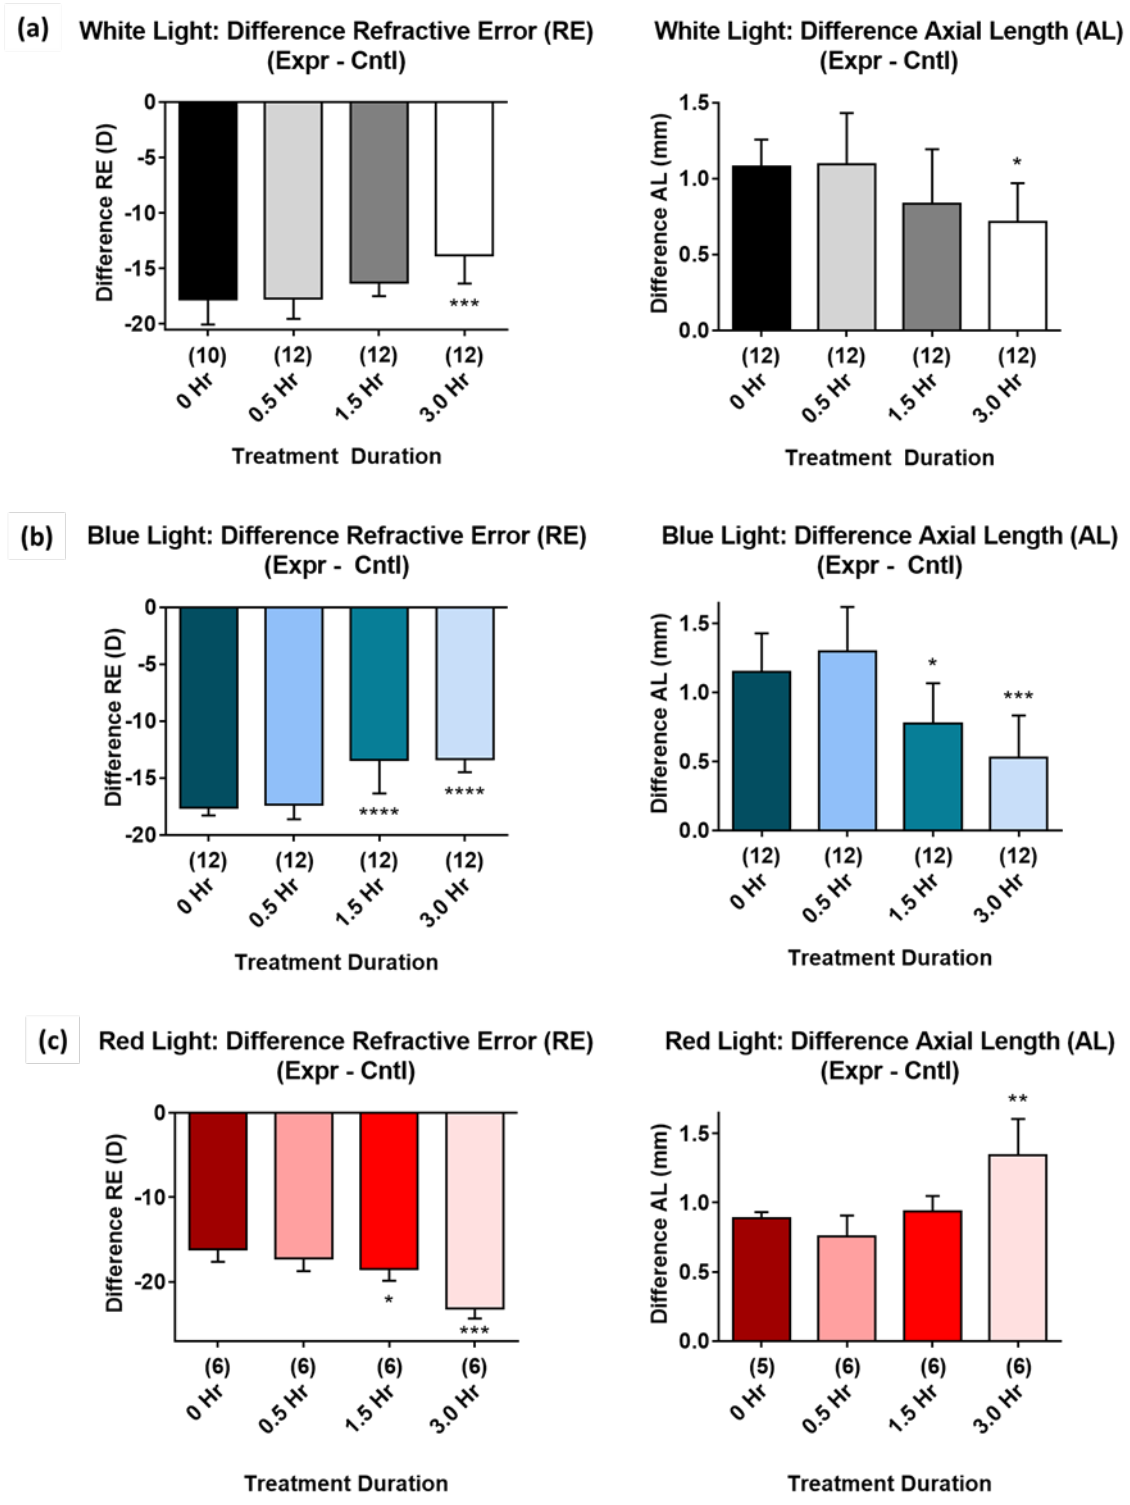

Figure 13. The effects of 10,000 lux white light (**a**), blue-filtered 10,000 lux light (**b**), and red-filtered 10,000 lux light (**c**) on form-deprivation myopia in chicks. STOP signals, and the ability of mice with intact rods, but no cones, to develop FDM has not yet been investigated. Thus, we would hope to see further evidence in support of this hypothesis.

Ganglion cells, and therefore cortical visual pathways, do not seem to contribute significantly to homeostatic eye growth, even though ganglion cell axons make up the optic nerve. Disconnection of the optic nerve – either by

surgery or toxins – has little effect on emmetropization and/or compensation to induced defocus (72-75), and eyes will still respond to deprivation myopia (26). Retinal efferent (centrifugal) fibres also run through the optic nerve, in birds and other animals. Unilateral lesioning of this system, while leaving retinal ganglion cell axons intact, results in hyperopia in the eye contralateral to the disrupted fibre tract. By 21 days after surgery, however, the eyes return to an emmetropic state (76) – suggesting, perhaps, that the initial hyperopic shift was due to short-term release of neuroactive substance(s) such as NO from the retinal axon terminals of the damaged cells, or retrograde signalling within the retina by axotomized RGCs. There is a precedent for a process such as this in the induction of rod-precursor proliferation in goldfish, which can be elicited by sectioning of the optic nerve and ablation of olfactory bulb/tract – the source of efferent fibres in fish (77). Many studies do not report intra-ocular effects of treatment, even though direct retino-retinal connections have been shown to exist in rats and mice (78, 79).

Amacrine cells are the visual processing powerhouses of the retina, and the most likely source of retina-derived eye growth-regulating molecules (19). There are as many as 30 different confirmed subtypes of amacrine cells, and it is likely that more remain to be discovered (80, 81). The majority of amacrine cells provide inhibitory feedback to bipolar cells via GABA- and glycine-mediated signalling; but they can also contact and provide feedback to other amacrine cells and ganglion cells (81, 82), as well as release neuromodulatory substances that modify properties such as excitability, gain, synaptic transmission, and cell-cell coupling of many retinal neurons and circuits, through non-synaptic mechanisms. They are responsible for higher-level processes in the retina such as detecting environmental changes in movement (83), contrast, and blur (84). For more information on amacrine cell function, see the Webvision chapter "Roles of Amacrine Cells" by Helga Kolb.

Many studies have shown that various signalling molecules found in amacrine cells can affect myopia onset and inhibition (47, 50, 85-88), such as dopamine (47), nitric oxide (46), and neuropeptides (VIP, glucagon, somatostatin, and neurotensin) (80). Destruction of subpopulations of amacrine cells by toxins has significant effects on normal eye growth and induction of form-deprivation myopia (61, 62, 89-91). The functions of most amacrine cells identified remain to be discovered, but the contribution of specific amacrine cell-derived signalling molecules to emmetropization and myopia inhibition will be discussed in more detail below. Most likely, signalling molecules originating from the retina do not control eye growth directly; instead, they are assumed to act via a signalling cascade that relays eye growth-regulating signals through the RPE and choroid, which may then release different signalling molecules that directly affect scleral growth (19) (Figure 16).

Muscarinic acetylcholine receptors, dopamine, and nitric oxide are strongly implicated in regulation of eye growth

Muscarinic acetylcholine receptors (mAChRs)

Muscarinic receptors in the eye mediate contraction of the pupillary constrictor muscle, as well as the ciliary muscle, which controls accommodation. As discussed previously, it was long thought that myopia inhibition could be achieved by blockade of accommodative fatigue. However, the failure of clinical trials such as COMET (discussed above), plus experimental evidence from animal models, does not support the hypothesis that mAChR antagonists (blockers) inhibit myopia via paralysis of the ciliary muscle alone (32). For example chicks can develop experimentally-induced myopia and/or respond to treatment with drugs such as atropine or pirenzepine – which block muscarinic receptors (92, 93) – even though their ciliary muscles are controlled by nicotinic receptors, which atropine and pirenzepine do not target. Pirenzepine inhibits the progression of myopia in humans (32) and a wide range of animal species (25) including monkey (94, 95), tree shrew (96, 97), and chick (92, 98-100), even though it has little effect on iris and ciliary musculature (95, 100-103). Finally, lesioning of the ciliary nerve does not impair development of either form-deprivation or lens-induced myopia; chicks with damaged ciliary nerves develop similar amounts of myopia as intact controls (104).

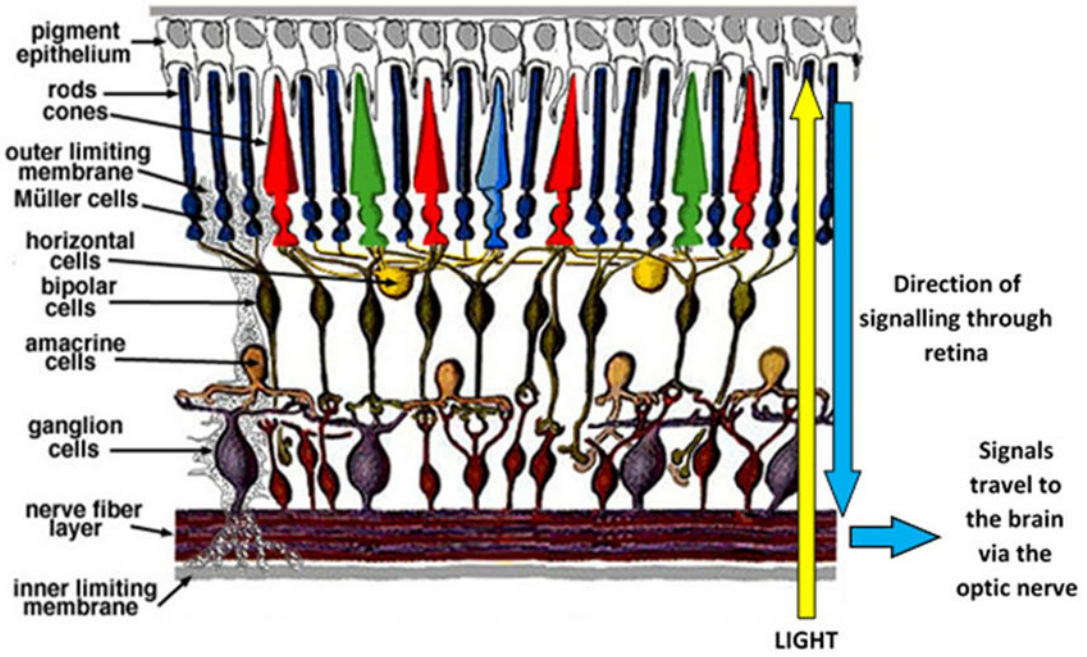

Figure 14. Light (yellow arrow) must first travel through the retina before interacting with the rod and cone photoreceptors (PRs). PRs signal their responses via synapses to bipolar cells (BCs) and hence to ganglion cells (RGCs) – thin blue arrow. Axons from the RGCs make up the nerve fibre layer, and relay retinal signals to the brain –horizontal blue arrow. Horizontal cells (HCs) and amacrine cells (ACs) help to fine-tune signals – between the PRs and BCs, and between the BCs and RGCs, respectively.

These data have largely ruled out accommodative activity or the ciliary muscle as an important eye-growth-regulator; thus, we have turned to the retina, choroid, or sclera as possible target sites for myopia-inhibition by mAChR antagonists. Muscarinic receptors are present in the retina, RPE, choroid, and sclera (105). Fischer et al. localized chick mAChR orthologues (cM_2, cM_3, cM_4) in chick eye tissues and showed that immunoreactive sites are present in the inner retina (cholinergic amacrine cells and ganglion cells), retinal pigment epithelium (RPE), and choroid, as well as the ciliary body (106). Expression patterns in the tree shrew (107), and rabbit (108) are similar to those reported for the chick (Figure 17). However, even though there is evidence for mAChRs in the ocular tissues, it remains uncertain exactly which ocular tissues, cells, or receptors mediate the anti-myopia effects of mAChR antagonists. The theorized mechanism of action of myopia-inhibition by these drugs is heavily dependent on the *assumption* that they block signalling through mAChRs, but this has never been proven conclusively.

In fact, substantial evidence argues for a non-retinal or non-muscarinic mode of action (109). For example, only some muscarinic antagonists inhibit myopia in humans (110-114) and animals (96, 98, 115), while the vast majority have no effect (98); high concentrations of these drugs are required for a significant effect. Protein and mRNA expression studies utilizing radioligand binding and real-time PCR techniques have found no change in receptor density or receptor gene expression for any mAChR subtypes in the retina or choroid of chick (116) or tree shrew (107), even when there is significant myopia development. This is strange, as it would be expected that significant changes in eye growth should cause changes in the expression of target receptors. Interestingly, the full population of amacrine cells that make the neurotransmitter required for action by mAChRs (acetylcholine) do not seem to be required for emmetropization, development of experimentally-induced myopia, or atropine-mediated suppression of form-deprivation myopia (117). This is again very strange, because 'orthosteric' mAChR antagonists such as atropine should have no action by themselves; they simply block access

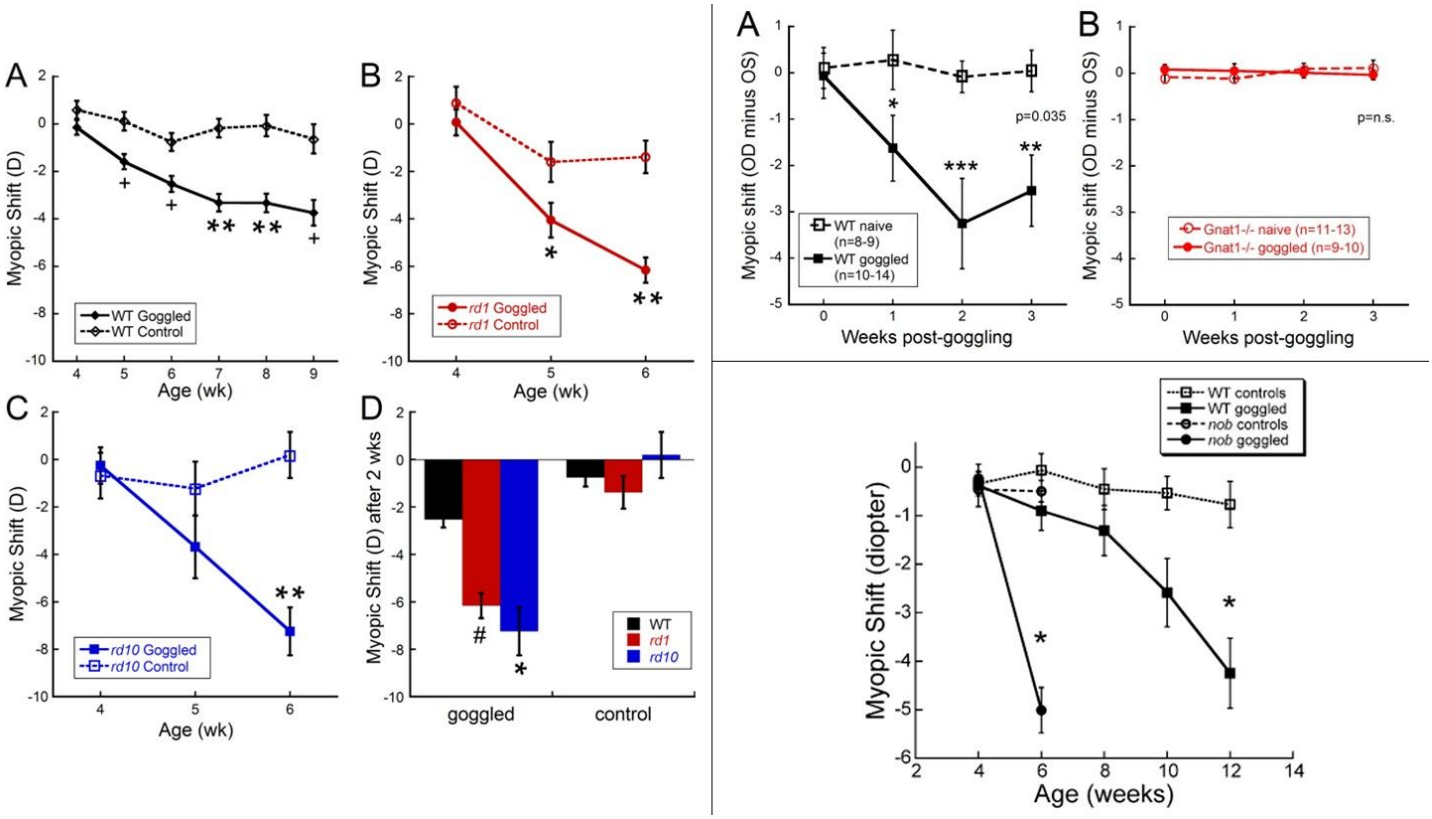

Figure 15. Results from studies utilizing mutant mice. Mice with mutations that cause degeneration of rods and cones($rd1^{-/-}$ & $rd10^{-/-}$) are more susceptible to form-deprivation myopia (FDM) than mice with no mutations (**panel A**). This is also the case for mice with mutations in signalling pathways that involved ON-bipolar cells ($nob^{-/-}$) (**panel B**). Mice with mutations that affect rods, but not cones ($Gnat1^{-/-}$), are not susceptible to FDM (**panel B**). Figures reproduced from: Park et al. (2013) (67); Park et al. (2014) (68) and Pardue et al. (2008) (69).

of the signalling neurotransmitter to the target receptor. Thus, if myopia inhibition by atropine is mediated by mAChRs, atropine should not inhibit myopia if the source of acetylcholine has been destroyed.

These data support a few possible theories: The first is that the cells responsible for myopia inhibition by mAChR antagonists are not in the retina, but instead in the RPE, choroid, or sclera. When muscarinic antagonists are administered by injection into whole, intact eyes, this is a possibility. For a drug to have a significant effect on a system, it must be present in a certain concentration at the receptor for binding and activation to occur. The inverse of this effective concentration is called 'potency'. Atropine is a very potent drug; thus, it requires an extremely low concentration to block mAChR signalling (1-10 nM). If it were working at a target far away from the intravitreal injection site (i.e., the choroid or sclera), the requirement for a large concentration of drug could be justified because it is possible that only a small amount of atropine might reach its target, through loss by diffusion through the vitreous, and/or blockade by the RPE and blood-retinal barrier. If the target tissues (retina, choroid, sclera) are isolated, however, the requirement for large concentrations of drug should be eliminated, because these barriers have been removed. One study examining the effects of mAChR agonists (stimulators) and antagonists on eye cups consisting of the RPE/choroid/sclera (*in vitro*; retina removed) demonstrated that stimulation of mAChRs by carbachol, oxotremorine, arecadinine, and pilocarpine resulted in choroidal thinning, and that pirenzepine caused choroidal thickening; atropine was not tested, and oxyphenonium had no effect (118). Another study on the effects of atropine on isolated scleral cells found that it can slow proliferation, which would be expected if atropine inhibited myopia by directly affecting scleral growth. Unfortunately, however, because the concentrations of drugs used in these isolated tissues were very high (0.6-5 mM), neither study conclusively indicates a non-retinal origin for mAChR-control of eye growth control.

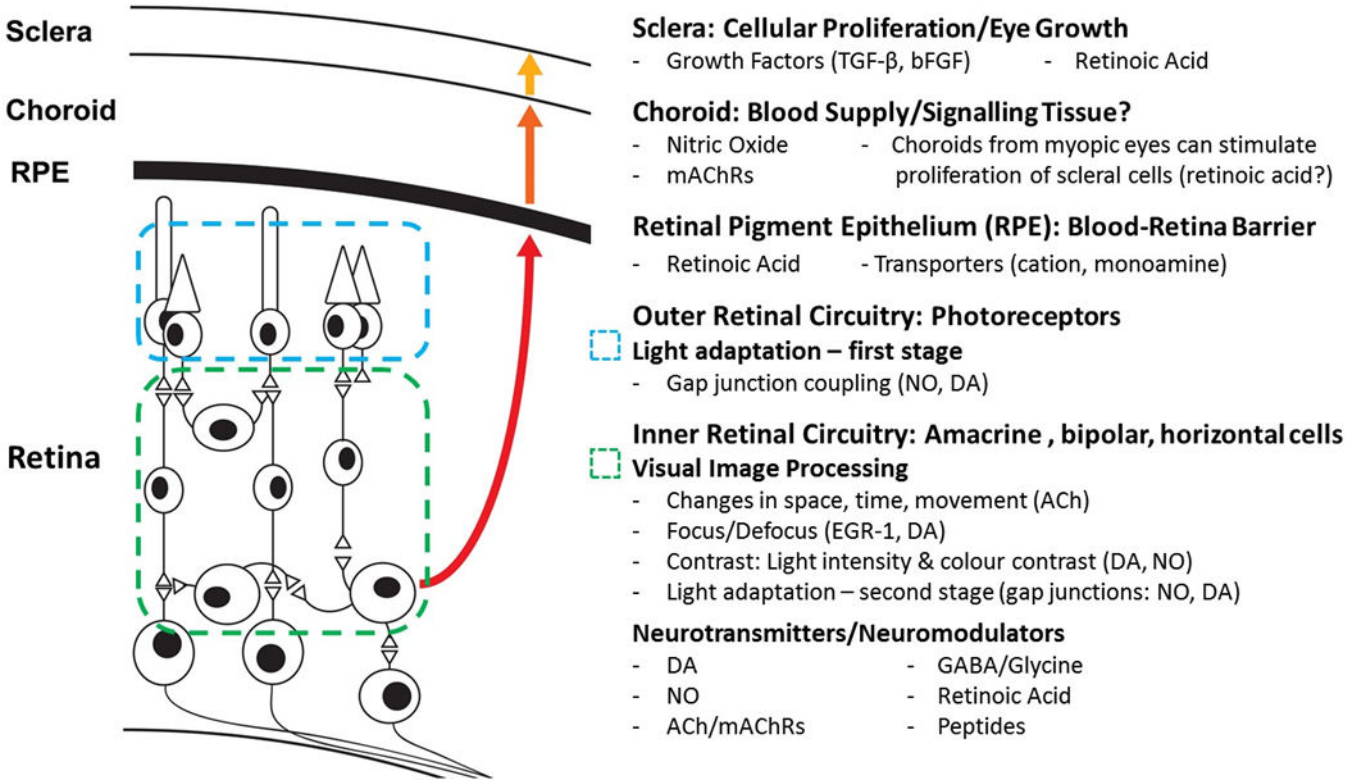

Figure 16. It is not likely that signals from the retina will control scleral growth directly. Instead, retina-derived chemical messengers probably activate signalling cascades that create a chain reaction of signalling, which moves through the RPE, choroid and sclera (arrows). For example, dopamine and/or nitric oxide signalling in the retina can cause changes in light adaptation, which might then result in the release of retinoic acid from the choroid. Choroidal retinoic acid release could then result in inhibition of scleral proliferation, and inhibition of myopia. Although all the molecules listed in the diagram have been shown to affect eye growth, the places where they may act are still theoretical, and have not yet been proven conclusively. ***Abbreviations:*** **TGF-β**, transforming growth factor beta; **bFGF**, basic fibroblast growth factor; **mAChRs**, muscarinic acetylcholine receptors; **NO**, nitric oxide; **DA**, dopamine; **EGR-1**, early growth response protein 1 (also known as **ZENK**); **ACh**, acetylcholine; **GABA**, gamma-aminobutyric acid.

A second possibility is that high concentrations of mAChR antagonists are required for myopia inhibition because these drugs are not acting at mAChRs, but instead at some other, unknown receptor. All drugs are "dirty", or promiscuous, meaning they can, and will, bind to unintended receptors; the risk of this "off-target" or "non-specific" binding increases as the concentration of drug increases. In the case of myopia-inhibition, extremely high concentrations – up to *one-million* times greater than those required for binding (1 mM used vs. 1 nM required; see above) – are used routinely. Thus, it's no great stretch of the imagination to speculate that when drugs are used at concentrations such as these, they will act in ways we cannot accurately predict. To determine whether "off-target" binding of mAChR antagonists is possible, we conducted *in vitro* experiments using isolated human mAChR M_4 receptor (M_4), chicken mAChR M_4 receptor (cM_4), and human $alpha_{2A}$-adrenoceptor (hADRA2A). Our hypothesis was that myopia-inhibiting mAChR antagonists would bind to hADRA2A – an "off-target" receptor – when applied at high concentrations. We found that myopia-inhibiting mAChR antagonists bind to hADRA2A when applied at concentrations similar to those expected to be present when these drugs are used to treat myopia in the chick model (0.001-1 mM) (98), while mAChR antagonists that do not inhibit myopia did not bind to this receptor with any significant activity, or at all. Interestingly, the correlations between the ability of mAChR antagonists to bind to M_4/cM_4 receptors and their reported ability to inhibit myopia in chick (98) were very poor, whereas correlations between mAChR antagonist binding at hADRA2A and myopia inhibition in chick were significantly better (Figure 18).

Of additional importance were our findings regarding the experimental anti-myopia ligand, MT3, a polypeptide isolated from venom of the green mamba snake. Recently, it has been reported that MT3 inhibits myopia in

chicks at concentrations significantly lower than those required for atropine (2.5-10 μM vs. 1-100 mM, respectively) (119, 120), and MT3 is known to be selective for mammalian mAChR M_4 over all other mAChR subtypes (121). Thus, the authors of these studies claimed that because MT3 inhibits myopia at a much lower concentration than atropine, mAChR M_4 must be the "myopia-controlling" receptor. However, in our studies, we found that MT3 is the *least* potent antagonist of all tested at the chicken (cM_4) receptor – 56x less potent than at human M_4 (Figure 19). This disconnect between MT3-potency at cM_4 and its rank as the most potent anti-myopia ligand in the chick – and the fact that MT3 binds with high potency, not only to mAChR M_4, but also to alpha$_{1A}$-, alpha$_{1D}$-, and alpha$_{2A}$-adrenoceptors (122, 123) – casts further doubt on the theory that M_4/cM_4 are the target receptors that mediate inhibition of myopia by muscarinic antagonists.

These data are preliminary, however, and should be interpreted with caution. They do not prove a role for alpha$_{2A}$-adrenoceptors in control of eye growth. Rather, they disprove M_4/cM_4 as a likely target, and offer alpha$_{2A}$-adrenoceptors as one possible alternative out of many – including other subtypes of mAChRs, such as M_1/cM_2. There is some evidence for a role of alpha-adrenoceptors and their neurotransmitters, norepinephrine (NE) and epinephrine (E), in the eye. NE and E are the primary neurotransmitters in the sympathetic nervous system, from which the superior cervical ganglion originates. This ganglion projects to the eye and controls processes such as pupil dilation via the iris dilator papillae, reduction of ocular blood flow via vasoconstriction, and regulation of intraocular pressure via control of aqueous humor outflow (124). A few studies have localized alpha-adrenoceptors in these ocular tissues, which is not surprising, but these receptors also seem to be present in the retina (125, 126). One hypothesized role of alpha$_2$-adrenoceptors in the retina is that they might be involved in regulation of dopamine synthesis (127-129). There is strong evidence that dopamine is a very important molecule in myopia-inhibition and regulation of eye growth (see below). Confirming these studies, and expanding upon them, may help to refine whether there is alpha$_2$-adrenoceptor-mediated signaling in the retina, whether it can affect retinal dopamine regulation, and possibly identify cell types that might be involved. Confoundingly, although there is evidence for the presence of alpha$_2$-adrenoceptors and the enzyme phenylethanolamine N-methyltransferase (PMNT) – which converts NE into E – in the retina, there is no significant evidence that either NE or E act as a retinal neurotransmitter (129). For now, the function and activating transmitters of the alpha-adrenoceptors in the retina remains largely unknown. Significant further investigation will be required to determine whether these receptors are a worthy target for anti-myopia therapies.

Dopamine

Dopamine is perhaps one of the most-studied neurotransmitters in regards to regulation of eye growth. For an in-depth review of the studies investigating the effects of dopamine and dopaminergic systems on myopia, please see "An updated view on the role of dopamine in myopia" by Feldkaemper and Schaeffel (47) and "Dopamine signaling and myopia development: What are the key challenges" by Zhou et al (130).

Dopamine is a catecholamine neurotransmitter/neuromodulator that acts as a light-adaptive signalling molecule in the retina (131). It is synthesized in and released from tyrosine hydroxylase-containing amacrine cells. Intravitreal injection of dopamine agonists is strongly correlated with inhibition of eye growth (24, 47, 50, 132-139) (Figure 20), while injection of dopamine antagonists before unrestricted vision prevents myopia rescue (140).

In addition to a direct role of dopamine agonism on inhibition of myopia in chicks, retinal dopamine levels and subsequent effects on myopia are sensitive to modulation by other drugs. Myopia-prevention by the cholinomimetic agent diisopropylfluorophosphate (141), mamba toxin-3 in chick (142), and mamba toxin-7 (MT7) in tree shrew (143), can be blocked by dopamine antagonism. Interestingly, intravitreal injection of atropine or *in vitro* application of atropine to the chick retina causes increased levels of dopamine metabolite DOPAC and retinal dopamine release (137), and like atropine (46), myopia-inhibition by dopamine is blocked by simultaneous injection of nitric oxide synthase inhibitors (48, 144). Interestingly, the effects of dopamine

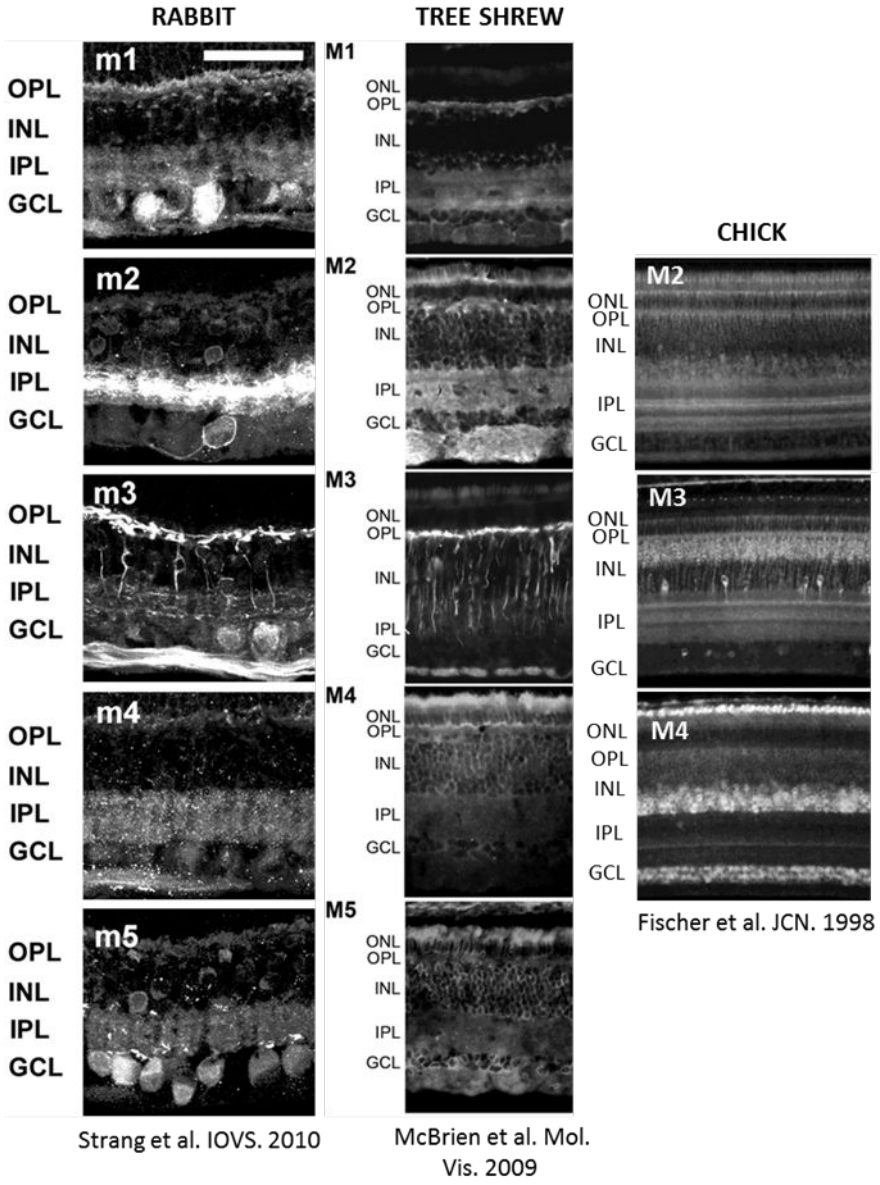

Figure 17. Reported expression patterns of retinal mAChRs in rabbit (left), tree shrew (middle), and chick (right). Chicks do not have an M1-type mAChR subtype (209). Modified and reproduced with permission from Strang et al. (2010) (108); McBrien et al. (2009) (107) and Fischer et al. (1998) (106).

agonists and muscarinic antagonists are not additive (138). This led the authors to suggest that acetylcholine and dopamine may act at different points of a common pathway to prevent myopia; further investigation into this hypothesis has not been undertaken.

Nitric Oxide

Nitric oxide (NO) is a small-molecule gas that can act as a non-conventional neurotransmitter and neuromodulator in the retina. It is difficult to image NO directly, because it is volatile and chemically unstable. Consequently, past studies utilized histochemical activity of the enzyme NADPH-diaphorase (145) and antibody-labelling of NO-synthesizing enzymes (nitric oxide synthase, NOS) to determine the localization of NO action in tissues. NADPH-diaphorase activity and immunoreactive neuronal NOS (nNOS, NOS-1) are found in subpopulations of all major cell types in the chick retina and choroid, and at least 15 types of identified retinal neurons (146, 147). Direct imaging of NO has been accomplished by means of an indicator molecule that

fluoresces after reacting with NO (148), which has been used to refine further the localization of various NOS isoforms, and where NO may act in the retina (149, 150).

The investigation of the role of NO as a regulator of eye growth is still in its early stages, but preliminary results are promising. Non-specific inhibitors of NO synthesis, L-NAME (151) and L-NMMA (152), cause transient thinning of the choroid – a change correlated with myopiagenesis. Blockade of NO synthesis with L-NAME abolishes the rescue effect of unoccluded vision (153), and experiments in mice have verified that pharmacological blockade of NO synthesis increases myopia susceptibility (154); this further implicates NO as a possible "stop" signal for eye growth. Finally, intravitreal injection of drugs that cause increased levels of NO in chick retina and RPE, dose-dependently inhibited the development of form-deprivation myopia (Figure 21).

The mechanism of NO-mediated prevention of myopia remains to be elucidated. Increased retinal NO acts as a signal for light-adaptation (155-158), and retinal NO synthesis is increased under intense illumination (45). NO donors in dark-adapted chicks mimic the adaptational effects of increased illumination (159), while NOS inhibitors mimic the effects of decreased illumination in light-adapted chicks (160). Thus, increased NO may be a possible mechanism by which high-intensity environmental illumination protects against myopia. In addition, NO inhibits cell-cell coupling via gap junctions in the retina (161), and uncoupling of gap junctions containing

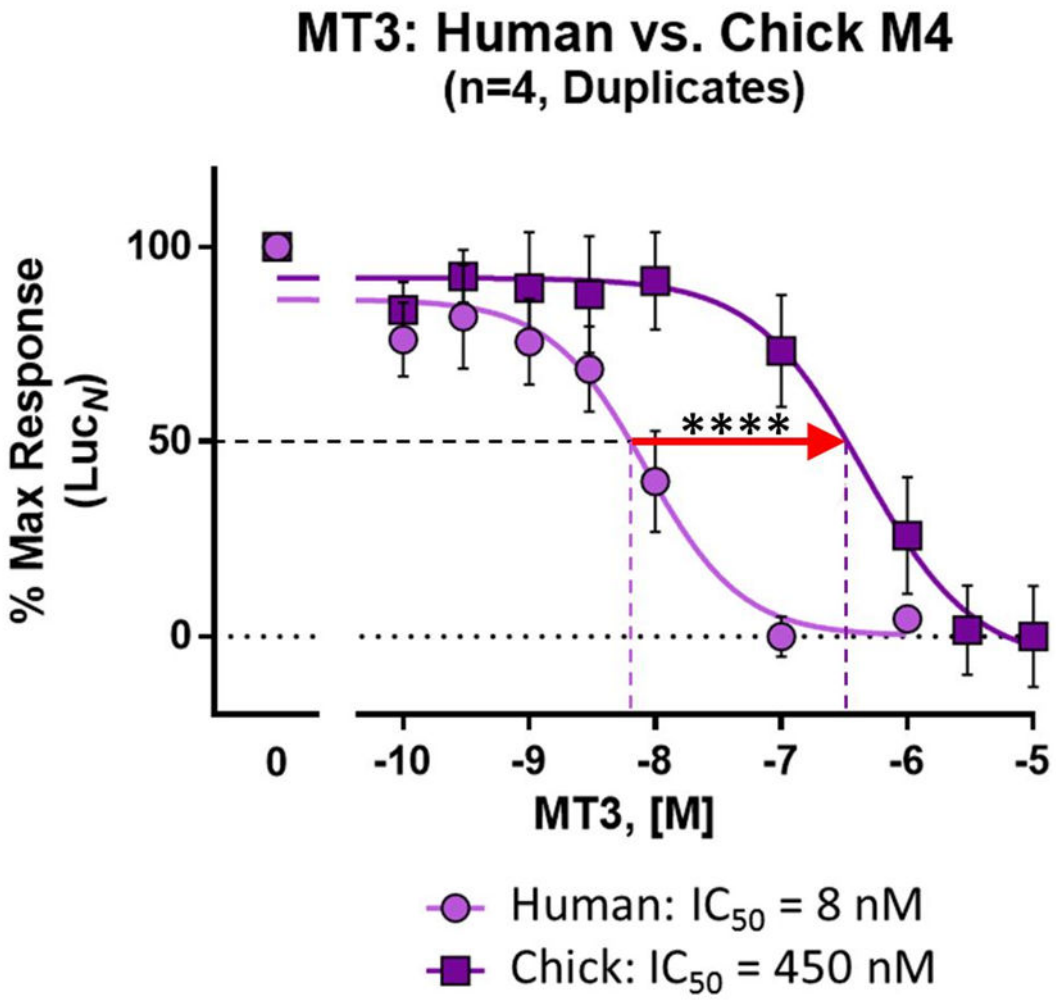

Figure 19. Inhibition curves for MT3 at the human (M_4) and chicken (cM_4) muscarinic receptors. MT3 is 56x less potent at cM_4 than M_4 at the 50% effective inhibitory dose (dotted lines, IC_{50}), effectively becoming a low-potency ligand at the chicken receptor; ****p<0.0001, unpaired t-test, two-tailed. connexin-35/36 (Cx35 in chicks) – which sharpens spatial tuning of retinal function – has also been implicated in myopia-inhibition (162) (and unpublished results of Teves et al (163)).

Although we do not know the receptors through which atropine may act, we do know that myopia-prevention by atropine is also dependent on induction of nitric oxide (NO). Simultaneous injection of atropine with nitric oxide synthase inhibitors – which blocks the ability of cells to make NO – completely abolishes all protective effects of atropine in chicks (46) (Figure 22).

Many other molecules can affect eye growth

Adenosine receptors and 7-methylzanthine (7-MX)

7-MX is a caffeine derivative, which has some affinity to adenosine receptors. Recent clinical trials of 7-MX have provided evidence that it may be useful in combatting axial myopia (164). Children with a fast base-line rate of myopia progression, fed daily tablets containing 400mg 7-MX for >2 years, experienced slowing of axial elongation and myopia progression compared to placebo controls. This myopia-inhibiting effect halted as soon

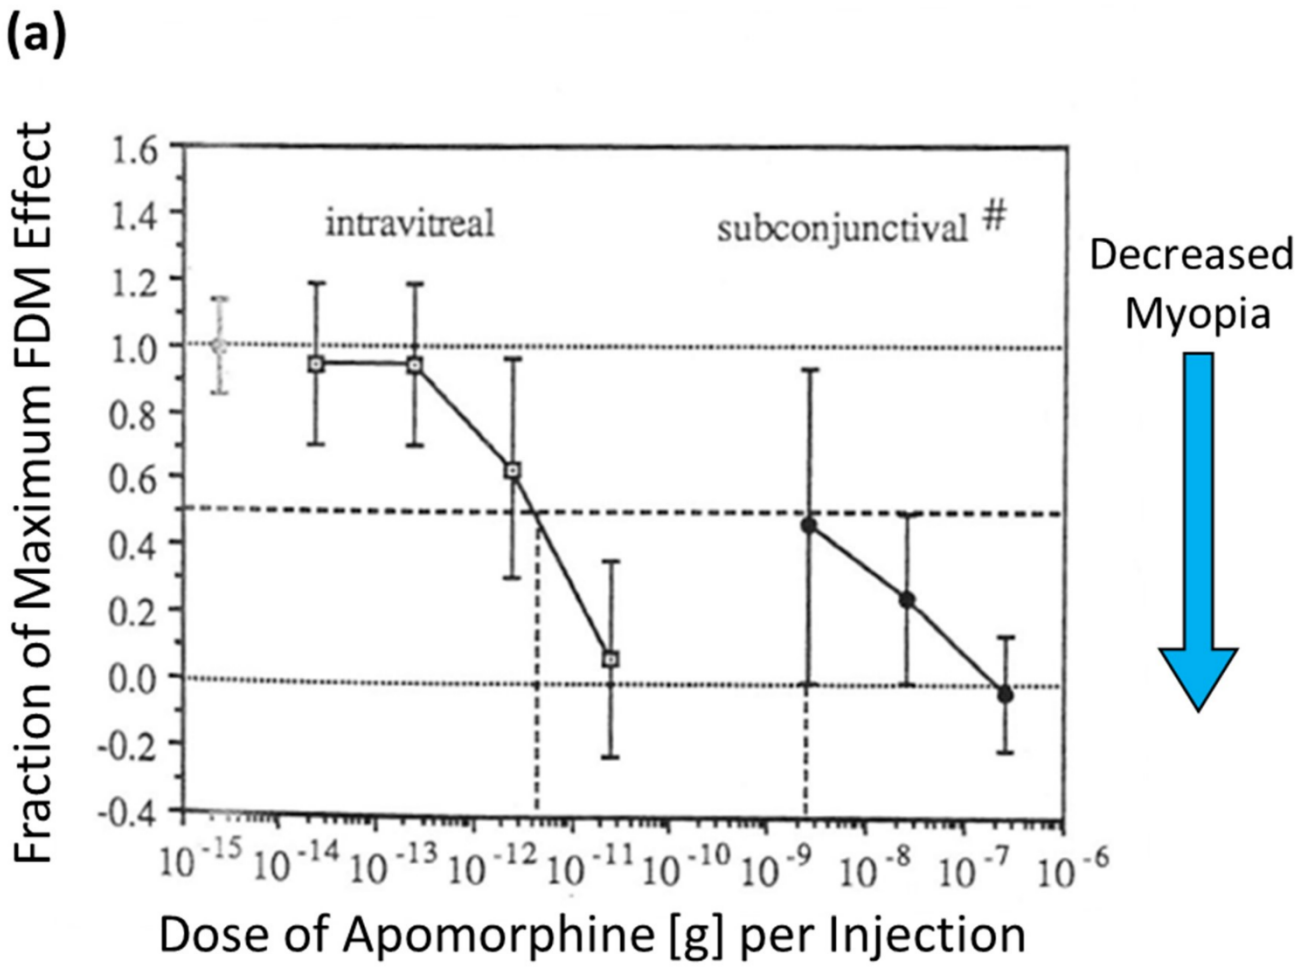

Figure 20. The non-specific dopamine-receptor agonist (activator), apomorphine, inhibits form-deprivation myopia in the chick when injected via intravitreal and subconjunctival routes. Reproduced and modified with permission from Rohrer, B., Spira, A. W. & Stell, W. K. (1993) (132).

as 7-MX treatment was discontinued. The mechanism through which 7-MX may prevent myopia is currently unknown, but there are two working hypotheses: (i) that it causes stiffening of the sclera, which prevents axial elongation (165, 166); or (ii) that it blocks adenosine receptors in the retina and/or ciliary muscle, and consequently causes changes in acetylcholine and dopamine neurotransmitter release (164).

Alpha$_2$-Adrenoceptors

Recent studies have shown that alpha$_2$-adrenoceptor agonists can inhibit form-deprivation myopia in the chick (167). Intravitreal injection of high concentration clonidine (200 nmoles) or guanfacine (20-200 nmoles) significantly inhibited changes in refractive error and axial elongation (Figure 23). These studies are appealing, because the alpha$_2$-adrenoceptor agonist brimonidine is already approved for use in humans, as a glaucoma treatment (168). Thus, it would be much easier to translate these findings into a clinical trial than it would for experimental ligands such as mamba toxin-3. These data are very preliminary, but could yield new pharmaceutical targets for anti-myopia therapies lacking the negative side-effects of atropine treatment.

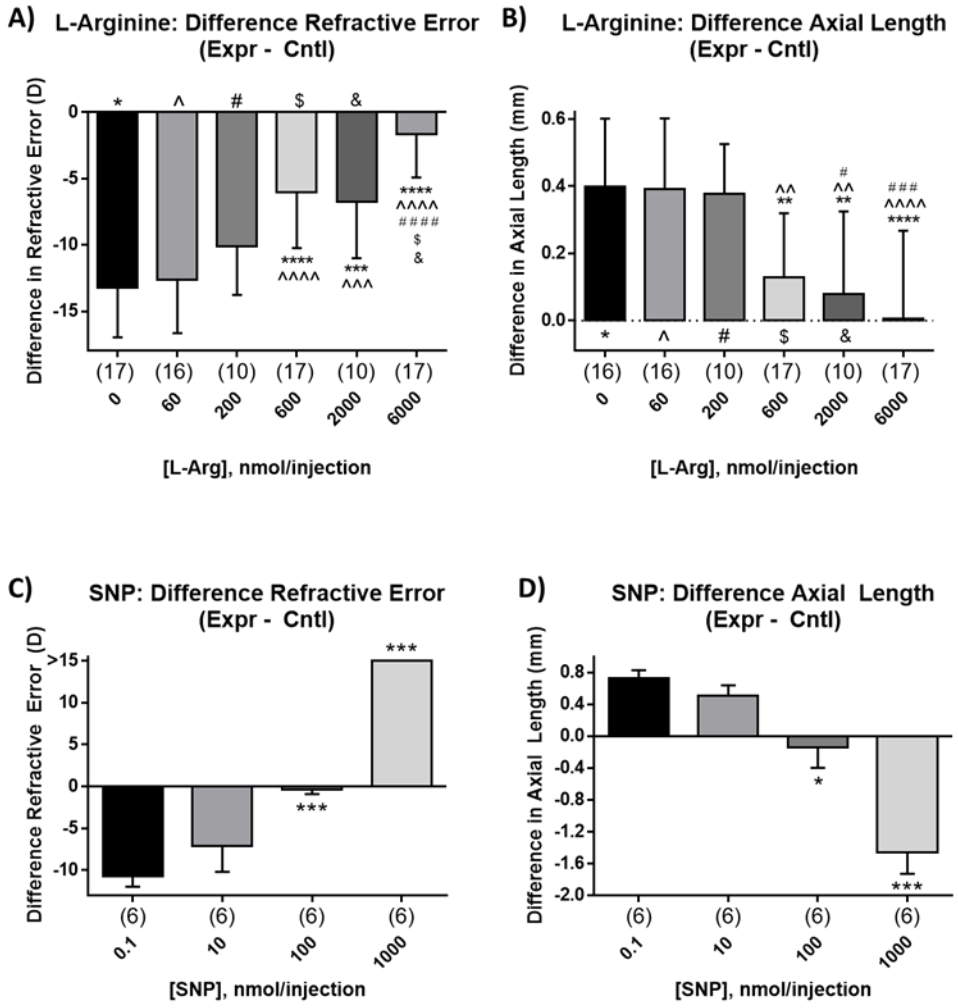

Figure 21. The effects of exogenous nitric oxide (NO), delivered intravitreally as NOS-substrate (L-Arginine; L-Arg) or NO-donor (sodium nitroprusside; SNP), on form-deprivation myopia in chicks, expressed as the mean difference between values in the goggled/drug-injected eye (gradations of gray fill) and in the contralateral open/vehicle-injected eye (solid black fill). L-Arg (**A,B**) and SNP (**C,D**) dose-dependently inhibited the development of myopic refractive error (**A,C**) and axial length (**B,D**) in goggled chick eyes. Doses represent the number of moles of drug injected, per injection, 3 times at 48-hr intervals. The refractions and sizes of control eyes were not affected by drugs delivered to the goggled eyes. Statistics: *p < 0.05, **p < 0.01, ***p < 0.001; One-Way ANOVA + Tukey's post-hoc (L-Arg) or Kruskal-Wallis + Dunn's post-hoc (SNP); n = 6. Reproduced with permission from Carr, B.J. and Stell, W. K. (2016) (46).

Gamma-aminobutyric Acid (GABA)

Gamma (γ)-aminobutyric acid (GABA) is the primary mediator of inhibitory synaptic transmission in the central nervous system (CNS). For more detailed reviews of the localization and function of the GABA in the retina, please see previous Webvision chapters, "Neurotransmitters in the Retina" by Helga Kolb, and "$GABA_C$ Receptors in the Vertebrate Retina" by Haohua Qian.

There is significant evidence that GABA receptors are involved in the regulation of eye growth. Daily intravitreal injections of a wide variety of GABA receptor antagonists into form-deprived eyes resulted in reduction of eye growth (mostly in the equatorial dimension) (169). One of the most effective anti-myopia GABAergic drugs is the $GABA_{AOr/C}$ antagonist (1,2,5,6-Tetrahydropyridin-4-yl)methylphosphinic acid (TPMPA), which has been shown to significantly inhibit goggle-induced myopic refractive error, vitreal chamber depth, and equatorial diameter in the chick (169) and guinea pig (170, 171). Novel $GABA_{AOr/C}$ drugs *cis*- and *trans*-3-ACPBPA also

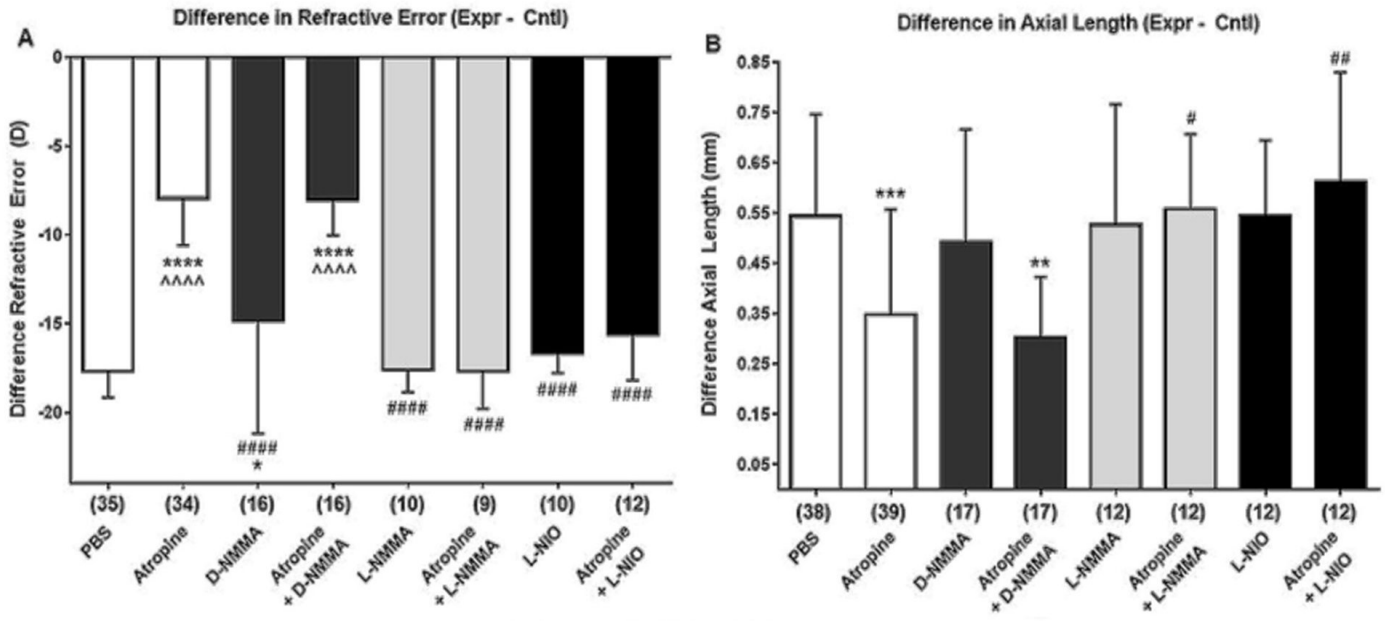

Figure 22. The effects of atropine (240 nmoles), NOS inhibitors (6 nmoles; L-NIO, L-NMMA), D-NMMA (6 nmoles), and the combination of atropine + NOS inhibitors (L-NIO, L-NMMA), or atropine + D-NMMA on refractive error (**A**) and axial length (**B**); doses represent the number of moles of drug injected, per injection, 3 times at 48-hr intervals. ***Abbreviations***: **L-NIO**: N^G-(1-Iminoethyl)-L-ornithine; **L-NMMA**: L-N^G-monomethyl arginine; **D-NMMA**: D-N^G-monomethyl arginine. ***Symbols***: asterisk (*): comparison to effect of PBS-treatment; pound (#): comparison to effect of atropine-treatment; caret (^): comparison to effect of D-NMMA-treatment. ***Statistics***: ●●●● $p < 0.0001$, ●●● $p < 0.001$, ●● $p < 0.01$, ● $p < 0.05$; One-Way ANOVA + Tukey's post-hoc. inhibit lens-induced myopia in chicks, the cis form being much more potent (172). How $GABA_{AOr/C}$ antagonists may inhibit myopia is not known, and GABA can be expected to play a role in practically every visual processing mechanism in the retina; but there is some evidence of interaction with retinal dopaminergic systems, in the particular (173), as well as possible effects on scleral glycosaminoglycans (174).

Growth Factors: TGF-β and bFGF

Transforming growth factor-beta (TGF-β) and basic fibroblast growth factor (bFGF) seem to operate in a push-pull manner to regulate scleral growth during experimentally-induced myopia. Intravitreal injection of bFGF in chicks is protective against myopia, and co-administration of TGF-β with bFGF blocks this effect (175). In the guinea pig, Chen et al. confirmed that bFGF prevents experimentally-induced myopia. They also reported that bFGF protein expression was decreased, while TGF-β expression was increased, in scleral tissues of eyes that had undergone light induced myopia for extended periods of time (15-30 days) (176). The mechanism of bFGF-mediated myopia inhibition has not been elucidated. Attempts were made to link bFGF with the dopaminergic system, because bFGF protein content is upregulated during light and it is co-localized with tyrosine-hydroxylase – the cell marker for dopaminergic amacrine cells (175). However, other studies revealed that the two pathways are likely not related (50).

Peptide Hormones: Glucagon and Insulin

Glucagon is a pancreatic peptide hormone whose best-known role in mammals is to raise the concentration of glucose in the blood; insulin, another pancreatic peptide hormone, plays the opposite role – to lower blood sugar levels. However, many (perhaps all) gut peptides and their receptors are also expressed by neurons in the central and peripheral nervous systems, where they presumably play neuromodulatory roles. Glucagon-positive cells in

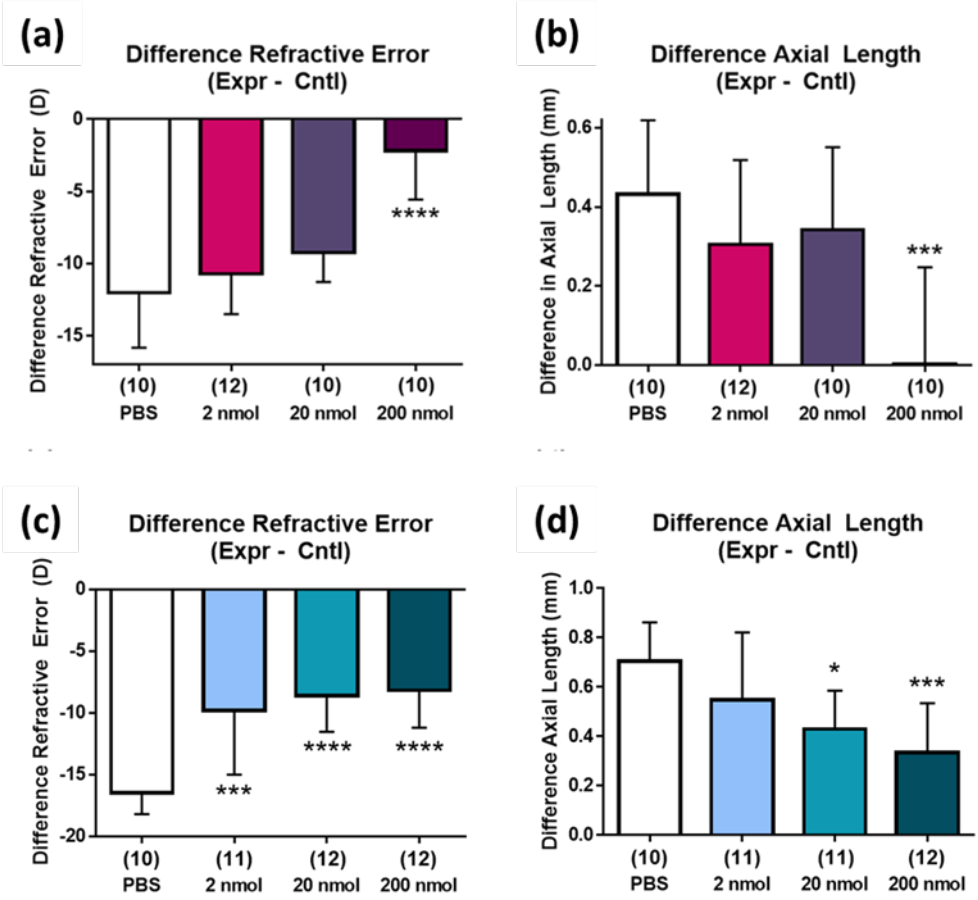

Figure 23. Effects of intravitreal injection of clonidine (top) and guanfacine (bottom) on FDM in chicks. 200 nmoles clonidine, and 20 and 200 nmoles guanfacine, significantly inhibited the induced difference in refractive error (a,c) and axial length (b,d), compared to PBS-controls. There was no significant effect of 2 or 20 nmoles clonidine-treatment or 2 nmoles guanfacine-treatment on difference in axial length. ***Statistics***: $^{****}p < 0.0001$, $^{***}p < 0.001$, $^{*}p < 0.05$; One-Way ANOVA + Tukey's post-hoc. Data are represented as the means of the difference in values for the experimental eye minus those for the control eye, ± SD; sample sizes (n) are denoted in brackets below each column. Reproduced from Carr BJ. (2017). PhD Thesis. University of Calgary (210) and Carr BJ & Stell WK. (210, 211).

the retina consist of a subset of amacrine cells in the inner retina of birds and reptiles, about 40% of which are also GABAergic (177, 178). The activity of glucagon amacrine cells in the chick retina changes dramatically in response to defocus, as revealed by changes in these cells' content of an activity-inducible transcription factor, early growth response protein 1 (EGR-1 or ZENK). Positive-lens defocus, or removal of the diffuser after inducing form-deprivation myopia, causes stronger and more widespread labeling of EGR-1, whereas negative-lens defocus or form-deprivation results in little or no labeling (179). The activity-dependent induction of Egr-1 is best interpreted as an indicator of cell depolarization, and therefore is an indicator of increased transmitter release. Egr-1 is likely to upregulate the transcription of genes whose products are important in functional compensation for prolonged increases in cell activity, rather than directly to affect downstream actions of the activated cell such as those involved in myopia-inhibition.

In the chick, injection of a glucagon agonist into form-deprived eyes inhibits myopia development (180), and injection of a glucagon antagonist blocks myopia recovery from clear vision (181). Intravitreal injection of insulin has the opposite effect, acting as a powerful myopiagenic agent (182). Glucagon inhibits the development of myopia in chicks, even after most amacrine cells have been ablated by neurotoxins, suggesting that (in chicks at least) glucagon amacrine cells could be the final or near-final output of "stop" signals acting on the RPE (183).

The relevance of these interesting findings in the chick model to the control of refractive development in mammalian eyes remains uncertain. A comparable role of glucagon in the retina of mammals remains elusive. To date, glucagon has not been identified or localized in any mammalian retina; and although many other members of the glucagon polypeptide family are present, their expression is not changed upon treatment of the eyes with form-deprivation stimuli. However, other kinds of amacrine cells, which have been labelled by similar focus- and defocus-dependent induction of Egr-1 in macaque monkey (184, 185) and tree shrew (186) are plausible candidates for playing similar roles in the control of eye growth.

Retinoic Acid

Retinoic acid (RA) is a member of the retinoid family of compounds, which also includes Vitamin A. Retinoic acid stands out among other candidate regulators in the control of eye growth, because its levels are bi-directionally modulated in response to opposing defocus stimuli (187). In the chick, retinal and choroidal RA levels and mRNA expression of its synthesizing enzyme, aldehyde dehydrogenase-2 (AHD2), are predictably changed in response to defocus stimuli; increasing in response to negative defocus and decreasing in response to positive defocus (187-189). Treatment of form-deprived chicks with a blocker of RA synthesis, disulfiram, caused myopia inhibition, but this effect was not carried over in response to lens-induced myopia (189). RA might act as a regulator of eye growth by inducing changes in scleral extracellular matrix (74) or modulating cell-cell coupling (74, 190, 191).

Choroidal changes correspond to changes in eye growth

Although the origin of homeostatic growth-regulating signals is most likely the retina, experimental and therapeutic treatments may affect any target within other ocular tissues – the retinal pigment epithelium (RPE), choroid, and/or sclera most likely. It is unlikely that a single kind of molecule is responsible for transmission of growth-regulating signals, because of difficulties in crossing the occluding junctions of the RPE (a major component of the blood-retina-barrier), and drug loss due to protein binding and dilution of the drug during *en route* transport into cells. More likely, a cascade of molecules may relay signals from retina-to-RPE, RPE-to-choroid, and then choroid-to-sclera (Figure 16).

Interestingly, the choroid responds to induced defocus in a compensatory fashion (192) – thickening in response to myopic defocus (positive lenses, removal of myopia-inducing goggles) and myopia-inhibiting treatments (118, 151-153, 193), and thinning in response to diffusers or hyperopic defocus (negative lenses) (Figure 24). Whether the directional changes in the choroid are responsible for scleral changes in eye growth – or just an initial compensatory step/by-product of other mechanisms that are themselves the primary regulators – remains to be determined, although the authors of a recent study have reported that changes in choroidal thickness are not predictive of changes in eye growth in eyes with experimentally-induced myopia (194). Nevertheless, it may be assumed that the choroid should play some role in the regulation of ocular refraction and/or the cause(s) and prevention of myopia (195), and that it may be the source of growth-regulating signals that act on the sclera (196).

Human therapies and recommendations for myopia prevention

Pharmaceutical Interventions: Atropine

Although many neurotransmitter/neuromodulator agonists and antagonists have been investigated for their ability to control eye growth, very few laboratory discoveries have been translated into clinical therapies. The most widely used pharmaceutical agent, atropine, was championed almost 40 years ago by Bedrossian (197) and subsequently became the subject of numerous clinical trials and scientific scrutiny. In 2006, Chua et al. published the results of the Atropine in the Treatment Of Myopia (ATOM) study (111). This was a two-year,

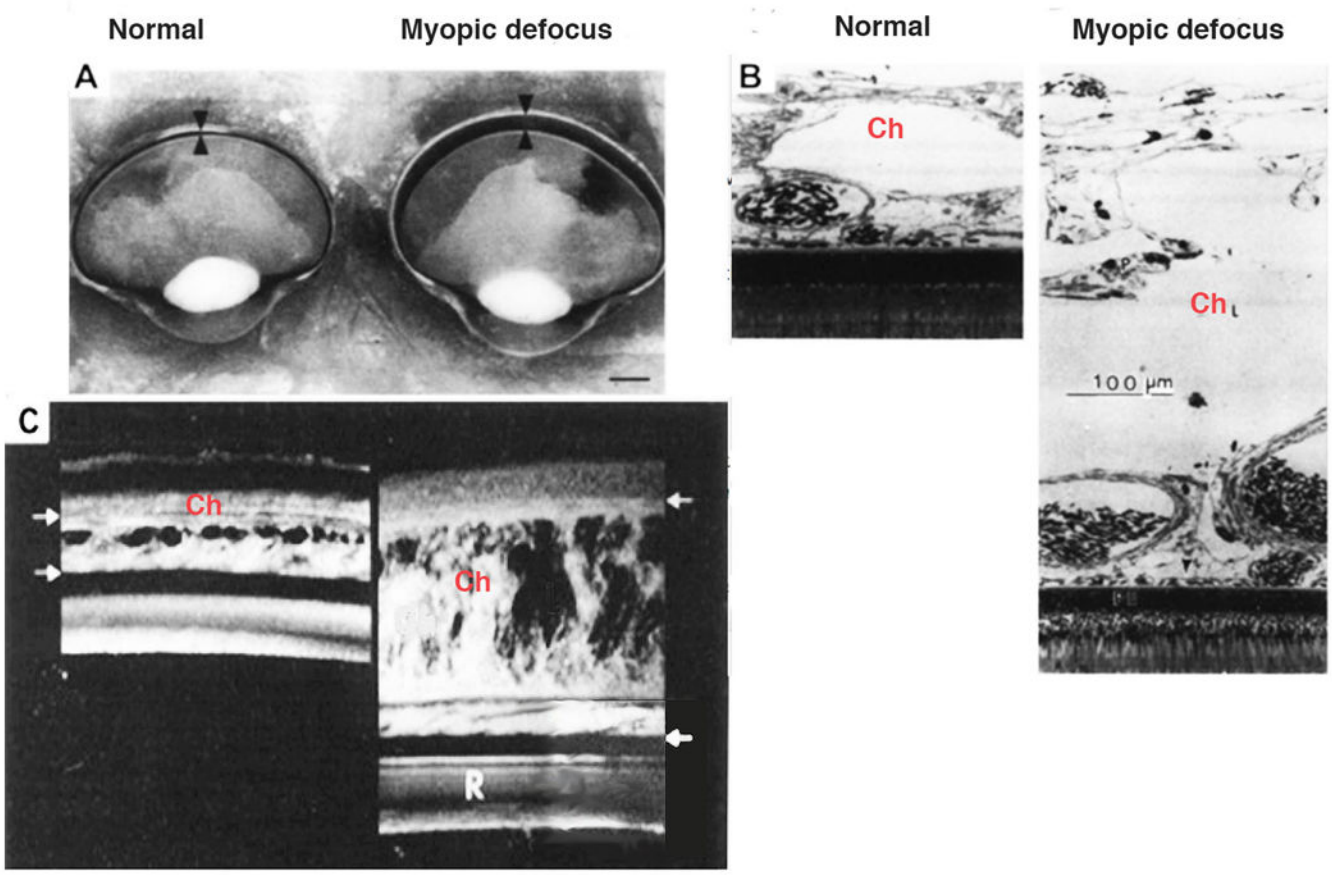

Figure 24. Choroidal modulation of refractive state. (**A**) Unfixed hemisected chick eyes. One eye is a normal control while the other has received myopic defocus. Arrowheads delimit choroidal thickness. (**B**) Plastic-embedded sections of the back of the eyes. Ch (red): choroid; R: retina. (**C**) One-mm-thick section of the posterior eye wall. Ch: choroid, delimited by arrows show the relative thickness of the choroid in normal and myopic defocus eyes. Reproduced with permission from Wallman et al., (1995) (192).

comprehensive, randomized, placebo-controlled, double-blind trial of 346 Asian children to determine the effectiveness and safety of daily 1% atropine eye drops for the prevention of myopia progression. ATOM was significant in that it was one of the first clinical trials with double-blind and placebo-controlled groups, which provided a much more objective measurement of the effects of atropine for human myopia. The outcomes revealed that atropine significantly reduced the mean progression of myopic refractive error: 84% of placebo-treated children experienced myopic progression of -0.5 D or more, while only 34% of atropine-treated children experienced the same (Figure 25). No serious adverse effects were reported, but the common side-effects – photophobia, glare, allergic reaction, and headaches caused by blurred vision – caused some children to drop out. In addition, a subset of children experienced a "rebound effect", in which myopia returned and progressed much more rapidly after atropine-treatment had ceased (198). Chia et al. (110) repeated the ATOM study (ATOM2), using lower concentrations of atropine (0.5%, 0.1%, and 0.01%) for two years, and found that the drug retained most of its efficacy at these lower concentrations. Minimal side effects were reported, but many children continued to suffer from blurred vision, conjunctivitis, and eyelid dermatitis at the higher concentrations. The "rebound effect" was also still present in the higher-concentration treatment groups (0.5% and 0.1%) (199).

In an attempt to address the rebound effect, the study was repeated, but with a different treatment schedule (200). Children were treated with 0.5%, 0.1%, or 0.01% atropine for two years, and then treatment was

discontinued for one year to see whether rebound would occur. Treatment was restarted only in children who experienced myopic progression of -0.50 diopters or more in at least one eye, and then continued for another two years. It was found that there was an inverse dose-related increase in myopia by the end of phase 2 (period with no treatment – 'wash-out') caused by rebound, resulting in the greatest effect of the 0.01% treatment group. Children requiring a second round of atropine-treatment were 24%, 59%, and 68% for the 0.01%, 0.1%, and 0.5% groups, respectively. Results from the second round of treatment confirmed that the most effective concentration of atropine was 0.01%; children treated with 0.01% atropine had the least rebound during the wash-out period, but still experienced significant inhibition of myopia-progression during treatment (Figure 26). Side-effects for the 0.01%-treatment group were mild – only minimal pupillary dilation, minimal loss of accommodation, and no significant loss of near-vision – compared with those at the higher concentrations.

Corneal-Reshaping Lenses: Orthokeratology

Orthokeratology (Ortho-K, Overnight Vision Correction, Corneal Refractive Therapy) uses gas-permeable contact lenses, worn at night and removed during the day, to temporarily reduce refractive errors. The lenses reshape the cornea while the user is sleeping, are removed in the morning, and refractive correction is maintained well throughout the day. Not only does Ortho-K correct myopia without drugs or surgery, but clinical trials of Ortho-K have demonstrated a strong correlation between Orth-K treatment and inhibition of myopia progression (201). The Longitudinal Orthokeratology Research in Children (LORIC) study, in Hong Kong, was a non-randomized two-year pilot study that investigated the ability of overnight Ortho-K lens wear (i) to correct myopic vision, and (ii) to slow the progression of myopia (n=35) (202). Positive results from this small pilot study led to the first larger-scale, single-masked, randomized clinical trial named the Retardation Of Myopia In Orthokeratology (ROMIO) study (203), in which 78 children (37 Ortho-K, 41 controls) took part for two years. The children wearing Ortho-K lenses experienced significantly slower axial elongation during the study than those wearing single-vision lenses, and at the end of the treatment period had significantly shorter eyes (Figure 27). Some children (5) did drop out of the study for ocular health reasons related to lens-wear, but their vision was not permanently affected once Ortho-K treatment was stopped. The mechanism by which orthokeratology inhibited myopia progression remains unclear, but studies have suggested that Ortho-K lenses may induce relative peripheral myopia, as well as increases in spherical aberration and amplitude of accommodation (204). However, alternative mechanisms – such as neurally mediated reflex control of ocular elongation or corneal curvature – have not yet been ruled out.

Alternative Strategies: High Environmental Illuminance

Human trials investigating the effects of high-intensity outdoor light on myopia prevention have so far been very promising (36, 38, 39) (Figure 10). Sending children outdoors is by far the least invasive treatment-option currently available. In countries where the intensity of outdoor light is generally lower, because of air pollution or short duration of natural daylight – such as Canada or Scandinavia in the winter, or Beijing year-around – sunlight therapy could be supplemented in the form of SAD lights (approved and used for Seasonal Affective Disorder), which have an output of ~2,000-10,000 lux and are sold to combat depressive symptoms brought on by seasonal affective disorder. This alternative will become even more attractive, when the spectral region responsible for myopia-prevention in primates has been identified.

Where do we go from here?

The world is experiencing a "myopia boom" (2), and viable treatment options are becoming more crucial than ever before. Atropine is considered to be the best pharmaceutical treatment we have. It is the only one currently available, and is rather widely accepted and used, despite remaining off-label for the purpose of treating myopia. Advocates of atropine use would claim that the occurrence of unwanted side-effects and its unknown mechanism of action are not serious enough drawbacks to warrant discontinuation of therapy. Unlike atropine,

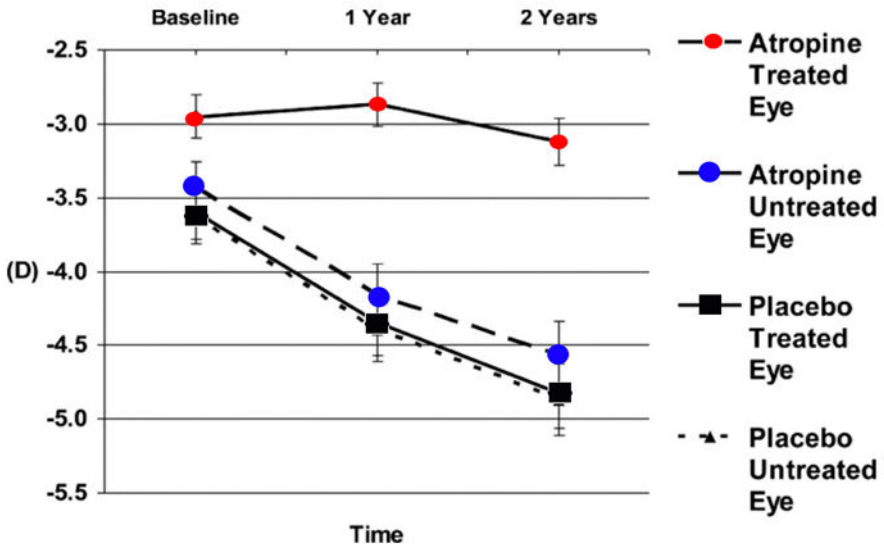

Figure 25. The effect of 1% atropine and placebo on the progression of myopic refractive error in children over the course of two years. Reproduced from Chua, W. H. et al. (2006) (111).

single-vision lenses do not prevent continued myopia progression, which can lead to blindness-inducing vision problems later in life; and overall, topical atropine-treatment in children has been proven to be effective and quite safe. Parents should be aware of the most common side effects: possible photophobia due to pupil dilation, impairment of near-vision due to paralysis of the ciliary muscle, allergic reactions, and rebound after cessation of treatment. It should also be noted, that not all children will respond to atropine-treatment (205).

It is imperative to determine the mechanism through which atropine inhibits myopia, because a better agent might be found, ideally, an agent as effective topically as atropine, but completely lacking the unacceptable side-effects of even 0.01% atropine eye-drops – mild photophobia, blur, and allergies. There is evidence that mAChRs may not be the receptors that mediate myopia-inhibition (109), and learning the true targets could effectively eliminate atropine's three most common side-effects. Lowering the required concentrations or treatment frequency could mitigate the allergic reactions caused by daily atropine use, and using a non-mAChR-specific drug would eliminate both photophobia and loss of accommodation, which are mediated by known target receptors of atropine (mAChRs).

Retrospective reviews have been performed to determine the safety and efficacy of Ortho-K lens-wear; however, although gas-permeable Ortho-K lenses have been determined to be quite safe (201, 206), caution is still advised. Long-term use of these lenses may be required, which can increase the risk of microbial keratitis, and discontinuation of use has resulted in a rebound effect similar to that seen in pharmacological treatments of myopia (198, 199, 204). Recently, a study was performed that combined the anti-myopia effects of atropine (0.01%) and Ortho-K. The authors reported that combining the two therapies resulted in a significantly greater effect than Ortho-K treatment alone (207). Long-term studies on the safety and efficacy of cornea-reshaping lenses are vital; whether overall eye health can be maintained while using lenses that change eye shape by applying a significant amount of physical pressure to corneal cells for many hours every day remains to be determined.

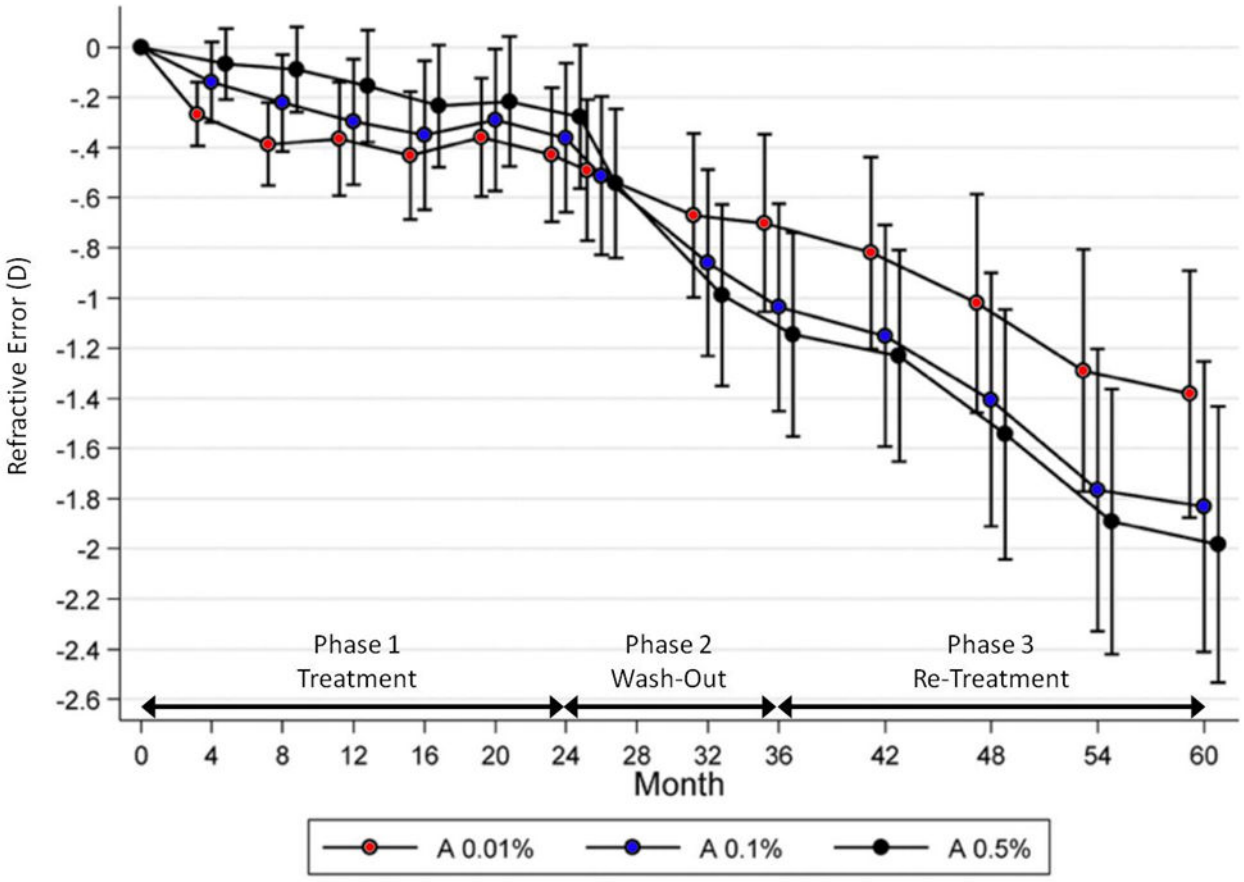

Figure 26. Mean change in refractive error over time within different treatment groups (atropine 0.01%, 0.1%, and 0.5%). Error bars represent 1 standard deviation. Reproduced from Chia, A., Lu, Q. S. & Tan, D. (2016) (200).

Outdoor-light therapy may offer the ideal treatment for myopia. Not only does encouraging children to play outside combat other major health concerns – such as childhood obesity, juvenile diabetes, and depression – but also, light therapy presents little to no serious health concerns or side-effects compared to those of other available myopia-treatments. Exposure to potentially-harmful UV radiation can be avoided by wearing UVA/UVB-blocking sunglasses and sunscreen. Alternative light sources such as commercially available SAD lights do not contain UV-radiation, and have been shown to be nearly equally effective in myopia-prevention in animal models. This approach seems to be particularly promising, if further testing of non-human primates, followed by clinical trials, confirms that long (rather than short) wavelengths of visible light are the ones that can protect humans against myopia, as blue-light can be potentially harmful to the retina (208).

Although we have made significant progress in determining possible treatments for myopia, much still needs to be done before we understand fully the homeostatic mechanisms responsible for regulation of eye growth. New discoveries about the way visual feedback regulates eye size may lead to new treatment options for myopia, and further our understanding of a fundamental mechanism of human eye development and emmetropization, a poorly understood, but highly important function of visual processing in the retina.

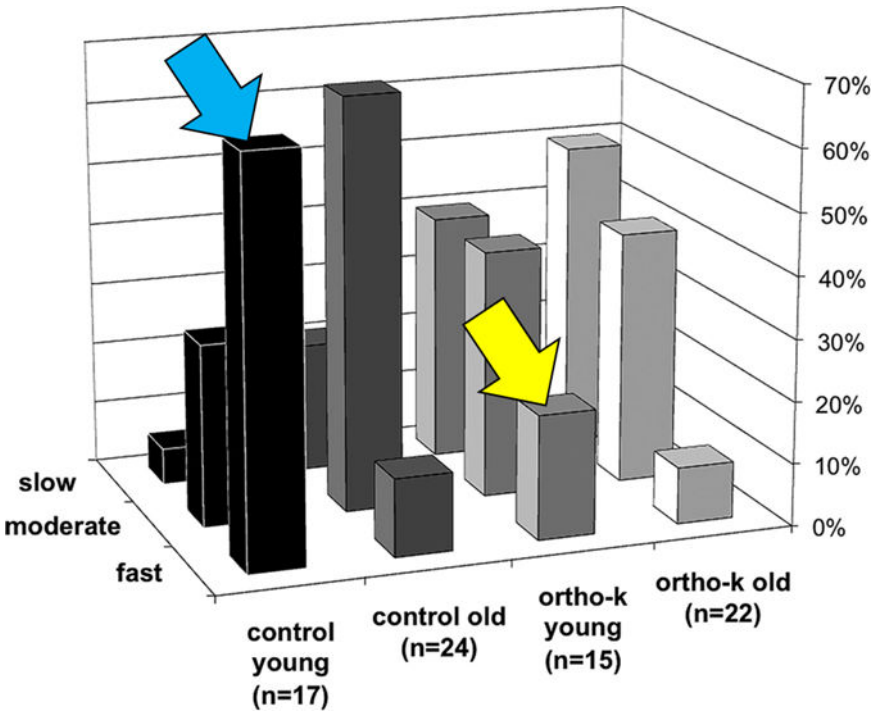

Figure 27. Percentages of subjects demonstrating slow (0.18 mm/y), moderate (>0.18 and ≤0.36 mm/y), and fast (>0.36 mm/y) myopia-progression in younger (6–8 years old) and older (9–10 years old) children, in the Ortho-K and control groups. The blue arrow indicates the percentage of young myopes that experienced rapid myopia-progression without Ortho-K treatment (65%), while the yellow arrow indicates the percentage of young myopes that experienced rapid myopia progression with Ortho-K treatment (20%). Reproduced and modified from Cho, P. & Cheung, S. W. (2012) (203).

About the authors

Brittany Carr graduated with Honours from the Bachelor of Health Sciences program at the University of Calgary in 2011, and earned her PhD in Neuroscience at the Cumming School of Medicine at the University of Calgary, Alberta, Canada, in April 2017. Mentored by Dr. William K. Stell and Dr. Morley D. Hollenberg, her doctorate research was concerned with investigating the signalling mechanisms involved in atropine-mediated inhibition of myopia. By investigating the pharmacological behavior of atropine and other myopia-inhibiting muscarinic acetylcholine receptor (mAChR) antagonists, she successfully demonstrated that myopia inhibition by atropine may not be controlled by mAChRs, but instead some other unknown target receptor(s) or pathway(s), possibly involving alpha$_{2A}$-adrenoceptors. She is currently a postdoctoral fellow, studying retinal degeneration at the University of British Columbia Centre for Macular Research (Vancouver, BC, Canada).

Bill Stell has been Professor of Cell Biology and Anatomy in the Cumming School of Medicine, University of Calgary, since 1980. He graduated from Swarthmore College with High Honors in Zoology in 1961, and received his Ph.D. in Anatomy in 1966 and M.D. in 1967, both from the University of Chicago. Subsequently he was at the NINDS, NIH, in the laboratories of Drs. Thomas G. Smith, Jr., K.C. Richardson, Henry G. Wagner, and M.G.F. Fuortes. In 1972 he joined the faculty of the Jules Stein Eye Institute, UCLA for 8 years, and finally found a home in Neuroscience at the University of Calgary, Alberta. Originally known for pioneering studies in EM of Golgi-impregnated neurons in fish retina, more recently Bill became interested in the retinal origins of myopia. Since then, he – with outstanding PhD. Students such as Dr. Carr – has made many and varied contributions to understanding the role(s) of the retina in causing and preventing myopia.

Crystalline Lens and Cataract

Joah F. Aliancy, MD[1,*] and Nick Mamalis, MD[1,†]

Created: August 15, 2017.

Introduction

The lens of the eye is a biconvex, relatively acellular, optically transparent intraocular structure that with the cornea serves to transmit light to the retina with minimal light scattering (Figure 1a). Early anatomists viewed the lens as the location of meaningful visualization. We now know that this is the function of the retina, with the lens serving as a conduit of light transmission and focus to the retina. The lens can change shape with the aid of the ciliary muscles, thereby changing the focal distance to the retina and bringing the image into sharp focus on the retina. This adjustment of the lens is known as accommodation (similar to the focusing of a photographic camera via movement of its lenses). The lens is flatter on its anterior side than on its posterior side. (Figure 1b).

Development of the lens

The mature lens originates from surface ectoderm and develops through a highly organized process correlated with the neuroectoderm germ cell layer. Early in embryogenesis the diencephalon, neuroectoderm derived tissue, forms two outpouchings called the optic vesicles. The optic vesicles induce formation of the immature lenticular cells when they come in contact with surface ectoderm. The immature lenticular cells thicken to form the lens placode. Concurrently, the optic vesicles invaginate causing an indentation on the lens placode called the lens pit (Figure 2a).

At this point, the lens vesicle is made up of a single layer of cells enveloped within an outer basement membrane. This basement membrane will eventually form the lens capsule. While encased in the basement membrane, the cells in the posterior pole of the lens vesicle extend anteriorly to form the primary lens fibers (Figure 2b).

The anterior cells become the lens epithelial cells, while the primary lens fibers collectively form the embryonic nucleus. Subsequently, secondary lens fibers begin to elongate from the lens epithelial cells to form the fetal nucleus during the gestation period and continue to grow multiple layers. As the secondary lens fibers elongate from the equator, they form Y-shaped sutures by meeting anteriorly and posteriorly during fetal growth. The secondary lens fibers eventually grow to form the adult nucleus with new layers of lens fibers forming the lenticular cortex. During lenticular development, the hyaloid artery delivers nutrition and growth factors through the tunica vasculosa lentis, a vascular structure that envelopes the lens nucleus. However, this structure undergoes involution prior to birth to resemble the avascular lens seen in the adult. A firm understanding of the embryology and development of the lens will provide great insight into the pathology associated with cataract formation.

Figure 3 shows a stained section of the adult human lens with anterior part of the lens in the top section and the posterior part in the lower section.

The lens is composed of 4 structures: capsule, epithelium, cortex and nucleus (Figure 3). The capsule is the basement membrane with type VI collagen elaborated by the epithelium layer, and stains positively with Periodic

† About the authors

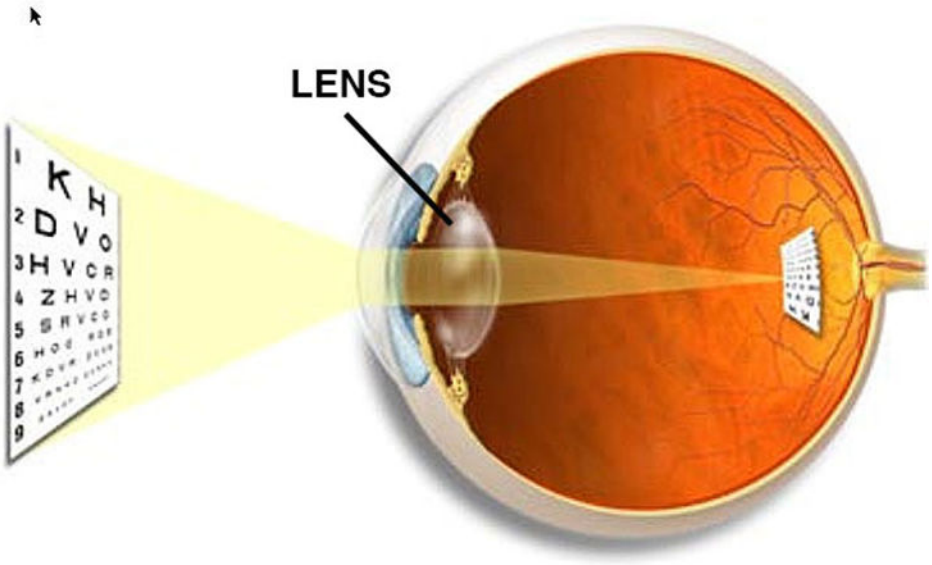

Figure 1a. A human eyeball cut in half to show the lens and the passage of light through it from the object ahead to the focus on the retina.

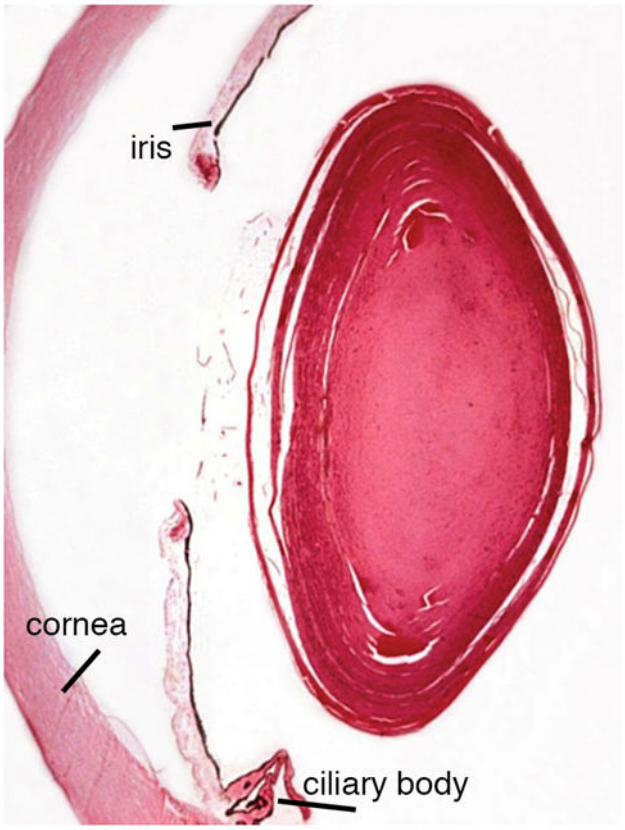

Figure 1b. Histological section of normal crystalline lens (H&E stain, X2). The sectioned iris is shown (**iris**) but the **ciliary body** is mostly out of the plane of the section. Notice the lens is flatter anteriorally, facing the cornea (**cornea**).

acid-Schiff (PAS) stain. It is optically clear and acellular. The lens is held in place by zonular fibers, otherwise known as the zonules of Zinn (Figure 4). These elastic fibers originate from the nonpigmented epithelium layer of the ciliary body and articulate with the outer layer of the capsule, the capsular lamellar layer. There is a reduction of zonular tension with contraction of the ciliary muscle leading to a more spherical shape allowing focus on more proximal objects. This process is called accommodation.

The lens epithelium has mitotically active cells that undergo further differentiation via an elongation process, increase in intracellular protein and loss of organelles. These cells are arranged in one layer across the posterior aspect of the anterior capsule. The equatorial bow region of the lens is where lens epithelial cells elongate to form lens fiber cells (Figure 5). Terminal differentiation of the epithelium eventually leads to the fiber layers of both the cortex and nucleus, with older fibers being located more centrally.

While the nucleus is denser, histologically, there is no distinction between the cortex and nucleus (Figure 5). The only appreciable difference is age, with older layers located more centrally. Interestingly, as the cortex and nucleus layers grow, the overall diopter strength of the lens increases owing to the increased diameter and curvature of the lens. The lack of organelles within the nucleus and cortex serves to provide an optically clear media for light transmission. The adult lens is almost three times the mass of its corresponding neonatal version, 90 mg to 250 mg.

In the adult, the lens lacks vascularity or innervation thus the metabolic demands of the lens are met by a constant flow of aqueous humor that serves as a conduit for both removal of waste and the delivery of nutrients.

Cataract formation and types of cataracts

Congenital cataracts

Congenital cataracts are lenticular opacities that cause significant light scattering at birth or are noted shortly after (Figure 6). An estimated 200,000 children worldwide are blind as a result of congenital cataracts, with an incidence of 40,000 in developing countries (1, 2). In regards to laterality, the prevalence appears to be the same for unilateral vs. bilateral (2). Surgical intervention for both unilateral and bilateral cataract is paramount to prevent long term deprivation amblyopia or visual loss (3, 4). Amblyopia is defined as a dysfunction in visual processing, characterized by poor visual acuity in one or both eyes and abnormal binocular depth perception (5). While both unilateral and bilateral cataracts are critical to detect, the long term severity of bilateral visual deprivation appears to be less than its unilateral counterpart (6).

Nuclear cataracts

A common cause of visual impairment in older adults is age-related cataract, which is subcategorized as nuclear, cortical or subcapsular in type. Cumulative incidence of nuclear, cortical and posterior cortical are 29.7%, 22.9% and 8.4% respectively (7, 8). Nuclear cataract is the most common age-related problem (Figure 7, Figure 8).

With age, nuclear fibers become more compacted and cause increased light scattering. As a result, sclerotic lens nuclei decrease in transparency and result in visual aberrations and annoying glare at night. Clinically, the sclerotic nuclear lens changes in color, from a clear transparent material to yellow or orange, eventually even to brown (brunescent) if left to mature (Figure 9). Histologically, nuclear sclerotic lenses are characterized by a dense homogenous material.

Aging causes the lenticular material to increase in overall size and become more amorphous. As the lens fibers continue to age, the nucleus becomes more compact and less pliable decreasing the ability of the lens to effectively accommodate. The increased coloration is due to protein aggregation in the nuclear lens, decreasing its transparency and leading to various symptoms including visual impairment, decrease in contrast sensitivity, dull color perception and a myopic shift.

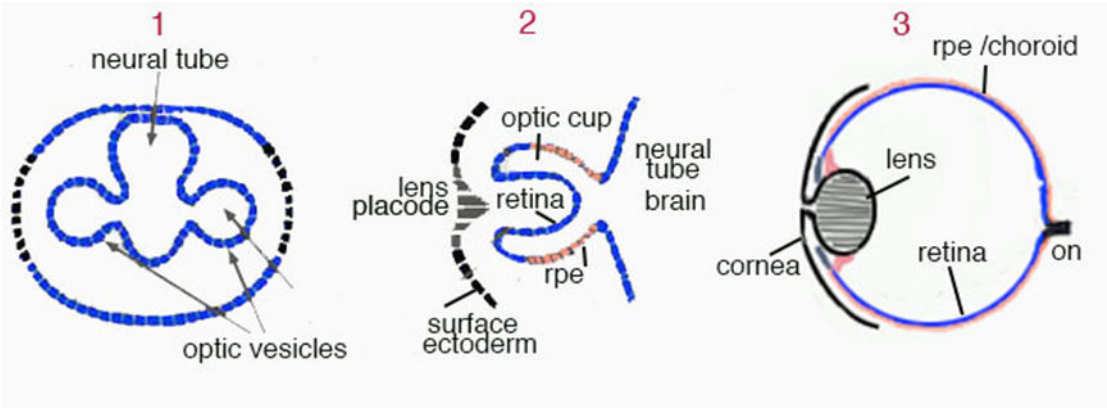

Figure 2a. A cartoon to show the development of the eye from the embryonic neural tube. 1. **Optic vesicles** form from the **neural tube**. 2. The **optic cup** forms by invagination, as the **retina** folds back upon the pigment epithelium. The developing optic cup induces the **lens placode** to be formed from the **surface ectoderm**. 3. Finally, the **lens** is pinched off and settles in place with the developing iris and ciliary body in the front of the eyeball. **rpe**; retinal pigment epithelium, **on**, optic nerve.

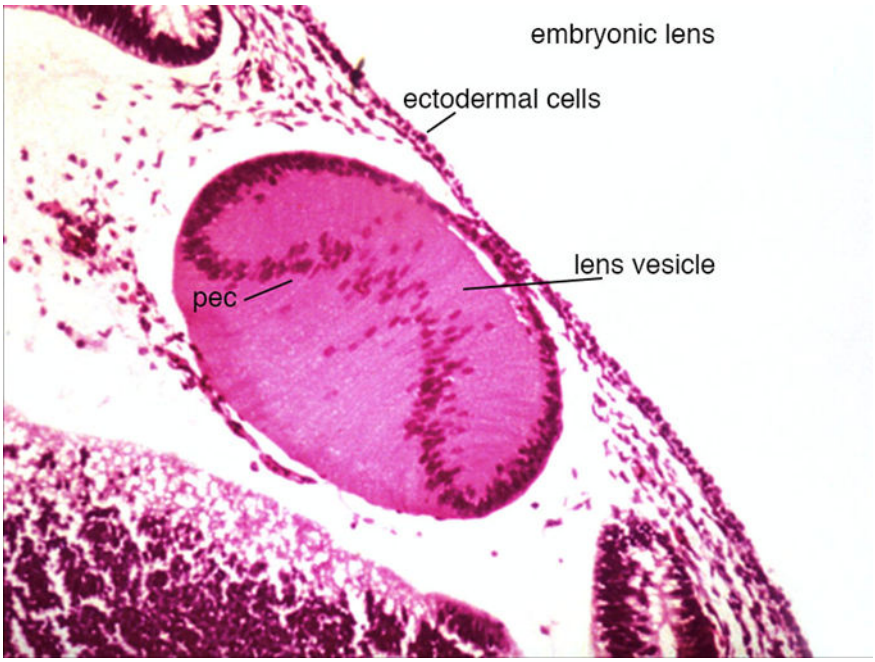

Figure 2b. **Embryonic lens**. **Lens vesicle** posterior epithelial cells (**pec**) elongate to form the primary lens fibers (H&E stain, X10).

As the cataract continues to mature, the cortical material begins to liquefy and the nucleus increases in opacity. A hyper-mature cataract is the final stage of the aging process. The liquefied cortex is resorbed, and the dense nucleus sinks within the capsular bag. If left untreated, proteinaceous material can leak across the capsular lining and cause trabecular meshwork (TM) obstruction leading to a phacolytic glaucomatous reaction. This inflammatory reaction is mediated by macrophages that respond to the leakage of lenticular protein and contribute to the TM obstruction. Changes within the lens nucleus do not occur independent of the other lenticular structure, instead, cortical subcapsular cataracts may and typically do occur simultaneously. However, nuclear sclerotic cataract is by far the most common age-related lenticular opacity.

Figure 10 shows a photograph of a patient's eye with dense mature cataract that has both nuclear and cortical (see below) components. Obviously, the patient was "blind" in this eye, and this cataract needed to be removed to restore sight to the eye.

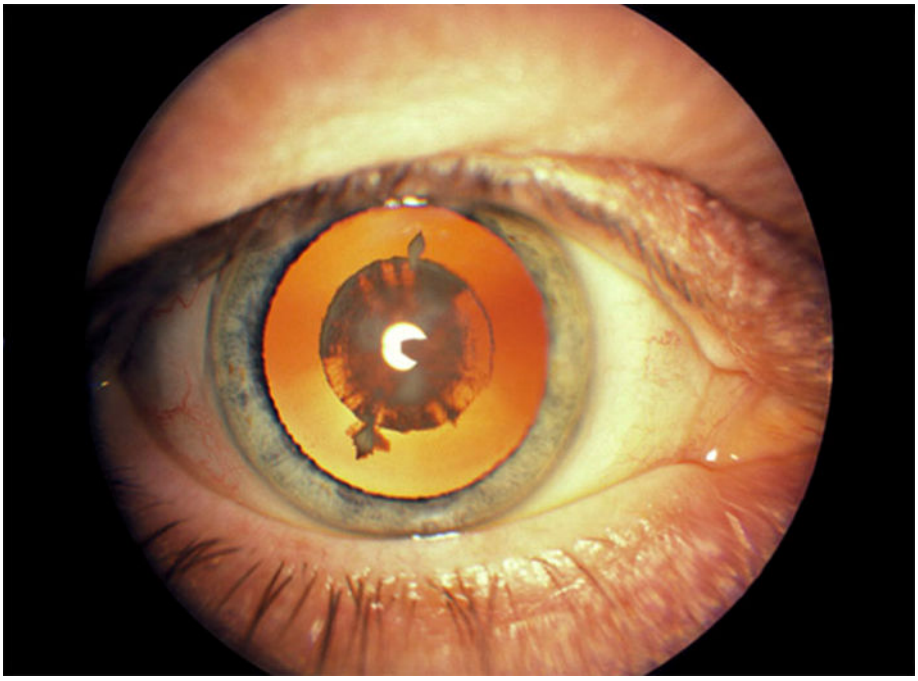

Figure 6. Clinical photograph of an eye with a dilated pupil to show a congenital cataract in the original fetal lens nucleus.

Cortical cataracts

As in nuclear sclerotic lens changes, aging can cause similar degenerative changes in the lens cortex. The opacities formed within the lens cortex are quite unique. Sharp clear fluid clefts, resembling opaque spokes

within the lens cortex, are seen. Figure 11 and Figure 12 show the typical appearance of cortical cataract shown from the front (Figure 11) and the back (Figure 12).

Histologically, cortical cataracts are characterized by an accumulation of pink staining eosinophilic fluid between cortical fibers (Figure 13). This fluid accumulation causes shifts between lenticular cells leading to displacement and degeneration of bordering cells. The shift accounts for the spokes seen clinically (Figure 11, Figure 12). Globules of proteinaceous material, called Morgagnian globules, may be released from the

Figure 9. Isolated brunescent cataract. Nuclear sclerotic cataract has a deep brown color with age.

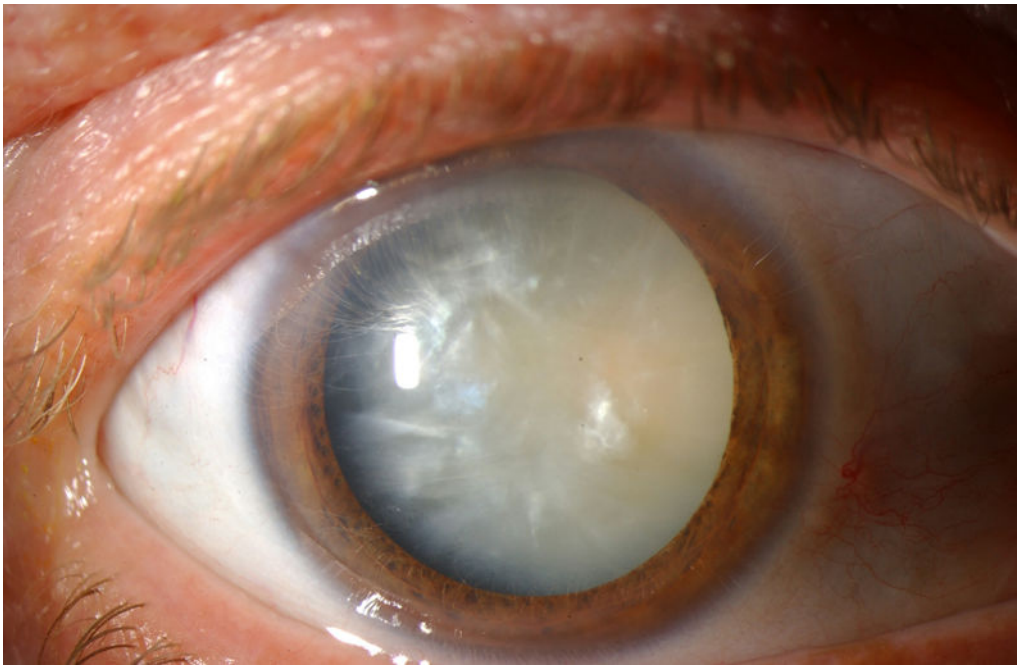

Figure 10. Photograph of a patient's right eye with a dense mature cataract. Courtesy of James Gilmore, Photography department at the Moran Eye Center.

degeneration of the cortical lens cells (Figure 14). As the cortical cataract continues to mature, the entire cortical region can be replaced by these globules and thus becomes a mature Morgagnian cataract (Figure 15).

Another characteristic appearance of the cortical cataract is a Christmas tree cataract. This occurs when crystals form within the deep cortex. These crystals are typically composed of cholesterol, lipids, calcium or other compounds. Interestingly, Christmas tree cataracts do not typically cause significant visual impairment.

While a cortical cataract can occur independently of a nuclear sclerotic cataract, biomechanical changes within the lens nucleus can actually induce cataractous changes in the lens cortex. The ability to effectively accommodate decreases with age, in general. The altered biomechanics between the sclerotic nucleus and cortex creates residual sheer stress and results in parallel micro-ridges at the area of lamellar separation. This process helps to explain the histologic patterns seen in cortical cataracts.

Posterior subcapsular cataract

Posterior subcapsular cataracts (PSC) develop due to the posterior migration of lens epithelial cells in response to external stimulus. Although most cases are spontaneous, PSC also can develop secondarily to metabolic causes, such as diabetes, inflammation, uveitis, or from long-term topical or systemic corticosteroid use. PSC tend to occur in younger patients and progress more quickly than the other cataract subtypes. The opacity is located at the posterior pole of the lens on the anterior surface of the posterior capsule (Figure 16, Figure 17).

An ultrastructural study involving 13 eyes with PSC showed the changes that took place as lens epithelial cells migrated from the equator of the lens to the PSC region. The study concluded that there was a mitotic change as cells migrated towards the posterior pole. The equatorial region cells resembled normal lens epithelial cells but the cells near the PSC showed increased mitotic activity. The authors suggested that the cells were responding to some type of noxious stimuli at the posterior pole. The resultant activity caused the cells to mature into lens fibers or enlarge into bladder-like cells called Wedl cells and the formation of PSC (Figure 18). The migrating cells probably contribute to cataract formation by secreting extracellular materials, cytolysis, cell dissolution, and possibly release of lysosomal enzymes (9).

Anterior subcapsular cataract

Anterior subcapsular cataracts (ASC) develop because of the degeneration of anterior lens epithelial cells. They can develop secondary to trauma, medical treatment iatrogenic causes, or spontaneously. The area of damage causes a migration of lens epithelial cells into the area and subsequent transformation of the cells into myofibroblasts in a process known as fibrous metaplasia. This results in an opacity on the anterior surface of the lens beneath the anterior capsule.

In one of the first studies on ASC, 5 lenses with ASC were examined by light and electron microscopy and confirmed the ability of the lens epithelium to undergo transformation to a fibrous plaque. The lens epithelial cells lost their normal cuboidal shape and elongated into a more spindle-shaped cell (Figure 19: a, b, c). These cells were found frequently to be in contact with one another, resulting in the fibrous plaque known as ASC. This process can be broken down into two phases: a proliferative and a degenerative phase. The proliferative phase was most evident near the periphery of the plaque, showing numerous spindle-shaped cells and mitotically active cells. It is followed by a degenerative phase, which results in an almost structure-less hyaline mass with fewer spindle-shaped cells (10).

Although the cause of ASC is varied, an association between ASC and the formation of synechiae after trauma or inflammation has been hypothesized. The synechiae would form between the posterior iris and anterior lens capsule, resulting in a stagnation of aqueous humor and accumulation of toxic metabolites that could produce a toxic effect on anterior lens epithelium (10).

Traumatic cataract

Direct injury to the head or eye can cause significant mechanical disruption and lead to cataract formation. A Vossius ring can occur if the insult caused the posterior iris pigment epithelium to imprint on the lens capsule. The pigment deposition may abate and resolve completely with time. Severe blunt injury can cause stellate lenticular opacities in the cortex and capsule. Such insult can lead to lens epithelium dysfunction, resulting in a significant edematous response to the superficial cortical lens. Vacuole pockets can then become trapped

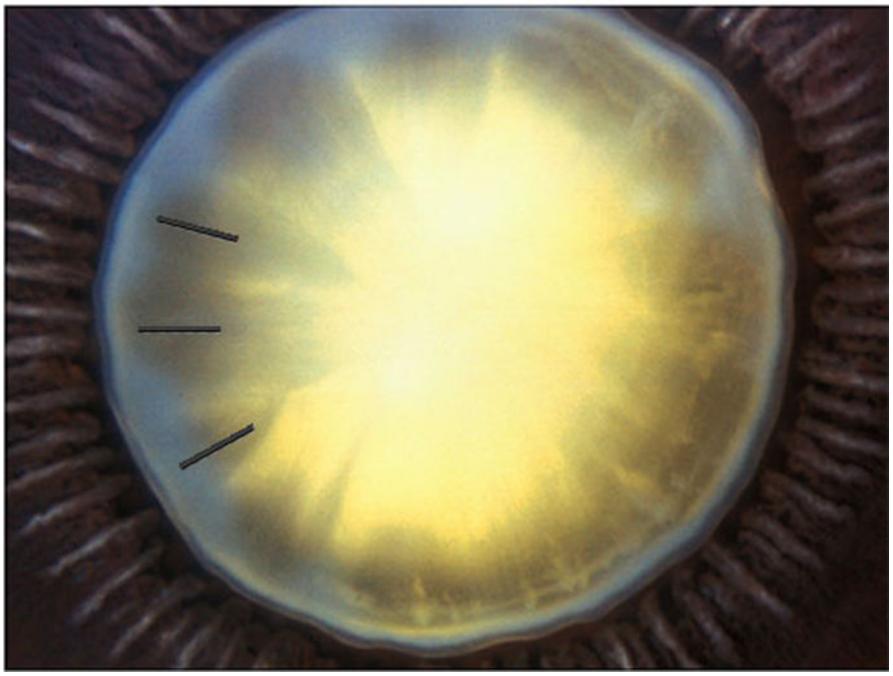

Figure 12. Posterior view of a cortical cataract using the Miyake-Apple technique to display the lens. The fluid clefts are obvious (black lines).

permanently within the lamellar zone, becoming integrated within the lenticular fibers while new layers are elaborated over the lesion. Alternatively, blunt trauma can also cause cataract formation within all the lenticular layers, leading to a diffuse fibrous metaplasia (Figure 20). Other forms of trauma that can lead to cataract formation include exposure to radiation, infrared, extreme heat and electrical injury.

Drug-induced cataract

Several pharmacological agents have been shown to cause cataract formation. Long term corticosteroid therapy and anabolic steroid use are among the most common agents associated with cataract formation, particularly posterior subcapsular cataract (11). The incidence and severity of PSC is directly related to the dose and duration of use (12). Interestingly, steroid therapy has become a frequent treatment option in the management of

retinal pathologies, and in turn increases the rates of cataract formation. There does not appear to be any distinction between PSC induced by steroid use or a pure age-related PSC (13). Phenothiazine is another

therapeutic agent that can cause lenticular opacities. Psychotropic agents, particularly phenothiazine, induce deposition of pigmented material into the anterior lens epithelium in a very distinct axial configuration (14). Other pharmaceutical agents known to cause lenticular cataracts include miotics, and amiodarone (15).

Other causes of cataract

While age-related changes remain the leading factor for cataract formation, specifically senile cataract, other contributory factors include smoking, systemic disease, excessive exposure to sunlight and the aforementioned pharmacological agents (16-19). Many systemic diseases can cause cataracts, such as, diabetes mellitus, hypocalcemia, myotonic dystrophy and Wilson's disease (19-21); In diabetic patients, cortical and PSCs appear to occur earlier, particularly among patients with poor glycemic control. Hypocalcemia-induced cataracts usually initiate as small white dot opacities that can coalesce into larger flakes.

Smoking, sun exposure and systemic disease management are modifiable risk factors, so taking measures to change these factors can delay the onset and progression of cataract formation. Phytonutrients, such as xanthophyll carotenoids, lutein and zeaxanthin may play a potential role in limiting or neutralizing light induced oxidative changes within the lens (22). Currently, there are several ongoing studies evaluating other possible protective agents. Although there is no definitive measure to prevent cataract formation, cataract surgery remains an extremely safe and highly successful intervention.

Cataract surgery

Surgery for cataracts has undergone extensive evolution. Ancient knowledge viewed the cataratous eye as an imbalance of humors that needed displacement to recover vision. Using a needle, the surgeon would proceed to displace the abnormal humor until the crystalline lens dislocated. Modern cataract surgery has undergone significant changes and is now characterized by several steps: corneal incision, continuous curvilinear capsulorrhexis (CCC), hydrodissection, phacoemulsification, cortical aspiration, and intraocular lens (IOL) implantation.

Earlier surgical interventions to remove the entire cataractous lens required a 12-mm incision with subsequent suture closure. However, a small 2.4 to 2.8 mm wide clear corneal incision is enough to facilitate entry of the phaco handpiece while remaining sutureless for closure. The CCC technique was developed by Gimbel and Neuhann in the 1980s and truly revolutionized the phacoemulsification technique (23). CCC involves creating a tear in the anterior capsule then continuing the tear in a circular continuous fashion while minimizing shear forces exerted on the zonular fibers. After creation of the CCC, phacoemulsification is used to fragment and emulsify both the cortical and nuclear material. Originally pioneered by Kelman in 1967, phacoemulsification remains a vital part of cataract surgery (24, 25). The CCC opening is large enough to allow implantation of the entire optic and haptics of an intraocular lens (IOL) within the remnant lens capsular bag. The prior use of non-foldable polymethylmethacrylate lenses required a relatively large clear corneal incision for implantation. However, the development of the foldable silicone and acrylic IOLs allowed insertion through a small incision mostly less than 4.0 mm in length. Innovation is constantly improving these steps of cataract surgery, from novel IOLs with unique design to minimize the corneal incision, to use of the femtosecond laser to create an automated corneal incision, CCC and to fragment the nucleus prior to aspiration (26, 27).

Details of the types of intraocular lenses, that are presently being used in cataract surgery, are presented in the following chapter in Webvision by Jason Nguyen, and Liliana Werner.

About the authors

Joah F. Aliancy, MD, originally from Haiti, received his undergraduate degree from the University of South Florida in Chemistry with honors distinction and his medical degree from Florida State University. Presently he is an ocular pathology research fellow at the John A. Moran Eye Center. In a year, Dr. Aliancy will attend the Harkness Eye Institute at Columbia University for his Ophthalmology residency training. His research interests

include novel intraocular lens technology, mechanisms to decrease capsular lens opacification, toxic anterior segment syndrome and nitric oxide as a treatment modality in glaucomatous disease. He has been honored with induction into both Alpha Omega Alpha and Gold Humanism Honor societies and recipient of the National Medical Association Rabb-Venable Award. Dr. Aliancy can be contacted at joah.aliancy@utah.edu.

Nick Mamalis is a Professor of Ophthalmology at the John A. Moran Eye Center of the University of Utah in Salt Lake City. He received his BA in Biochemistry from Harvard University and his MD from the University of Utah, School of Medicine. After a fellowship in Ophthalmic Pathology at the University of Utah he completed his residency in Ophthalmology at Loyola University Medical Center. He is currently the Director of Ophthalmic Pathology as well as the co-Director of the Intermountain Ocular Research Center at the University of Utah. He is the Editor of the *Journal of Cataract and Refractive Surgery* as well as a member of the Cataract Clinical Committee and the Executive Committee of the American Society of Cataract and Refractive Surgery (ASCRS). Dr. Mamalis is a former President of the Utah Ophthalmology Society. He was given the American Academy of Ophthalmology Honor Award in 1994, Senior Achievement Award in 2005, and a Life Achievement Honor in 2015. He was the recipient of the Brinkhorst Medal of Honor in 2013 by the ASCRS. He is known nationally and internationally, has published over 200 peer review journal articles and has written multiple textbooks and textbook chapters. Dr. Mamalis can be contacted at nick.mamalis@hsc.utah.edu.

Intraocular Lenses for Cataract Surgery

Jason Nguyen, MD[1,*] and Liliama Werner, MD, PhD[1,†]

Created: August 5, 2017.

Introduction

The crystalline lens contributes approximately +15 to +20 diopters (D) to the refractive power of the human eye in its non-accommodative state. A further 43 diopters is provided by the cornea (see chapter “Facts and Figures” in webvision). So, when cataracts occur (almost inevitably in the ageing eye) the cataractous lens must be removed to restore a clear image passage through to the retina. After removal of an opacified crystalline lens in cataract surgery, the refractive power of a normal clear lens needs to be restored (1) In modern cataract surgery, a central opening of approximately 5.5 mm is made to the anterior capsule of the crystalline lens (capsulorhexis) and the opacified contents within the capsular bag are then removed by phacoemulsification and irrigation/aspiration. An artificial intraocular lens (IOL) is then placed within the intact capsular bag. However, if an IOL is not implanted inside the eye, the refractive power of the removed cataractous crystalline lens can still be restored by contact lenses or spectacles (2). And that is what happened in the old days. The offending cataractous lens was removed and the patient was given a pair of thick spectacles. An eye with a natural crystalline lens is called a phakic eye and without a natural crystalline lens but with an IOL is called a pseudophakic eye.

During World War II, Sir Harold Ridley, an ophthalmologist in London, saw Royal Air Force casualties with eye injuries, and observed that when splinters of acrylic plastic from aircraft cockpit canopies became lodged in their eyes, this did not trigger inflammatory rejection as did glass splinters. This led him to propose the use of artificial lenses made of Perspex (polymethyl methacrylate - PMMA), to treat cataracts. On 29 November 1949 at St Thomas' Hospital, Ridley achieved the first implant of an IOL, although it was not until 8 February 1950 that he left an IOL permanently in place in an eye (2).

Cataract surgery with IOL implantation has now become the most prevalent eye operation in the United States with more than 3 million procedures performed in 2006 alone (3). For patients with dense cataracts this surgery has become a “miracle” restoring clear sight again. A variety of new artificial IOL designs, manufactured from different biomaterials, are continuously being made available to cataract surgeons nowadays. In this chapter, we provide an overview of the characteristics of IOLs used in cataract surgery (Video 1, Video 2), as well as possible complications associated with their use.

IOL materials

IOL materials can be broken down into four general types. The initial breakdown can distinguish between groups of lenses made of acrylic or silicone material. When describing acrylic lenses, composed of acrylic acid, they can be further broken down into non-foldable or foldable types, referring to their flexibility. The non-foldable lenses are made up of Polymethyl methacrylate (PMMA) material. Within the foldable lenses, they can be further broken up into hydrophobic acrylic or hydrophilic acrylic materials. Silicone lenses are the last group of materials, and all silicone lenses are foldable. The utility of flexible, foldable materials is that the lenses can

then be inserted (with forceps) or injected (with injector systems) into the eye via small incisions, generally 3.0 mm wide or less (4-7).

Polymethyl methacrylate (PMMA) lenses were the first lenses to be used in the human eye (in 1949). They were rigid and required a large incision to be placed in the eye. As cataract surgery technology has advanced, they are now the least used IOL material in developed countries (5).

The decrease in usage of PMMA lenses was primarily attributed to the advent of small incision cataract surgery techniques utilizing ultrasound phacoemulsification, and the increase in popularity of the foldable acrylic lenses. Foldable acrylic lenses can either be composed of hydrophobic acrylic or hydrophilic acrylic material. Generally, hydrophobic acrylic lenses absorb very little water (<1%). On the other hand, hydrophilic acrylic lenses absorb significantly higher amounts (18-38%). Each currently available foldable acrylic lens design is manufactured from a different copolymer acrylic, resulting in a different refractive index, glass transition temperature (the polymer is flexible above this temperature and rigid below), water content, mechanical properties, etc. The flexibility and high water-content allows for certain hydrophilic acrylic lenses to be inserted through very small incisions, approximately 1.8 mm, in microincision cataract surgery (4).

Silicone lenses were the first foldable IOLs available on the market. They are composed of a polyorganosilone backbone and have refractive indexes (e.g., 1.46) that are usually lower than those of acrylic lenses (e.g., 1.55). As a result, they are thicker lenses than their acrylic counterparts (4,7).

Ultraviolet (UV)-absorbing compounds (chromophores) are another important element of the IOL optic component. They protect the retina from UV radiation in the 300-400 nm range, a feature normally provided by the normal crystalline lens. Yellow hydrophobic acrylic IOLs containing a blue light-filtering chromophore (different from the standard chromophore for protection against UV radiation) are also available on the market (Figure 1). The addition of a covalently bonded yellow dye results in an IOL with an UV/visible light transmittance curve that mimics the protection provided by the normal crystalline lens in adult humans. There is indirect evidence showing that this may result in a reduction of the risk for development and progression of macular degeneration. But this remains a controversial issue (4).

IOL designs

In modern cataract surgery, an IOL is ideally fixated within the capsular bag. If the capsular bag is not intact at the end of surgery, an IOL can still be fixated at other sites. However, the design of the lens has to be adapted for implantation in each different site of fixation. IOL designs can be categorized in different ways. According to the fixation site, IOLs may be implanted in the anterior or posterior chamber of the eye. Anterior chamber lenses can be placed in the anterior chamber angle or fixated to the iris. Posterior chamber lenses can be fixated within the capsular bag or the ciliary sulcus (Figure 2) (5).

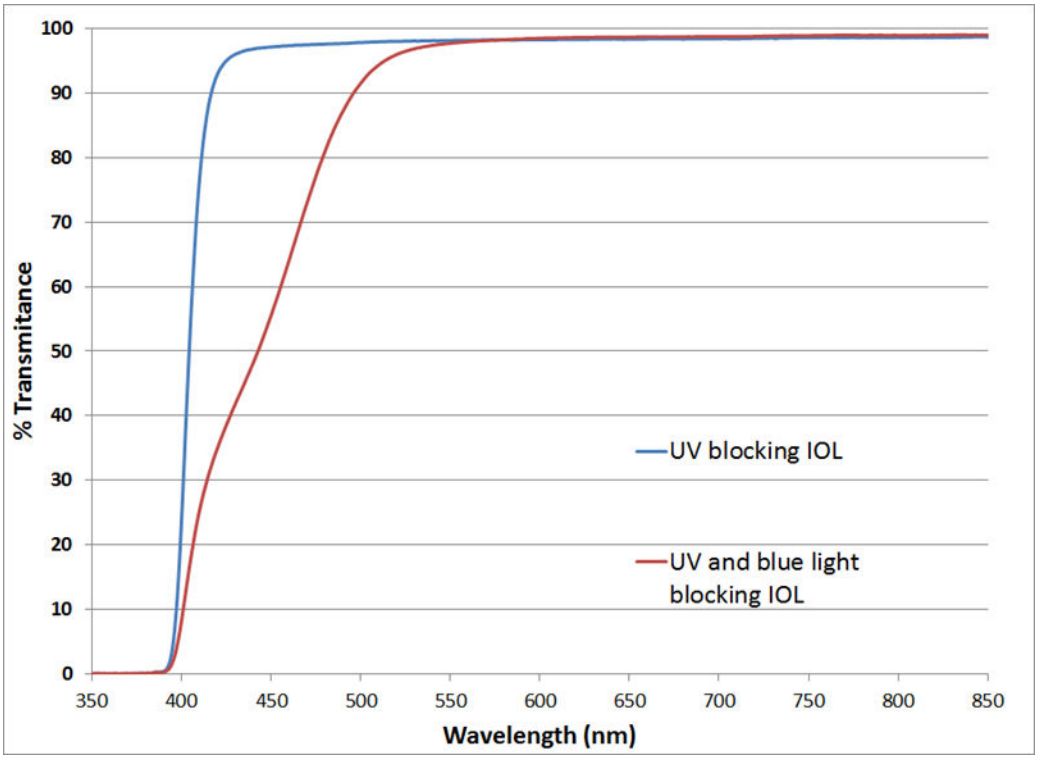

Figure 1: Light transmittance curves of a UV blocking IOL and a UV blocking IOL with a blue chromophore added. The curves demonstrate the difference in light transmittance between the two lenses. The addition of the blue-light filtering chromophore (red line) shifts the curve to the right, providing additional protection similar to that of a normal crystalline lens.

IOLs can also be described as single-piece (the entire lens is manufactured from the same material) or multi-piece (generally described as 3-piece lenses, the optic lens from one source and the loops manufactured from a different material). Anterior chamber lenses placed in the angle that are currently available on the market are based on the Kelman Multiflex design (Figure 3). These are single-piece lenses made of PMMA with open loops. The overall diameter of these lenses generally ranges between 12 and 14 mm. The size is chosen according to the anterior chamber diameter of the eye receiving the implant. There is an angulation between the optic component and the loops that makes the optic more anteriorly located.

Anterior chamber lenses fixated to the iris are generally based on the iris-claw design (Figure 4). These lenses are also single-piece lenses made of PMMA, with an overall diameter of approximately 8.5 mm. The fixation of the lens to the iris stroma is obtained through small claws situated on both sides of the optic component (Figure 4, arrows) (5).

Posterior chamber lenses designed for fixation within the lens capsular bag come in a large variety of designs (Figure 5). They can be single-piece or multi-piece lenses. Single-piece lenses may be open loop designs or overall plate lenses. Overall plate lenses can incorporate a number of different fixation elements, generally represented by small open or closed loops (otherwise known as haptics). Different materials may be used for the manufacture of the haptic component of three-piece lenses, including PMMA, polypropylene (Prolene), polyimide (Elastimide) and poly(vinylidene) fluoride (PVDF) (5,8). Fixation of flexible-looped IOLs is achieved by exerting centripetal pressure on the surrounding ocular tissues. During IOL insertion, the loops are bent centrally and re-expand as the forces exerted on the loops are released. The two factors that contribute to the ability of IOL loops to maintain their original symmetrical configuration are loop rigidity, the resistance of the haptic to external forces that act to bend the loops centrally, and loop memory, the ability of the loops to re-expand laterally to their original size and configuration. Ideally, IOL loops should have enough flexibility to allow easy insertion and accommodation to the circular shape of the eye. Furthermore, they should prevent

damage to supporting structures during insertion and in the postoperative period. They should also have appropriate rigidity to resist external forces, such as capsular bag contraction from capsular fibrosis (8).

There must be some angle between the optic component and the loops of 3-piece lenses manufactured for implantation in the posterior chamber of the eye (capsular bag or ciliary sulcus (Figure 2), to make the optic component more posteriorly located. If the capsular bag is not intact at the end of the surgery, a posterior chamber lens may be fixated in the ciliary sulcus, in front of the anterior lens capsule if there is enough capsular support present. Clinical evidence suggests that IOLs fixated in the sulcus should have a smooth rounded anterior optic edge and thin haptics (Figure 6, A). This will minimize their interaction with the posterior iris surface and prevent complications such as pigmentary dispersion syndrome (9,10). The diameter of ciliary sulcus fixated lenses must be sufficiently large to prevent IOL displacement from the center (at least 13 mm). If the residual capsular support is insufficient, a posterior chamber lens can still be fixated in the ciliary sulcus by suturing the IOL loops to the sclera. There are also techniques to suture the loops of these lenses to the iris.

Biocompatibility

Biocompatibility is one of the most important prerequisites of an IOL. It is important to note that IOLs are progressively being used at earlier stages of life. As a result, it is vital that they can stay in the intraocular environment and remain transparent without complications for many years.

The term uveal biocompatibility is generally used to describe the inflammatory response of the eye towards the artificial IOL (foreign-body reaction) (11-13). Cataract surgery with implantation of an IOL results in a breakdown of the blood-aqueous barrier, causing a release of proteins and cells into the anterior chamber. Protein adsorption on the surface of the IOL is the first phenomenon observed and it influences the subsequent cell interaction between the interface material and tissue. The complement system is activated by the alternative pathway, which results in the attraction of polymorphonuclear leukocytes and monocytes. These cells are the beginning of the macrophages and giant cells that constitute a foreign-body reaction against the IOL (Figure 7). Inflammatory cell deposits are a normal occurrence on the lens surface for up to 1 year after surgery. This consists of two distinct processes: a response with small round and fibroblast-like cells, which peaks by 1 month, and a later giant cell response, which peaks at 3 months. Giant cells then degenerate and detach from the IOL surface, leaving only an acellular proteinaceous membrane usually surrounding the IOL, which isolates it from the surrounding ocular tissues (11-13).

One of us (Liliana Werner) reviewed several published studies that analyzed postoperative flare values and found that there were no clinically relevant differences between different biomaterials. She further went on to note that there was variation in the intensity and duration of each cellular inflammatory response (small cells or giant cells) amongst different biomaterials. However, the cellular reaction was low grade and therefore clinically insignificant (4).

Capsular biocompatibility

When discussing capsular biocompatibility, the relationship of an IOL with remaining lens epithelial cells (LECs) within the capsular bag after cataract surgery (11), it is important to understand the epithelium of the normal crystalline lens. This consists of a sheet of anterior epithelial cells ("A" cells) that are in continuity with the cells of the equatorial lens bow ("E" cells) (see Chapter on "Lens and Cataract" in Webvision, by Alliancy and Mamalis). The two cell types differ in function, growth patterns, and pathologic processes. E cells are germinal cells that undergo mitosis and form new lens fibers, whereas A cells do not. When disturbed by pathologic processes (or surgery), A cells do not have the tendency to migrate whereas E cells tend to migrate posteriorly toward the posterior lens capsule. A-cells tend to transform into fibrous-like tissue (fibrous metaplasia). In contrast, E cells typically enlarge into bladder-like cells referred to as Elschnig pearls (see accompanying chapter). These cells' differences become particularly important when examining different forms of

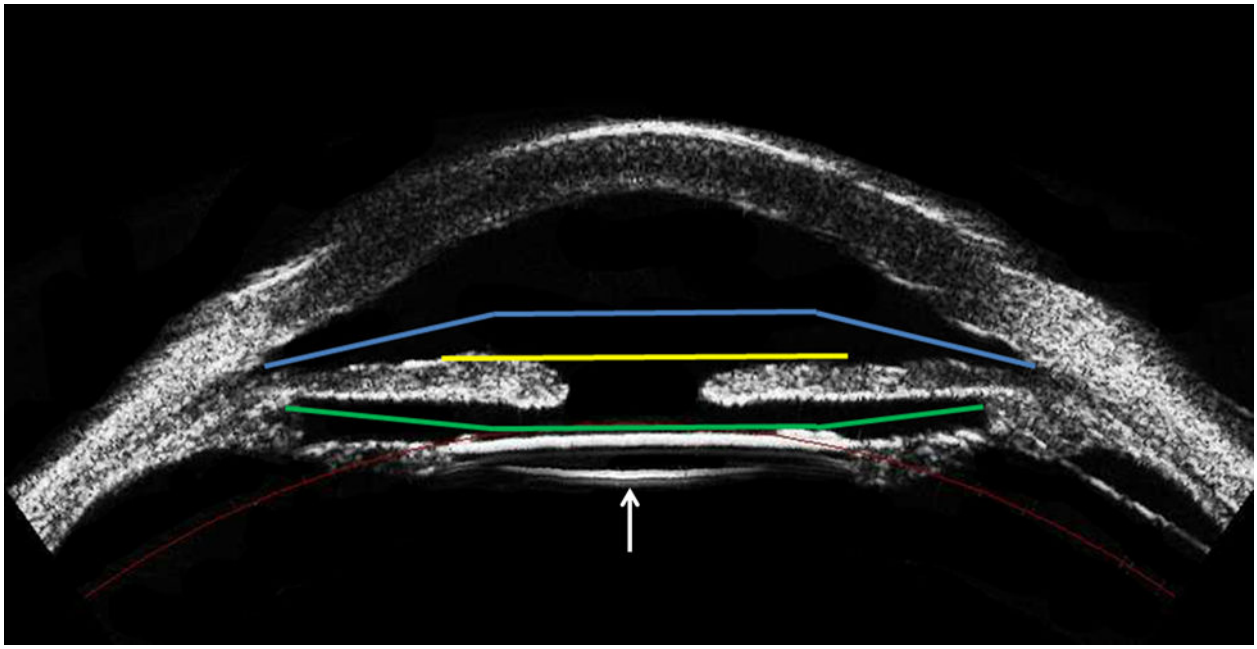

Figure 2: High-frequency ultrasound scan of the anterior segment of a human eye containing an IOL fixated within the capsular bag (arrow). The colored lines indicate the other sites where an IOL can be fixated in the anterior and posterior chambers. Blue: Anterior chamber angle. Yellow: Iris. Green: Ciliary sulcus.

postoperative opacification of the capsular bag, such as anterior capsule opacification and posterior capsule opacification (14).

Anterior capsule opacification (ACO) occurs as a result of the anterior surface of an IOL optic coming in contact with the posterior aspect of the residual anterior lens capsule (Figure 8). This causes the A cells of the lens to undergo fibrous metaplasia and results in capsule opacification (15-16). ACO is essentially a fibrotic reaction. This is of concern due to the development of the new accommodating IOLs, which are usually designed to move within the capsular bag during accommodation. The resulting fibrosis may restrict these movements.

Contraction of fibrotic tissue may also cause capsulorhexis phimosis (which is the decrease in diameter of the capsulorhexis opening to less than 3 mm), which may lead to the IOL being thrown off center and possibly even deformation of IOLs that are very thin and flexible (Figure 9) (17-19). ACO may be prevented by surgical polishing of the inner surface of the anterior capsule during surgery that results in the removal of residual A cells. Also, ACO can be prevented by implantation of an IOL that does not maintain a large area of contact with the inner surface of the anterior capsule (20).

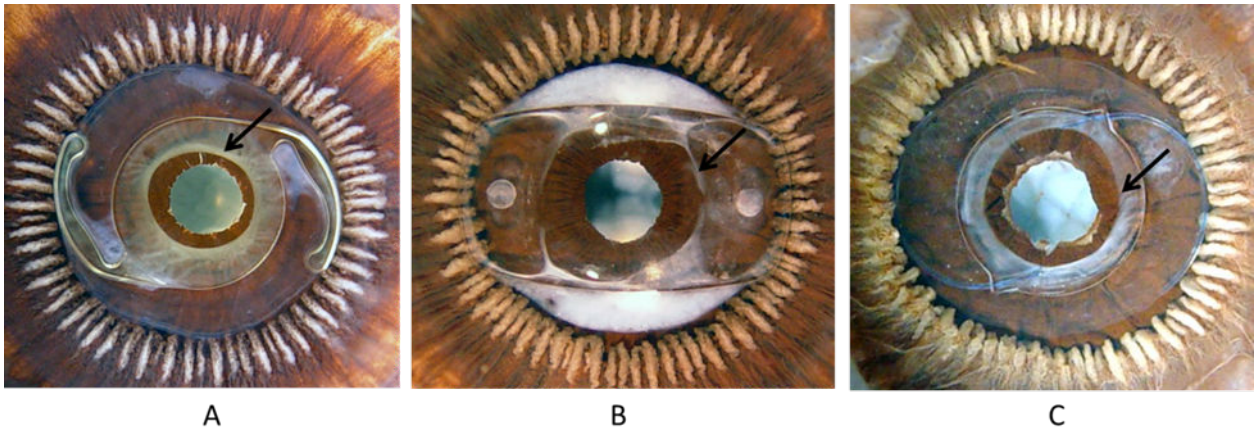

Figure 5: Gross photographs taken from the posterior or Miyake-Apple view of the anterior segment of pseudophakic human eyes obtained postmortem, showing different designs of posterior chamber IOLs. The arrows show the capsulorhexis opening in all eyes. A) Single-piece hydrophobic acrylic IOL. The loops and optic are made of the same material. B) Plate haptic silicone IOL. C) Multi-piece silicone IOL, with PMMA loops.

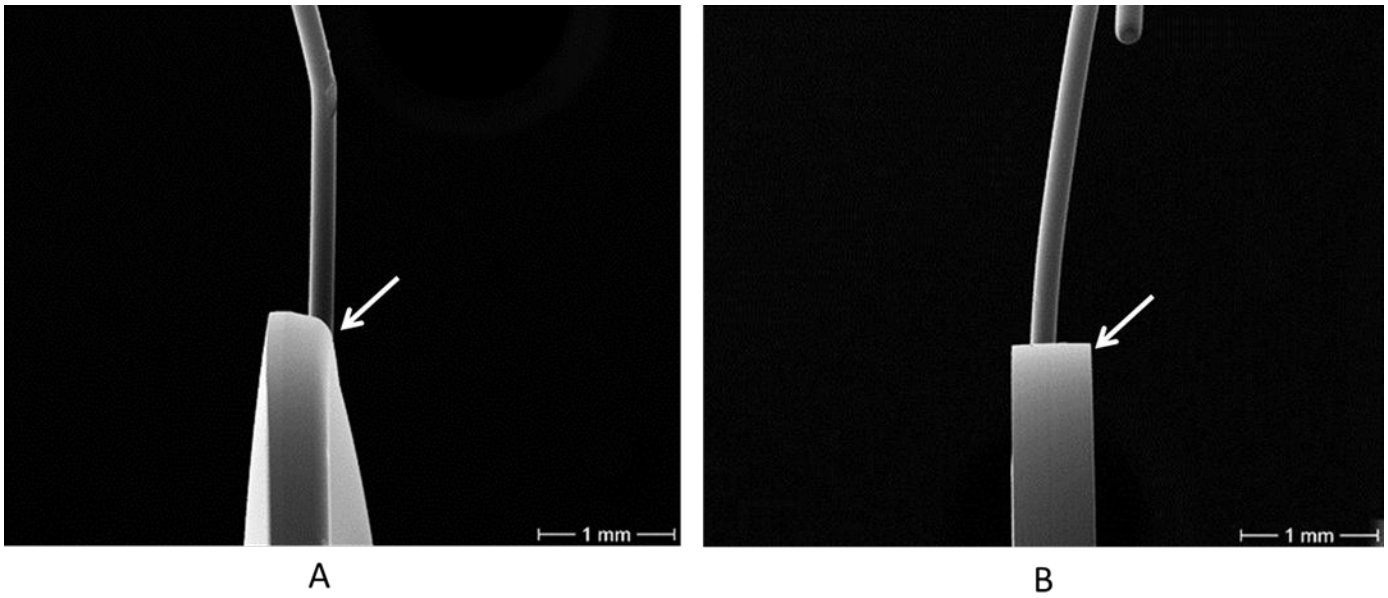

Figure 6: Scanning electron photomicrographs of two types of 3-piece hydrophobic acrylic IOLs. The arrows show the anterior optic edge of the lenses. A) Round edge. B) Square edge.

Whereas ACO is more of an effect of the residual A cells, posterior capsule opacification (PCO) has fibrotic and regeneratory or "pearl" components (21-24). PCO is the most common postoperative complication of cataract surgery, occurring at a rate of between 3-50% in the first five postoperative years. It occurs because of residual LECs that remain within the capsular bag following the removal of the crystalline lens during cataract surgery. These cells can proliferate and migrate across the posterior capsule where they may cause wrinkling and complete opacification of this structure. As a result, the patient will describe distortion, decrease of vision, and glare. The LECs have higher proliferative capacity in younger patients; therefore, the incidence of PCO formation is higher (21-24).

Regeneratory PCO is attributed more to the action of residual E Cells (24). These cells are responsible for formation of a Soemmering's ring, defined as a doughnut-shaped lesion composed of retained/regenerated

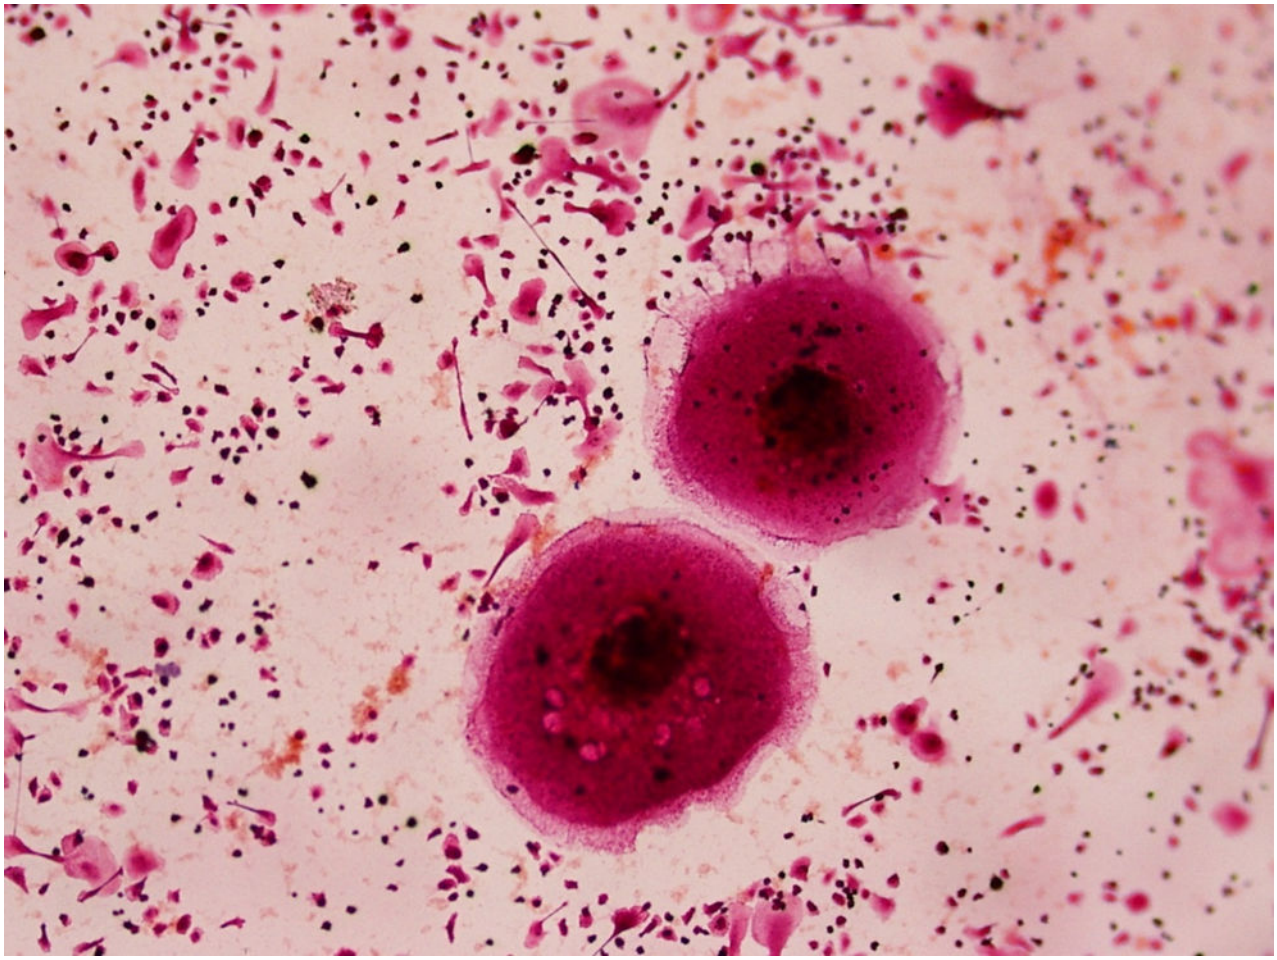

Figure 7: Light photomicrograph of an explanted IOL after implant cytology stain. Cell deposits composed of 2 giant cells, multiple fibroblastic-like small cells, and macrophages can be observed on the surface of the lens.

cortex and cells that may form following any disruption of the anterior lens capsule. For practical purposes, it is useful to consider this lesion as the basic precursor of classic PCO, especially the "pearl" form (Figure 10) (23).

The treatment of PCO is typically neodymium:YAG (Nd:YAG) laser posterior capsulotomy (Figure 11). This is a simple procedure in most cases, but it is not without risks. Complications include IOL damage, IOL subluxation or dislocation, retinal detachment, or secondary glaucoma. Therefore, prevention of this complication is important, not only because of the risks associated with its treatment, but also because of the costs involved in the procedure (14, 23).

While basic research on the effective mechanism for PCO eradication evolves, the practical surgeon can already apply some principles to prevent it. Studies in our laboratory and clinical studies at other centers resulted in the definition of three surgery-related factors that help in the prevention of PCO: 1) Hydrodissection-enhanced cortical clean-up, 2) In-the-bag IOL fixation, and 3) Performance of a capsulorhexis slightly smaller than the diameter of the IOL optic (for a shrink-wrap effect of the IOL by the capsule). The same studies helped in the definition of three IOL-related factors for PCO prevention: 1) Use of a biocompatible IOL to reduce cellular proliferation, 2) Enhancement of the contact between the IOL optic and the posterior capsule, and 3) An IOL with a square, truncated posterior optic edge. The last two IOL factors enhance the barrier effect of the IOL optic against material coming from the Soemmering's ring, a precursor for PCO (Figure 12) (14, 23, 25-30).

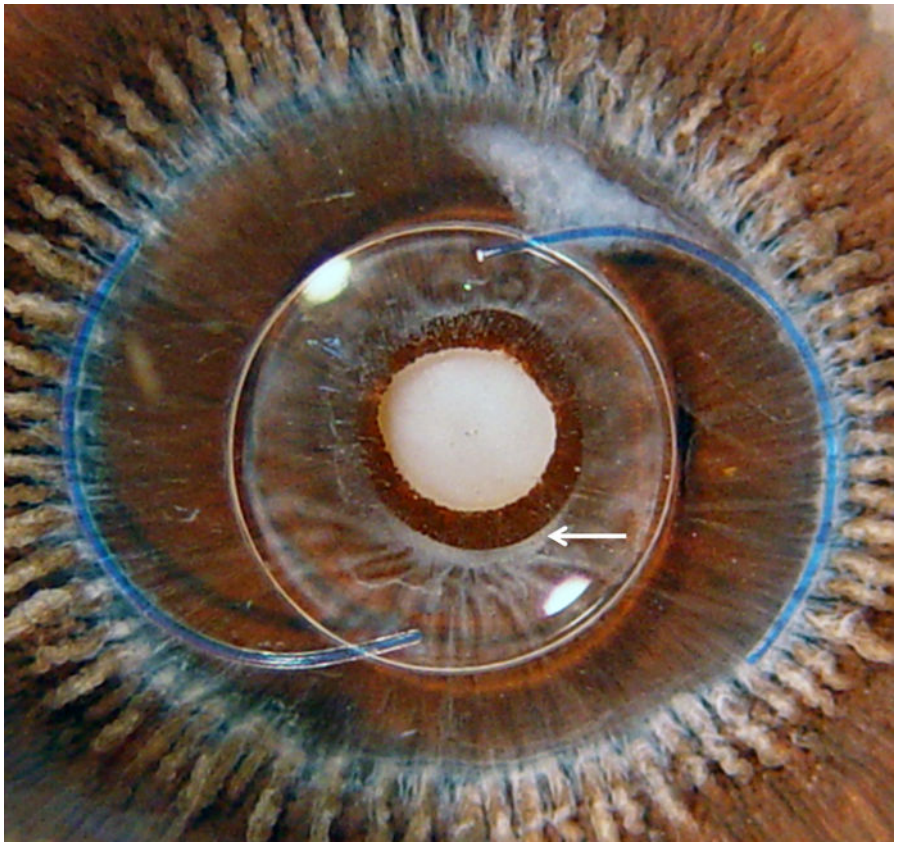

Figure 8: Gross photograph taken from the posterior or Miyake-Apple view of the anterior segment of a pseudophakic human eye obtained postmortem, containing a 3-piece silicone lens. The anterior capsule is opacified where it keeps contact with the IOL surface. The arrow indicates the phimosis of the capsulorhexis opening (the opening is less than 3 mm in diameter) that can take place due to contraction of fibrotic tissue.

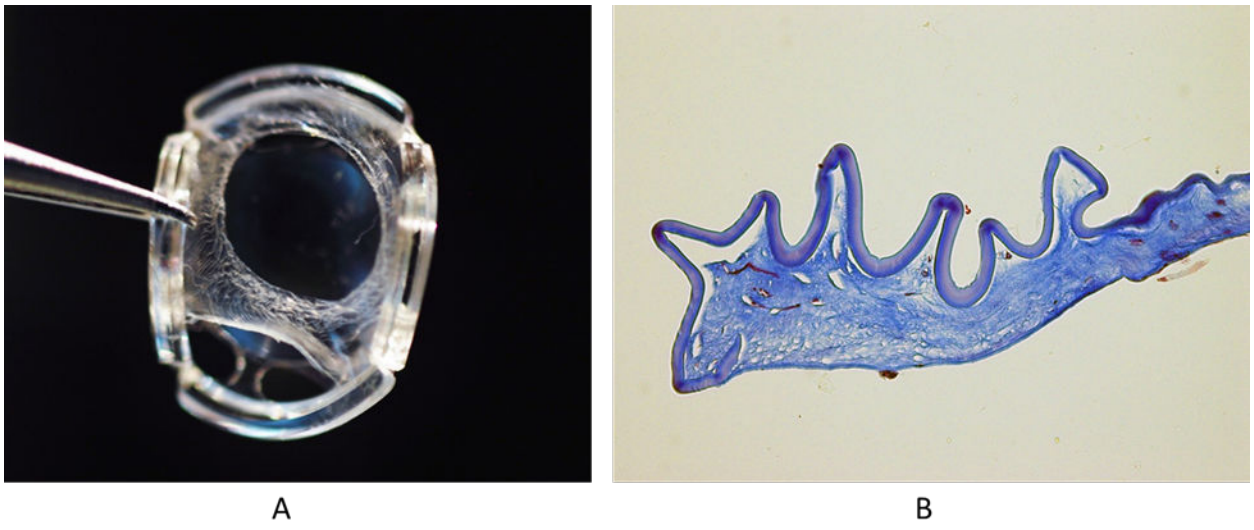

Figure 9: A) Gross photograph of an IOL that was explanted within the capsular bag. The IOL is deformed/flexed due to extreme contraction of the capsular bag. B) Light photomicrograph of a histopathological section cut through the same specimen, showing the fibrotic tissue attached to the inner surface of the anterior capsule. Contraction of the tissue led to significant folds in the anterior capsule.

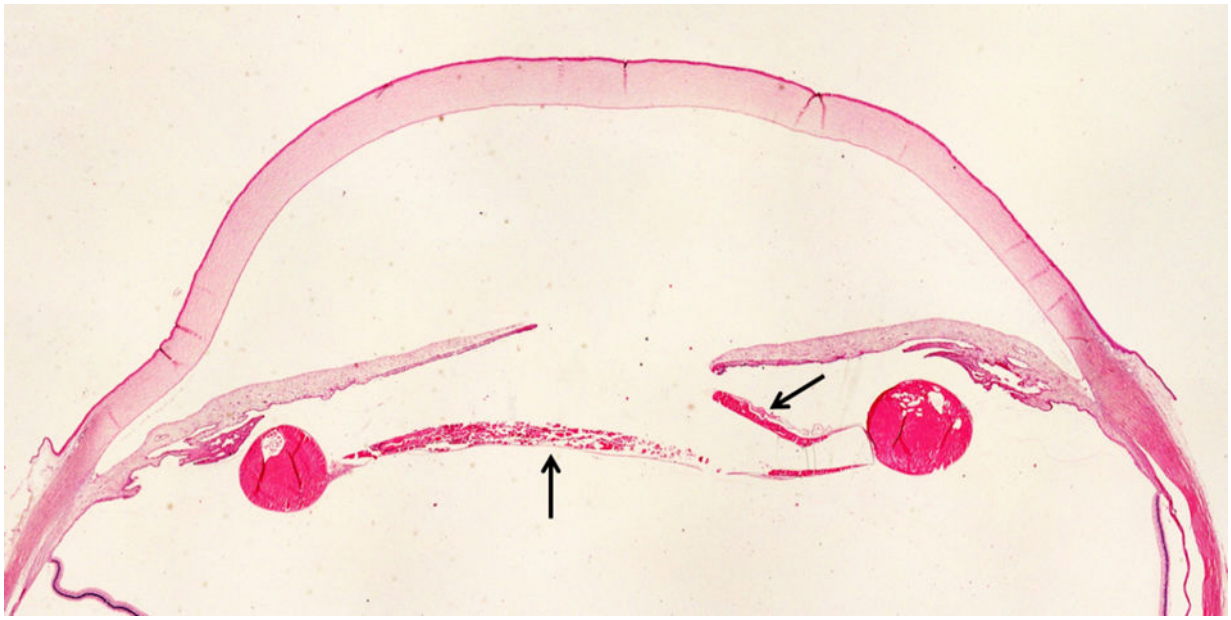

Figure 10: Light photomicrograph of a histopathological section cut through a rabbit eye that had been implanted with an IOL. Soemmering's ring formation (red spherical structures) can be seen on both sides of the section. The arrows indicate the anterior and posterior capsules, which are opacified due to proliferative material growing on their inner surface.

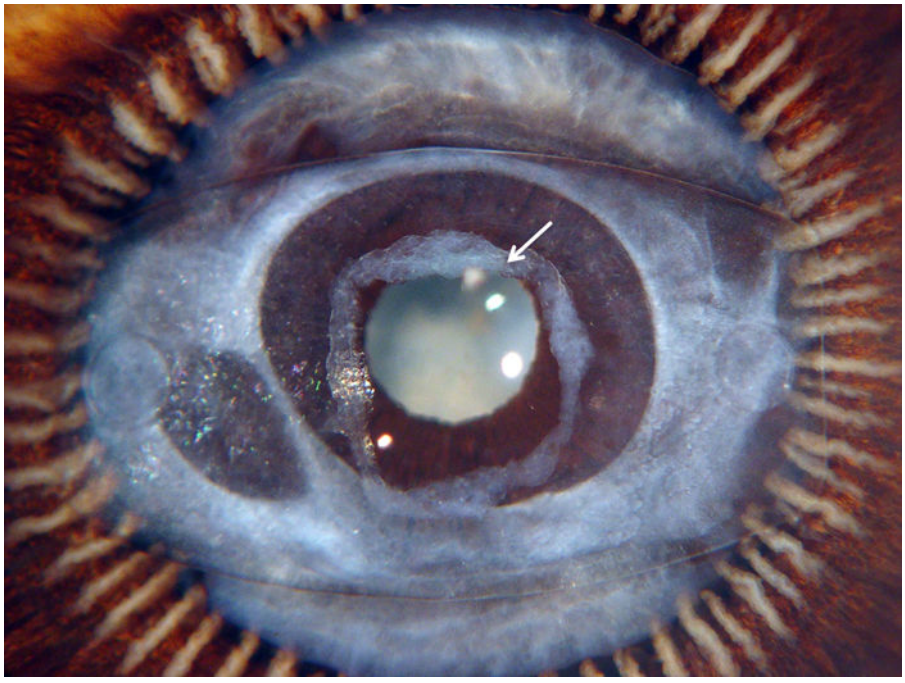

Figure 11: Gross photograph taken from the posterior or Miyake-Apple view of the anterior segment of a pseudophakic human eye obtained postmortem, containing a silicone plate lens. The eye exhibits anterior and posterior capsule opacification. The arrow indicates the opening of the Nd:YAG laser posterior capsulotomy, which was performed to treat PCO.

Causes of IOL opacification

Postoperative opacification of the IOL optic is a rare complication, but it can ultimately lead to the necessity of explantation and exchange of the IOL because of decreased visual function (31). Postoperative calcification may be observed with some hydrophilic acrylic lenses. Additionally, silicone lenses can also suffer from calcification

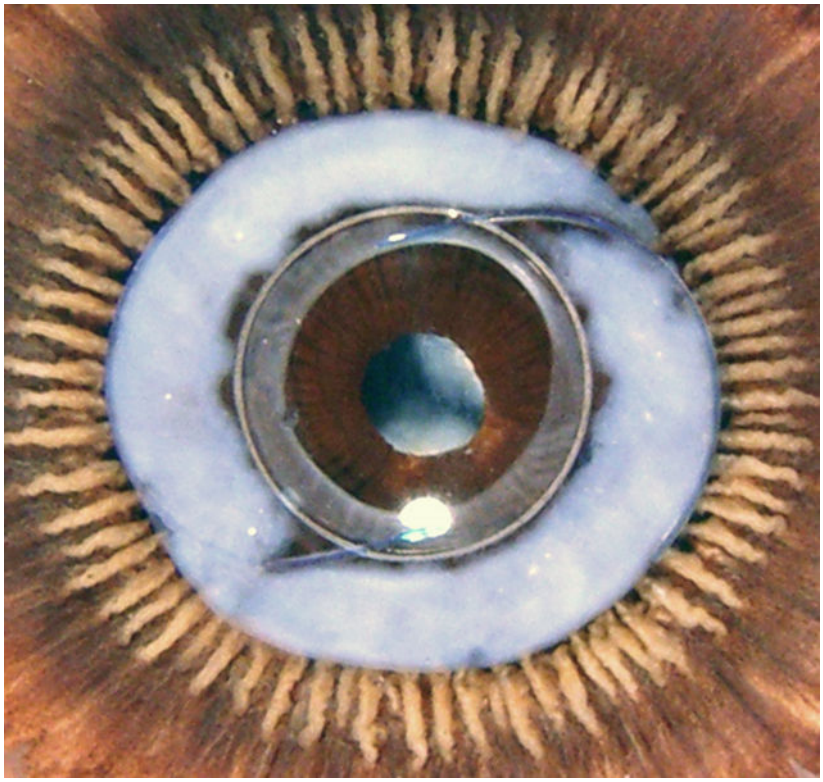

Figure 12: Gross photograph taken from the posterior or Miyake-Apple view of the anterior segment of a pseudophakic human eye obtained postmortem, containing a 3-piece silicone lens. A prominent Soemmering's ring formation can be observed. The square edge of the IOL optic caused a barrier effect, preventing PCO formation. The anterior capsule is opacified where it keeps contact with the IOL surface (ACO).

in certain conditions (history of asteroid hyalosis, which is a condition where there are many calcium deposits floating in the vitreous). Some PMMA lenses may exhibit a specific form of degeneration called snowflake degeneration (32).

Calcification of hydrophilic acrylic lenses appears to be caused by many problems. Factors related to IOL manufacturing, IOL packaging, surgical techniques and adjuvants, and the patient's metabolic condition are possible causes. As the exact combination of factors and sequence of events ultimately leading to calcification of the lenses is still unsure, continuous research on this complication is ongoing (32,33). The majority of the studies on calcified hydrophilic acrylic lenses describe explantation during the second postoperative year or earlier. In some cases the deposits causing the opacification are found on the optical surface or subsurface of the lenses (Figure 13, A, B) (34,35). However, in other cases they are predominantly found within the optic substance (Figure 13, C) (36,37).

In cases of calcification of silicone lenses in eyes with asteroid hyalosis, studies demonstrated deposits only on the posterior optic surface of the lenses (Figure 13, D). The deposits can be partially removed with Nd:YAG laser, but there is a re-accumulation after the procedure because the asteroid bodies are rich in calcium/phosphate. Asteroid hyalosis is a degenerative condition in which hydroxyapatite (calcium/phosphate) bodies form in the vitreous of the eye. The opacification formed on the silicone IOLs is unique because this type of calcification had not been reported in patients without asteroid hyalosis (38-41).

Snowflake degeneration is a slowly progressive opacification that has been observed in three-piece PMMA lenses implanted between the early 1980s and the mid-1990s. They were generally manufactured by a technique called injection molding. Snowflake degeneration is the result of PMMA degradation caused by long-term UV light exposure, not calcium deposition. The degree of optic opacification on the majority of the PMMA lenses

requiring explantation may take 10-20 years to develop. The intraoptic spherical lesions (resembling snowflakes) observed in these cases are thought to correspond to sites of degenerated PMMA material. The lesions are clustered around the center of the optic as opposed to the periphery, which could be protected from UV exposure by the iris (Figure 14) (42-46).

Conclusion

In summary, cataract surgery is the most prevalent operation in the United States, and likely worldwide, resulting in implantation of large numbers of artificial IOLs every year. A variety of new IOL designs, manufactured from different biomaterials, are continuously being made available to cataract surgeons to replace the refractive power of the removed opacified crystalline lens. The biomaterials used in IOL manufacture are basically divided into acrylic (rigid and foldable) and silicone (foldable). Posterior capsule opacification PCO remains the most common postoperative complication of cataract surgery. Its incidence has decreased over the past few decades as the understanding of its pathogenesis has become available. Advances in surgical technique, IOL design, and materials have all contributed to the gradual decline in PCO incidence. Although relatively rare, explantation of an IOL may be required due to problems related to postoperative opacification of the IOL, among others. With the increasing number of new lenses in the market every year, constant vigilance regarding overall IOL biocompatibility is warranted and ongoing in our laboratory.

About the authors

Liliana Werner, MD, PhD is a Tenured Professor of Ophthalmology and Visual Sciences, and Co-Director of the Intermountain Ocular Research Center, at the John A. Moran Eye Center, University of Utah. She has an MD/Ophthalmology degree from Brazil, and a PhD degree (Biomaterials) from France (Université Paris V, René Descartes). Dr. Werner's research is centered on the interaction between ocular tissues and different intraocular lens designs, materials and surface modifications. These include intraocular lenses implanted after cataract surgery, and also phakic lenses for refractive surgery and ophthalmic implantable devices in general. She has authored more than 300 peer-reviewed publications and book chapters on the subject, co-edited 3 books, and received numerous awards in international meetings for scientific presentations, videos and posters. She has also been a guest speaker in different international meetings in at least 20 countries, and is a consultant for different companies manufacturing IOLs and other ocular biodevices. Liliana can be reached at liliana.werner@hsc.utah.edu

What is glaucoma?

David Križaj, Ph.D.[1,2,3,4,*]

Created: May 30, 2019.

Abstract

Glaucoma, a leading cause of blindness in the world, can be challenging to diagnose because symptoms often appear at late stage of the disease, and challenging to treat because of the irreversible loss of retinal neurons. The term encompasses a heterogenous group of diseases that are characterized by altered biomechanics of anterior and posterior eye. These diseases tend to manifest as stiffening of the trabecular meshwork and increased production/reduced drainage of aqueous humor, together with retinal inflammation associated with activated microglia, Müller cells and astrocytes, and degeneration of retinal ganglion cells. In general, the phenotype is caused by a conjunction of risk factors such as age, family history, ethnic origin, high myopia, vascular disease and intraocular pressure (IOP). Current treatments are limited to lowering and stabilizing IOP, indicating that glaucoma is principally a disease of ocular mechanotransduction. Although the events that lead from IOP elevations to ganglion cell damage are not well defined, a body of recent work has pointed at mechanotransducing TRPV4, piezo and TREK-1 channels and immune mechanisms as key pressure targets in trabecular meshwork, ciliary body, retinal ganglion, endothelial cells and glia. Data indicate that dysfunctions of mechanotransduction mechanisms within the ganglion cell soma-dendrite, Müller cells and microglia may precede axonal degeneration, cupping of the optic nerve head and visual field damage which over the years have represented the golden standard of glaucoma diagnosis. Collectively, these recent studies predict the development of new therapies and diagnostic strategies to be contingent upon systematic delineation of molecular mechanisms that sense and transduce pressure in the eye. Thus, neuroprotection, a currently elusive goal, may be achieved via parallel suppression of pressure sensing in the anterior eye, retinal neurons, blood vessels and glia in order to achieve normalization of neuron-glia-blood vessel interactions, and the attendant reduction in immune activation.

Introduction

Glaucoma, a group of optic neuropathies characterized by progressive degeneration of retinal ganglion cells (RGCs), represents the leading cause of irreversible blindness in the developed world. Typical symptoms include gradual loss of peripheral (side) vision that is followed by progressive loss of central vision. If left untreated, glaucoma can progress to complete blindness. Because the damage to the eye is slow and painless, only half of the carriers are aware of the disease and irreparable harm often takes place long before diagnosis. Glaucoma is generally identified by abnormal regulation of intraocular pressure (IOP) and/or pathological mechanosensitivity of ocular cells but the relationship between mechanical forces and the disease remains enigmatic and a matter of considerable academic, clinical and economic interest. The proportion of blindness attributable to glaucoma varies considerably from the lowest values in South Asia to high prevalence in sub-Saharan Africa (1). By 2020, the disease is expected to affect >76 million people, with an estimated 3 million afflicted in the United States alone. There is currently no cure because retinal neurons that die do not regenerate, however, progression of the disease may be slowed with drugs that lower intraocular pressure (IOP). The

* About the authors

economic burden (medical costs, assistance programs in the U.S. estimated at ~$3 billion/year) doubles when considering indirect costs associated with productivity loss, physical consequences (increase in hip fractures; increase in family care) and decreased quality of life. Given that early detection of glaucoma, initiation and adherence to treatment strongly correlate with socioeconomic status (2), there is much room for improvement in providing care.

First descriptions of glaucoma-like eye disease conditions are from ancient Greece. Aristotle and Hippocrates (~500 BC) used the term *glaukos* (γλαυκός) to describe a late-stage condition characterized by the gray-green-blue hue of the pupil (3). In a remarkable approximation of close angle glaucoma, Galen (c.129-199 AD) linked this glaucous hue to deficient levels of aqueous humor, a shallow anterior chamber and/or anteriorly prominent lens. The "Book of Hippocratic Treatment" by Al-Tabari, a 10th century Arab physician, may have provided some of the first references to intraocular pressure yet medieval Europe continued to categorize glaucoma as an incurable green (*viriditas*) cataract ("waterfall") and "excessive hardness" of the lens (4). Confusion ensued when removal of the opaque lens turned out to improve vision but the link to IOP was resurrected in the mid- 19th century by Franciscus Cornelius Donders (Dutch) who developed the first tonometer. Albrecht von Graefe (German) and Antoine-Pierre Demours (French) linked the disease to the iridocorneal dysfunction however glaucoma was defined and canonized by William Mackenzie (Scottish) in his "Practical Treatise of the Diseases of the Eye" (1853) (5). The medieval designation of glaucoma as "green cataract" continues to persist in some languages (such as Slovenian).

A distinctive feature of glaucoma is the obligatory association between biological processes that take place in two distinct locations within the eyeball (Figure 1). A pressure gradient in the **anterior eye** contributes - through mechanisms that are still unclear – to optic neuropathy in the **posterior eye** (retina). To adapt to increased mechanical forces, trabecular meshwork cells in the anterior eye, retinal ganglion cells and glia undergo structural and functional changes known as glaucomatous remodeling. This process involves includes many mechanisms at nanoscale (gene expression), mesoscale (changes in enzymes, ion channels, cytoskeletal proteins, receptors and secreted molecules) to macroscale (neuropathy) levels with the final common consequence of the lost retinal output to the brain (Figure 1).

Among the broad range of risk factors that influence the likelihood of developing glaucoma are age, ethnic origin, family history, corneal thickness, low blood pressure, cerebrospinal fluid pressure, intraocular pressure and vascular dysregulation. The multiplicity of these stressors, some of which are IOP-independent, underlies the differences in the rate of glaucomatous progression and response to treatment across individual patients.

It is important to note that criteria for diagnosing glaucoma cannot yet identify molecular and physiological markers of the disease and that the **lack of a structure-function framework that unifies the bewildering constellation of glaucoma risk factors and phenotypes represents a significant unmet need in both the diagnosis and treatment of glaucoma**. The widely used textbook definition of glaucoma as "*an optic neuropathy defined by 'cupping' of the optic nerve head*" is an antiquated description of a late stage condition at which early warnings stages of IOP- induced changes in retinal neuronal excitability, synaptic remodeling, neuroinflammation and altered light responsiveness have already taken place. It also fails to bring insight into the ongoing debate whether glaucoma is one disease with a continuum across phenotypes or a group of diseases with distinct genetic origin and signaling mechanisms. This review presents a bird's eye overview of some of the current topics of controversy and/or areas where knowledge is currently lacking. It reflects the author's personal views and also regrets that the large majority of the relevant studies could not be cited directly (although many are referenced in the secondary literature).

Diagnosis of glaucoma

The current clinical diagnosis of glaucoma is based on the measurements of IOP, visual function and retinal structure. Stereoscopic "slit lamp" ophthalmoscopy and optical coherence tomography (OCT) check for the

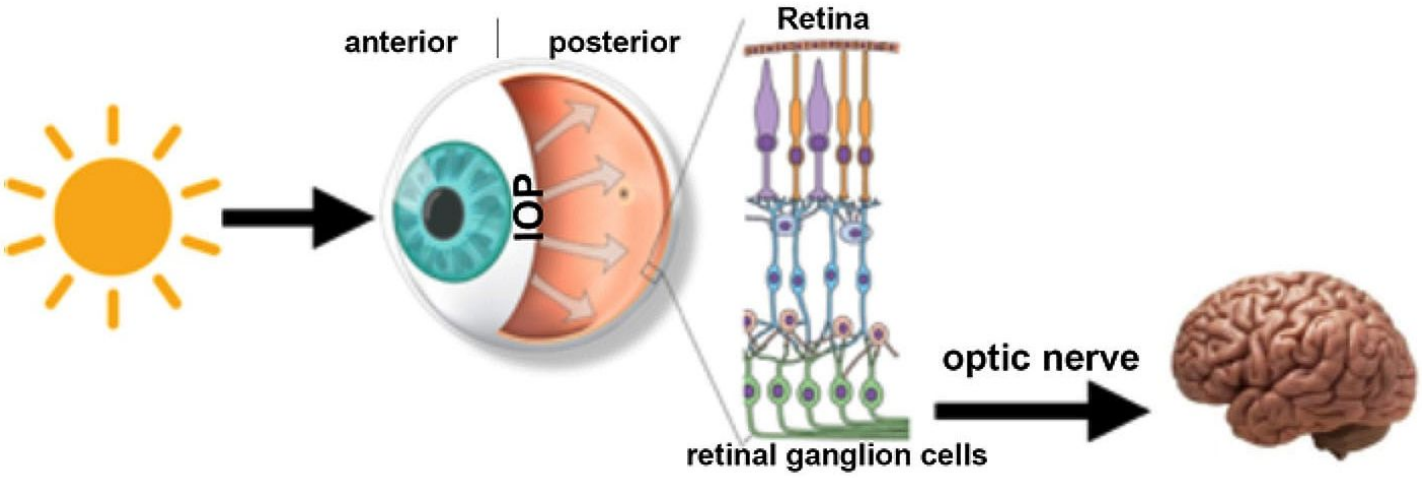

Figure 1. IOP generated in front of the eye (anterior) compromises the function of retinal ganglion cells (green, RGC) located in the back of the eye (posterior). RGC axons traveling through the optic nerve represent the sole output through with the eye communicates the visual signal to the visual areas of the brain. Axonal loss in glaucoma therefore impairs vision and may lead to blindness.

"cupping" (concavity) of the optic nerve head and degeneration of the retinal nerve fiber layer (composed of RGC axons); perimetry documents the functional damage in vision by testing for arcuate scotoma (regional loss of peripheral vision), and tonometry is used to measure IOP (6, 7). Patients at risk for the primary angle-closure type of disease (see below) are additionally examined with gonioscopy, which bounces light into the eye using a specialized lens. An example of the ophthalmoscopic examination of the interior surface ("fundus") of the eye is shown in Figure 2 and Figure 3. An "excavated" or "cupped" optic nerve head in Figure 2 is associated with reduced vascularization of the foveal region whereas Figure 3 shows a typical late-stage example, with magnified views of the optic nerve head of a normal patients retina (left) and the same view of a patient's retina with severe glaucoma (right).

In the glaucomatous eye the optic nerve head appears larger because the neuroretinal rim is narrower and the center is cupped. In fundus photos of advanced glaucoma, degeneration of ganglion cell axons can be seen by the appearance of remaining axons in so called "wedge-shapes" that differ from the picture of healthy ganglion cell axons radiating in superior and inferior arches to the optic nerve head (Figure 4).

In general, functional loss can be detected once >30% of RGCs have died, although patients and animals may not notice that their vision is compromised until much later. Figure 5 shows that RGCs are the main neuronal cell type lost in a non-human primate retina with induced glaucoma. Macaque retinas with induced glaucoma (8) show substantial loss of RGCs following chronic IOP elevation (Figure 5A) but show visual sensitivity that is compromised only after the monkeys lost ~50% of their RGCs (Figure 5B).

Patients with glaucoma often describe experiencing colored "haloes" that may reflect corneal epithelial edema and transient compression of the ONH. Many anecdotal cases link strong emotional trauma to acute manifestation of the disease however the relationship between the emotional/anxiety states and glaucoma remains to be systematically evaluated. In contrast to the wealth of studies in non-human primates, there have been relatively few histological investigations of glaucomatous human retinas. One example is shown in a 2003 study by Pavlidis and colleagues (Figure 6) (9). Like the macaque (Figure 5), few ganglion cells remained in the human retina with advanced glaucoma. The rare ganglion cells that were stained are atrophied, with few dendritic branches and loss of bushiness (Figure 6, panel K), shrunken cell bodies and notably beaded axons running in the nerve fiber layer (Figure 6, panels B,C,E, F and H, I) compared with normal midget ganglion cells (Figure 6. panels A, D, G and J). Larger cell types such as parasol ganglion cells were similarly affected in the advanced glaucomatous retina (9). For ganglion cell types in human retina see "Primate ganglion cells" in

Morphology and circuitry of ganglion cells section in Webvision. For rodent **models**, see later in this chapter and review by Nickells et al. (2012) (10).

Types of glaucoma

"Primary" glaucomas show optic neuropathy in the presence or absence of elevated IOP (i.e., the cause of the disease is not known) whereas "secondary" glaucomas are defined by known pathological mechanisms that elevate IOP above normal. Both types of disease have in common dysfunction of the anterior eye, symptoms (RGC loss and optic neuropathy) and treatment (IOP lowering). Diagnosis continues to be a problem, as all too often glaucoma is identified after many RGCs (green cells in Figure 1) had been irretrievably lost. The most common forms of glaucoma do not show Mendelian inheritance, yet genetic and racial background is clearly important as ethnic groups show striking differences in the prevalence of types of glaucoma. For example, primary open-angle glaucoma (POAG) is widespread in Africa (4.2%) whereas primary angle closure glaucoma (PACG) is more common in Asia (1.1%). With respect to the population sizes, however, Asians still account for the majority (~53%) of worldwide POAG cases (2, 11). In general, gene mutations with large biological effects (i.e., optic neuropathy) are rare whereas gene variants associated with smaller effects are common (12) (see below). Treatment for all forms of glaucoma is limited to pharmacological lowering of IOP (the sole treatable risk factor) and, in rare cases, anterior eye surgery and laser photo/thermocoagulation but there are no treatments for neuronal degeneration (reviewed in (13-15)).

Primary open-angle glaucoma (POAG)

POAG is the most common form of glaucoma that accounts for >80% of cases in the Western hemisphere. The 'angle' refers to the iridocorneal cleft between the iris and the cornea which is "open" in normal eye and POAG (Figure 7A & Figure 7B) and offers access to aqueous humor flowing into the trabecular meshwork and Schlemm's canal. Clinically, POAG is diagnosed by the open angle, IOP > 21 mm Hg and loss of visual field associated with the degeneration of ganglion cell axons ("optic neuropathy") (16). While relatively uncommon under the age 50, POAG strikes nearly 8% of Americans over 80; it is about five times more common among African Americans than Caucasians, with earlier onset and faster time-course of progression in individuals with African heritage (17). On the other hand, people with European ancestry are more vulnerable compared to Africans or Asians when assessing the odds ratio of POAG per decade (18). The prevalence seems to be higher in men. In most cases of POAG, the disease may progress to total blindness without the patients experiencing any pain or discomfort, which however may occur when the rate of tension is very high, and IOP exceeds ~50 mm Hg.

A key, heritable OAG risk factor is IOP, which varies between ~7 and >20 mm Hg. Every 1 mm Hg increase in baseline elevates the risk of developing the disease by 10-14% over any 5 – 9 -year period (19). Untreated eyes with IOP in the range of 21 – 25 mm Hg show ~14.4 years to progress from early to late stage of POAG but the lag period is shortened to ~2.9 years at IOP >30 mm Hg. Individuals with myopia are at risk for both elevated IOP and POAG, possibly due to weaker connective tissue support (18). It is important to note that the disease is unpredictable as there is a substantial fraction of patients with elevated IOP who show no signs of axonal degeneration, visual field defects and vision loss.

POAG has a clear genetic foundation, with heritability amongst twins ~0.95, and siblings of affected individuals having nearly an eight-fold increase risk of developing the disease. In contrast to macular degeneration (AMD), in which genome-wide studies (GWAS) identified ~60% of responsible genes, known POAG sequences comprise less than 10% of known cases. These include ~50 gene loci, with mutations in three Mendelian genes - myocilin (MYOC), optineurin (OPTN) and TANK binding kinase (TBK1) accounting for ~5% of POAG cases with little influence from other genes or environmental factors (12, 20). MYOC is a secreted calcium-binding protein with no known function, and is expressed in TM cells, retinal pigment epithelium and astrocytes. Mice and humans

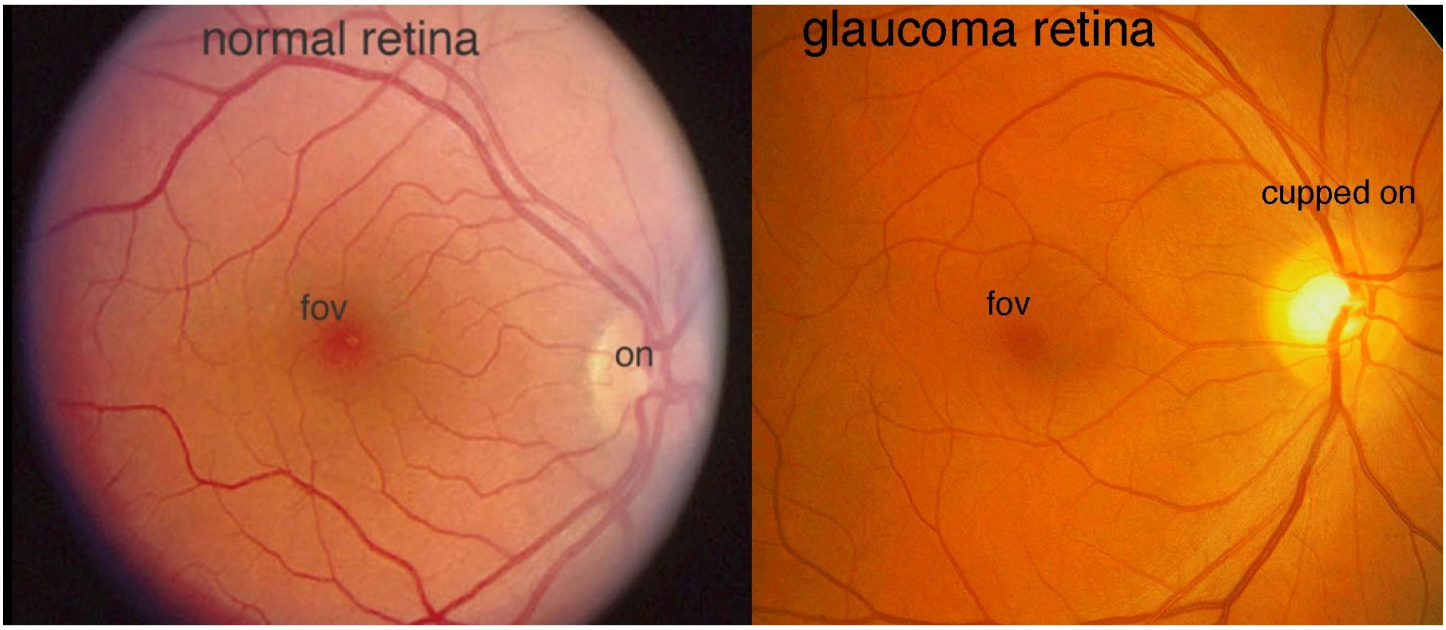

Figure 2. An ophthalmoscopic view of the retina (right) of a patient who has glaucoma, in comparison to a normal retina (left). The characteristic picture is of a cupped optic nerve head (on) and poor vascular supply towards the fovea (fov). Courtesy of James Gilman, Ophthalmology photography, Moran Eye Center.

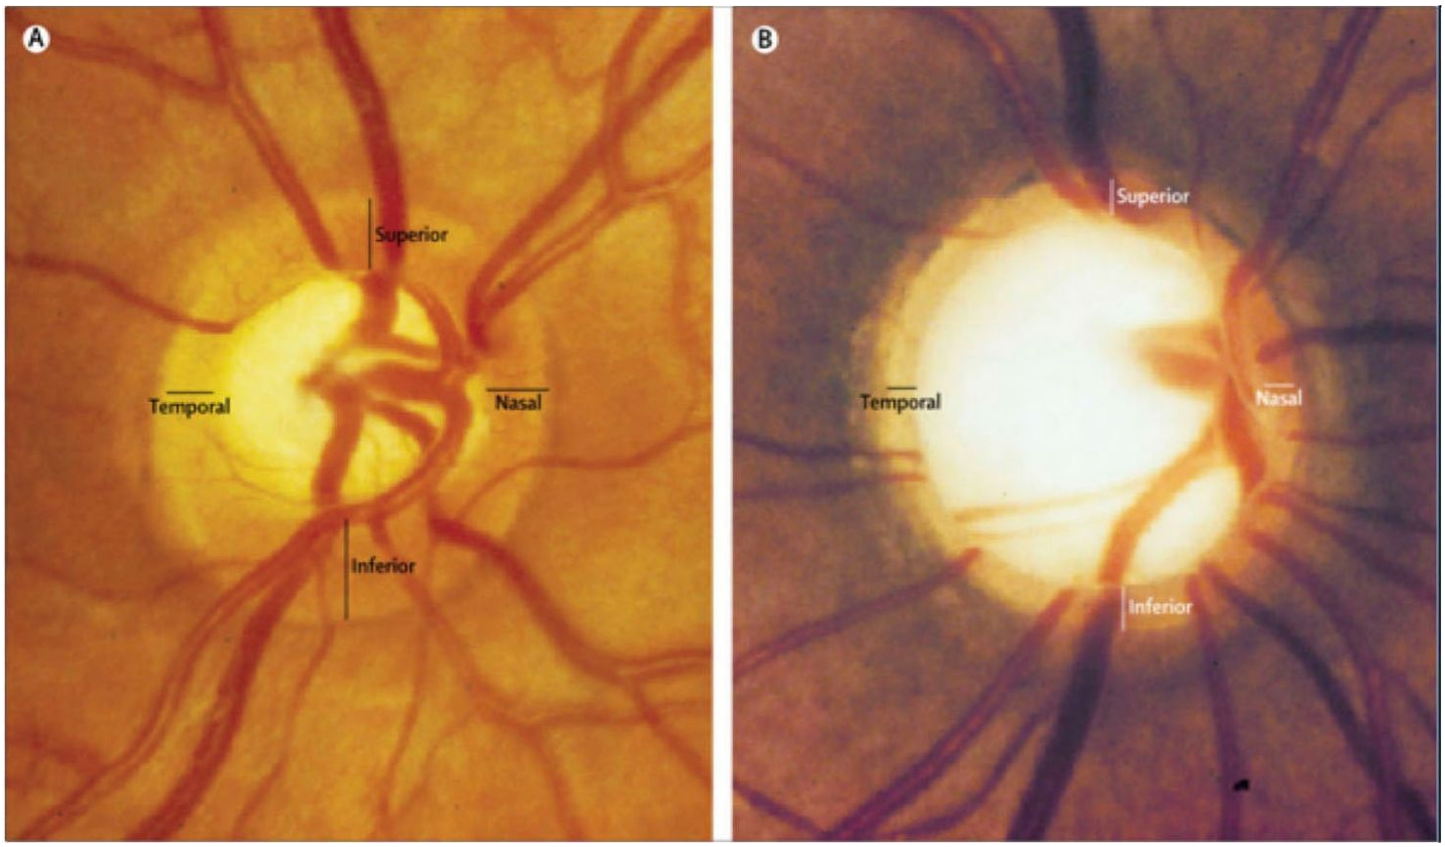

Figure 3. Ophthalmic photographs of healthy (A) and a glaucoma patient optic disks (B). The optic disk is the optic nerve head. (A) The optic disk is a normal shape, with a normally sized neuroretinal rim (superior, inferior, nasal and temporal). In (B) the neuroretinal rim is thinner, and the optic disk is larger, with a deep cup.

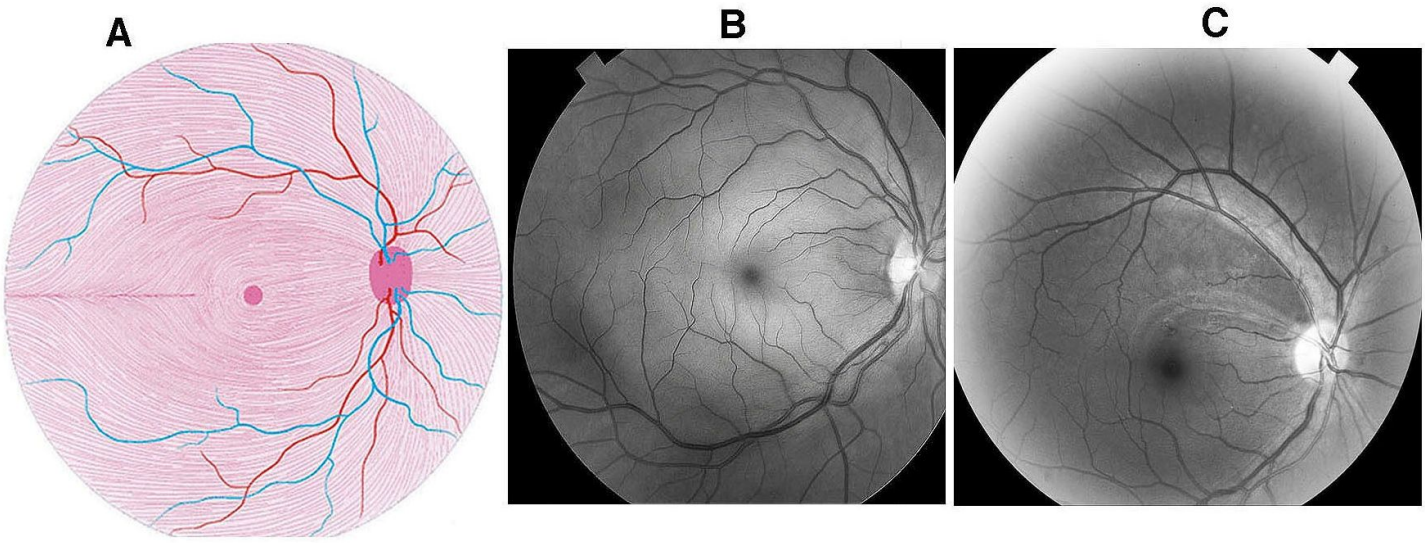

Figure 4. The course of ganglion cell axons towards the optic nerve head. (A) Schematic of normal nerve fiber layer axons (137). (B) Retinal fundus photograph of a normal retina where the nerve fiber layer appears as an even, white area composed of fibers sweeping towards the optic nerve head. The nerve fibers are particularly obvious in this patient due to a central retinal artery occlusion. (C) In advanced glaucoma the fiber layer (white streaks) is defective and appears to have a wedge shape. This indicates drop out of ganglion cell axons. (B) and (C) courtesy of James Gilman, Photography Department, Moran Eye Center.

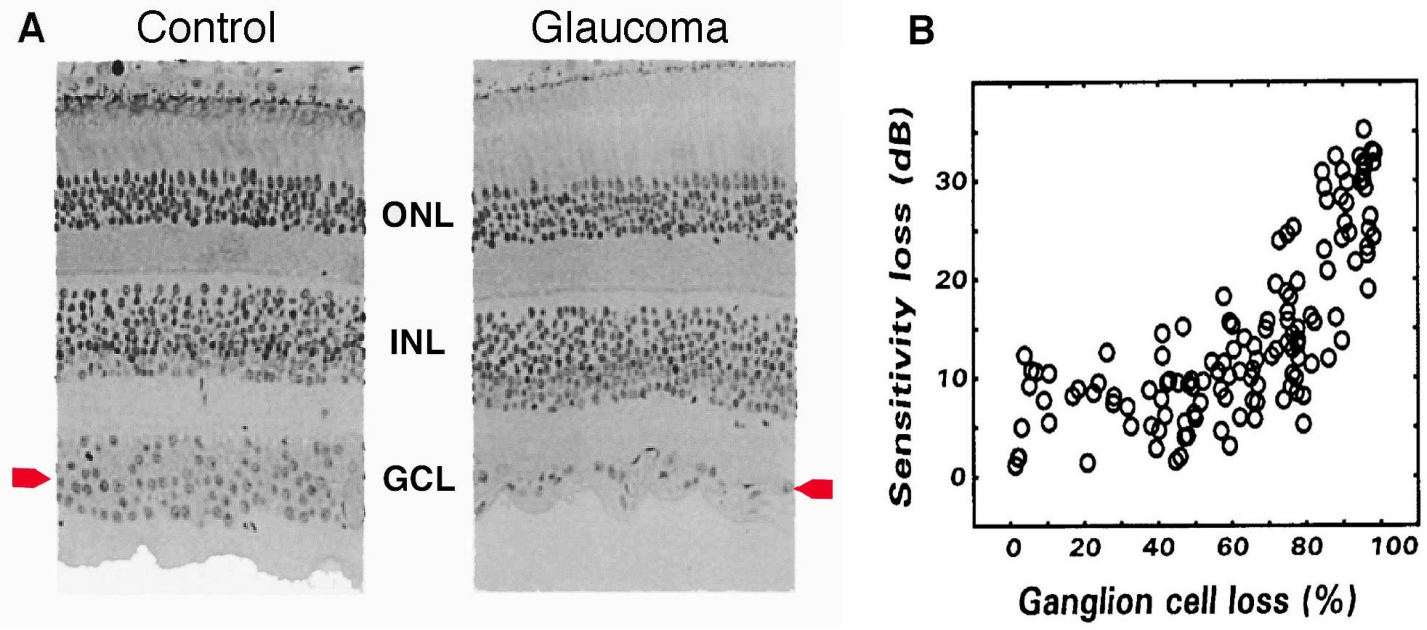

Figure 5. Retinal morphology in the primate (macaque) model of experimental glaucoma. (A) IOP elevation selectively compromises the survival of retinal ganglion cells (RGCs, arrowheads). (B) Vision loss takes place when a significant proportion (~50%) of RGCs are lost.

that lack or overexpress MYOC have normal aqueous drainage and do not develop high IOP whereas mice expressing the human Tyr437His mutation in the olfactomedin domain develop elevated IOP and optic nerve damage that mirrors human glaucoma (21). Carriers of MYOC mutations develop glaucoma in ~90% of cases, presumably due to deranged protein-protein interactions, intracellular accumulation of misfolded proteins and ER/endosomal stress (12). OPTN encodes a scaffold protein that has at least 23 binding partners, 8 protein

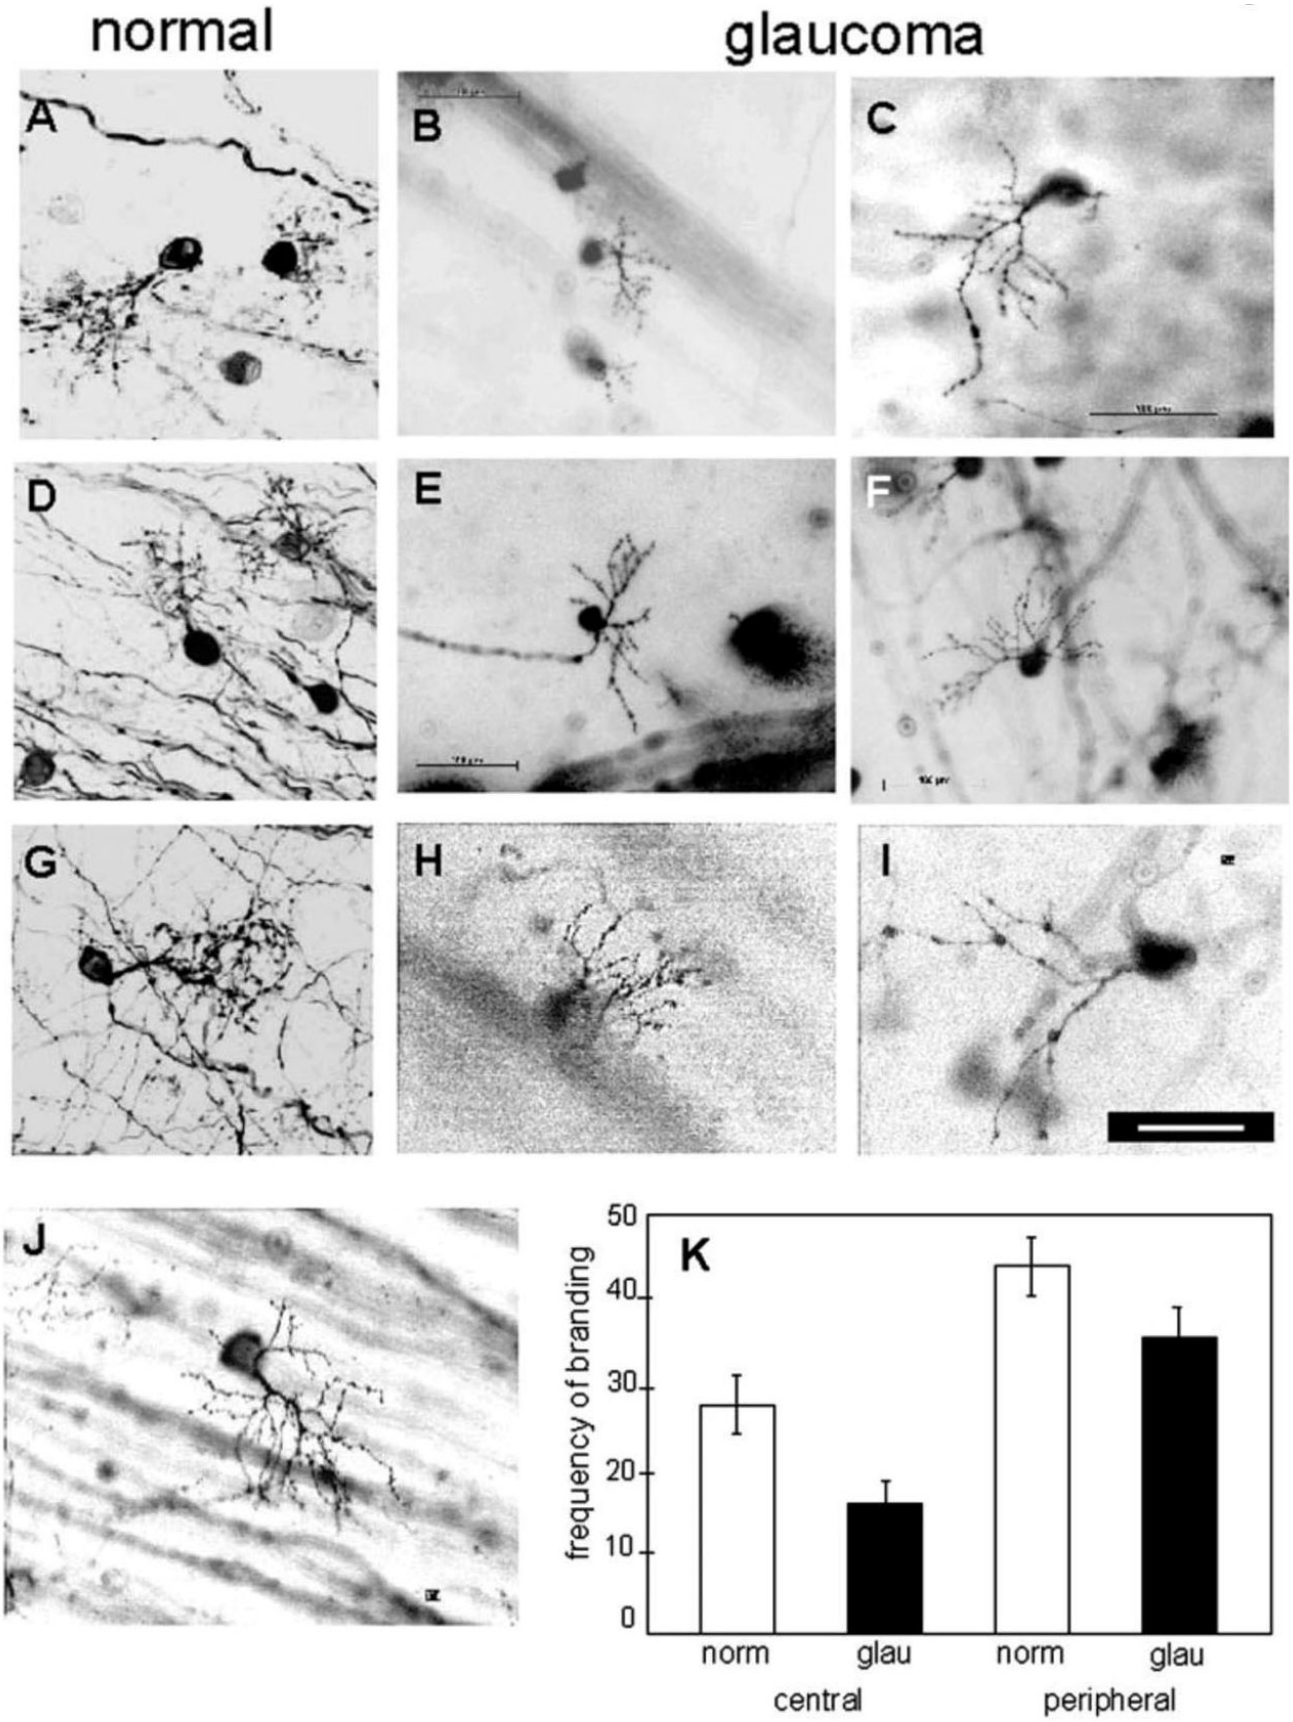

Figure 6. (A, D, G, J) Normal midget ganglion cells stained at increasing eccentricity from the fovea. Carbo-cyanine dye (DiI) staining. (B, C, E, F, H, I) Midget ganglion cells stained by DiI in the glaucomatous retina at similar distances from the fovea as the normal cells. Note the absence of surrounding stained cells and stained ganglion cell axons in comparison to the normal retinas. Also, there is distinct atrophy of the dendritic branching compared to normal midgets as shown in the histogram (K). From Pavilidis et al, 2003 (9).

binding sites and likely roles in multiple signaling pathways, including autophagy and vesicle trafficking in TM cells and RGCs (22).

A widely shared view of POAG is that of a multifactorial disease in which multiple genes, protein and lipid signaling pathways are dysregulated, but may also be influenced by environmental stressors and epigenetic mechanisms. The molecular "interactomes" that underpin pressure-sensitive and insensitive aspects of POAG remain to be fully characterized with potential clues from recent genome-wide association study (GWAS) analyses of adult-onset POAG loci including genes that encode cholesterol-binding caveolin proteins CAV1/2, ABCA1 (ATP-binding cassette transporter 1), TGFBR3 (transforming growth factor beta receptor 3), FOXC1 (forkhead box C1), ELOVL5 (elongation of long chain fatty acids family member 5), ATOH7 (atonal homolog 7), CYP1B1 (a cytochrome P450 enzyme) and ATXN2 (ataxin isoform 2) proteins. On their own, these proteins may be harmless – and/or independent of IOP - but may accumulate risk when combined with pathological mechanotransduction. IOP-independent [e.g., SIX6 (a transcription factor) and CDKN2AS (a non-coding RNA)] genes (12) could compound pressure-mediated injury. Some GWAS loci may be ethnicity-specific: lipid rafts - macromolecular complexes that regulate cell mechanotransduction - have been linked to POAG in European cohorts (23) via mutations in CAV1 and CAV2. Accordingly, cholesterol-lowering drugs (e.g., statins) may decrease the risk of contracting POAG in these populations (24). In addition to changes in gene composition, glaucoma risk may also be associated with copy number variations (base deletions/duplications) (25).

Pressure-dependent dysregulation of signaling mechanisms in anterior eye is reflected in aqueous humor composition, which shows altered levels of a striking number of signaling molecules that include adenosine, nitric oxide, ATP, endothelin-1 (ET-1), lipids (endocannabinoids, prostaglandins, cholesterol), transforming growth factor (TGFβ), CTGF (connective tissue growth factor), angiotensin II and cochlin. ET-1 and TGFβ2 modulate the deposition of ECM molecules within the trabecular pathway, which in turn might affect aqueous outflow (26). Another protein of interest is CYP1B1, a member of the cytochrome P450 enzyme consortium that metabolizes fatty acid molecules downstream from arachidonic acid. CYP1B1 mutations were associated with glaucoma in children and young adults (2), with the protein expressed in glaucoma-relevant ocular tissues such as the trabecular meshwork, retina and the ciliary body where it could affect the cells' sensitivity to mechanical stressors (27). The calcium-permeable TRPM3 channel (expressed in the ciliary body and lens) represents a combined risk factor for high-tension glaucoma and cataracts (28). Other important signaling mechanisms involve Rho and MAP kinases which modulate the expression of proteolytic enzymes, proinflammatory cytokines, autophagy and contractility (29, 30).

Normal-tension glaucoma (NTG)

NTG is seen in ~30% of POAG patients in which degenerating RGCs show the typical hourglass pattern of axonal loss and visual field defects at "normal" IOP (31), i.e., levels that are consistently lower than 21 mm Hg. Risk factors including female gender, race (more common in Japanese than Caucasians), vascular dysregulation and low blood pressure (32). Two NTG genes (OPTN and TBK1) with prevalence of 1-2% are shared with POAG and encode proteins associated with autophagy (an intracellular protein degradation mechanism) (33). Axonal injury in NTG could be augmented by the pressure gradient caused by abnormally low cerebrospinal fluid pressure across the optic nerve head (32). IOP-lowering regimens improve the prognosis in some patients: after 6 years, ~55% of patients treated with IOP-lowering medications showed stable vision as opposed to ~40% of untreated patients (31, 34). Given that pathological responses NTG patients appear to involve innocuous mechanical stressors, these patients could possess gain-of-function mutations that increase their sensitivity to IOP. Similar hypersensitivity (hyperalgesia) to mechanical stressors is a well-known property of neuropathic pain mechanisms that involves altered function of mechanosensitive ion channels in the peripheral nervous system (35).

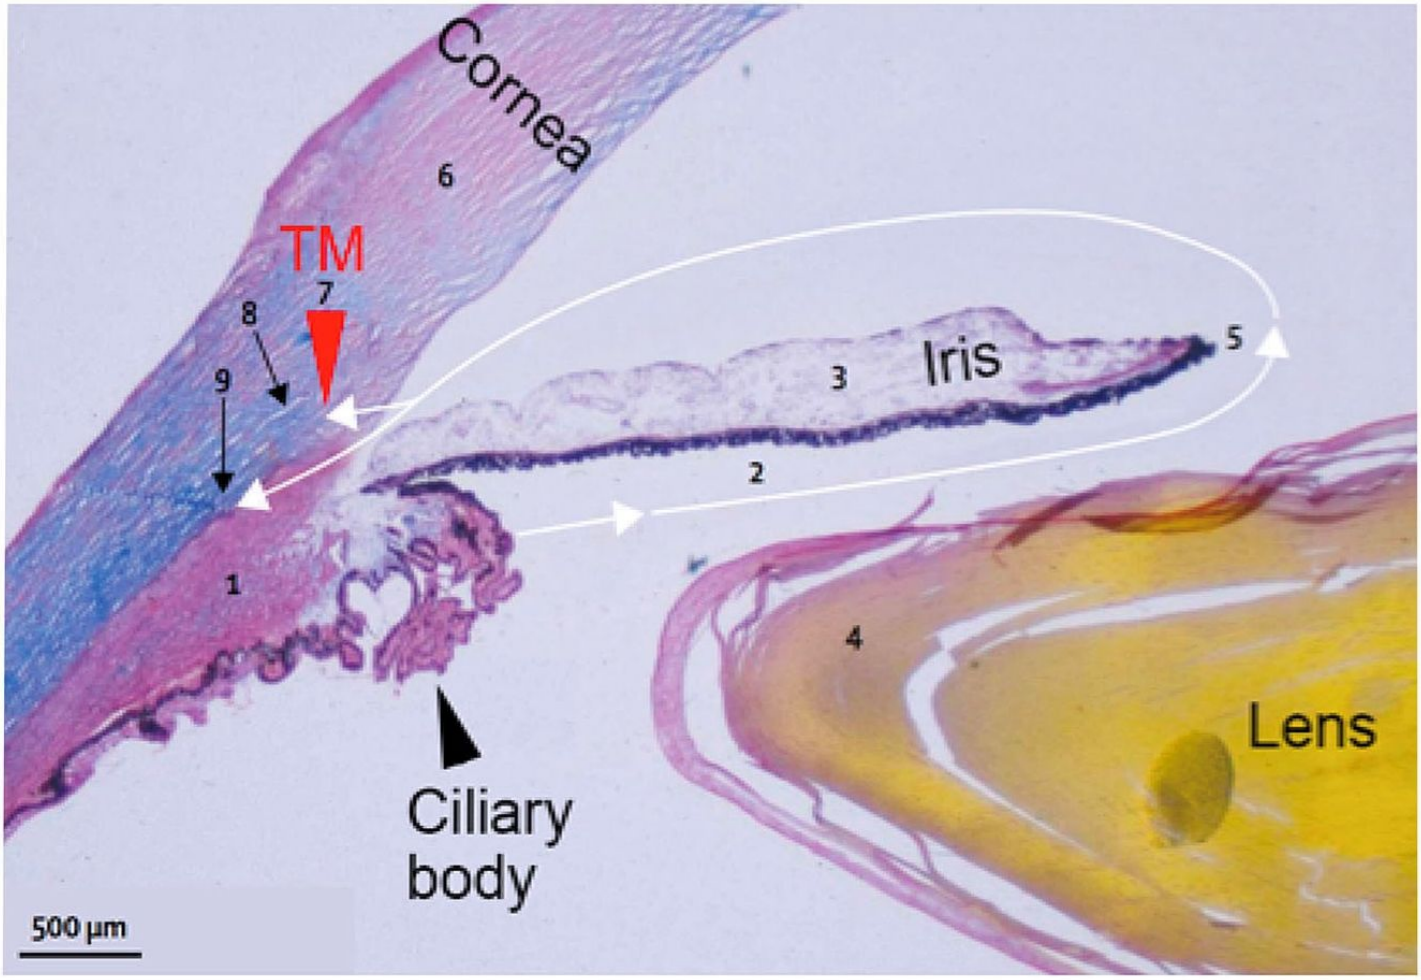

Figure 7A. The anterior chamber contains the ciliary body **1**, the site of aqueous humor production. The aqueous humor percolates around the lens **4** and the iris **3** to drain (white lines **2**) from the posterior chamber into the anterior chamber through the pupil **5**. The anterior chamber angle is located between the peripheral cornea **6** and the peripheral iris, and it contains the trabecular meshwork (TM **7** red arrow) and Schlemm's canal **8**. The aqueous humor leaves the eye through the trabecular meshwork and Schlemm's canal, and through the uveo-scleral outflow pathway in the ciliary muscle **9**. Modified from Jonas et al, 2017 (13).

Primary angle-closure glaucoma (PACG)

Angle-closure glaucoma, common in East Asian populations and rare in Caucasians, is responsible for a disproportionate number of patients with severe vision loss. The pathology is caused by disorders of iris, lens and retrolenticular structures which impede drainage of aqueous humor by narrowing the angle between the iris and the cornea (Figure 7B). It is more likely in women and persons with extreme hyperopia (farsightedness). In about a third of PACG patients, an abrupt increase in IOP (often above 30 mm Hg) triggers acute symptoms (severe pain and nausea, conjunctival hyperemia, corneal edema and vomiting) that require immediate medical intervention (12). The disease is highly heritable with gene association studies implicating genes that encode polymorphisms in extracellular matrix (ECM) molecules (e.g., MMP, HSP70, NOS3) or ocular development (the Frizzled related MFRP protein, hepatocyte growth factor HGF). Additional candidates identified by GWAS studies include collagen XI (COL11A1), pleckstrin homology domain proteins (PLEKHA7, PLEKHC1; required for the stabilization of adherens junctions), protein glycosylation (DPM2), acetylcholine biosynthesis (CHAT), ST18 (suppression of tumorigenicity 18) and transcriptional regulation (GLIS3) (36). Unsurprisingly, many of these risk genes encode processes associated with cell adhesion, ECM homeostasis and mechanotransduction (focal adhesion, cell junctions, collagen).

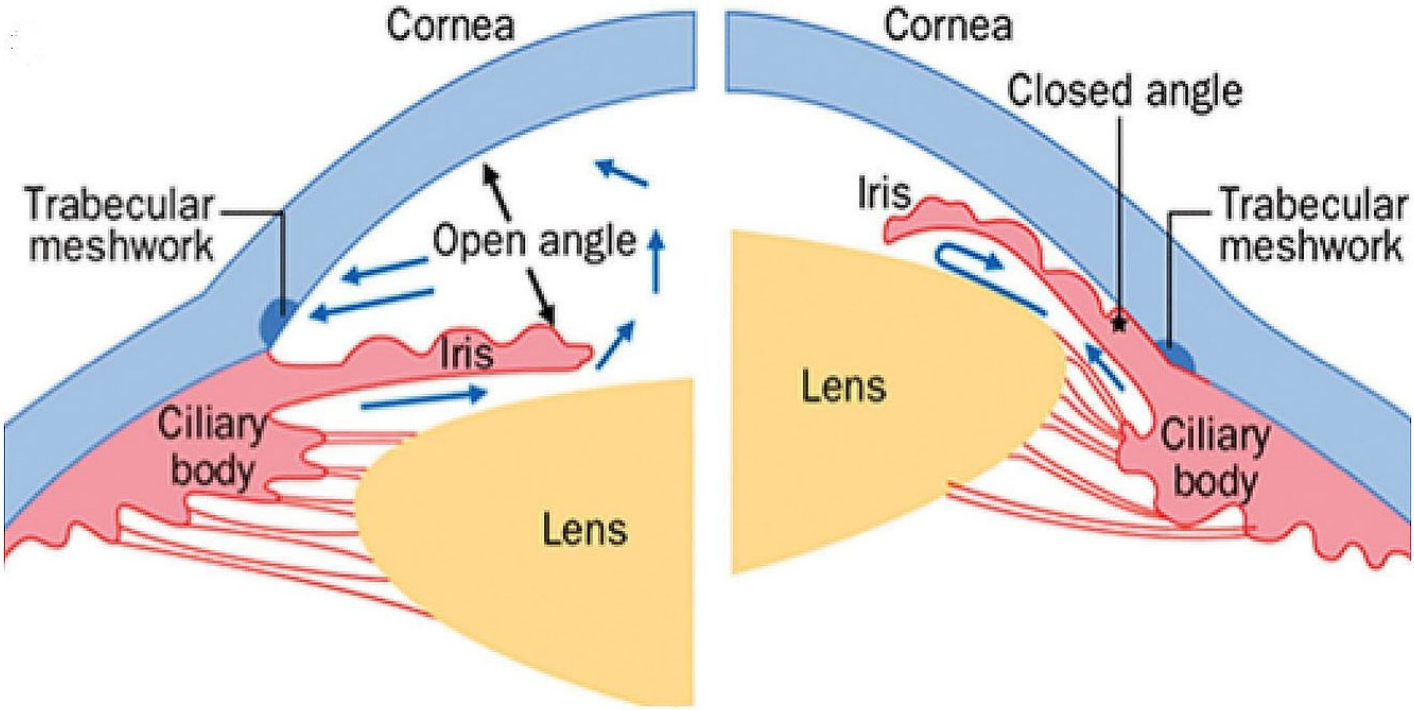

Figure 7B. A schematic diagram of the anterior eye in open angle (left) and closed angel (right) glaucoma, showing how the displacement of the lens and the iris obstructs the fluid outflow across the Trabecular meshwork (TM) in the case of closed angle glaucoma. From Wiggs and Pasquale, 2017 (12).

After an acute PACG there may be a period of normal tension, taking the eye multiple days or week to recover from the shock and start producing aqueous fluid at a normal rate that elevates IOP to levels that conform to the extent of angle closure (12).

Secondary glaucomas

Secondary glaucomas reflect pathological mechanisms that elevate IOP above the normal range due to pathological production and/or reduced drainage of aqueous flow. Variants include pseudoexfoliative glaucoma, neovascular glaucoma, pigmentary glaucoma and steroid-induced glaucoma. ***Pseudoexfoliative glaucoma*** occurs when clumps of protein accumulate in the anterior chamber and clog the outflow through the trabecular meshwork. It has higher incidence in Scandinavian populations, shares risk factors with Parkinson's disease and Alzheimer's diseases and was associated with mutations in the lysyl-oxidase-like 1 (LOXL1) gene, and mutations in loci encoding CACNA1A, TMEM136, SEMA6A and other genes. ***Neovascular glaucoma:*** proliferation of blood vessels in the iridocorneal angle ("iris tufts") results in leakage of fibrous material which closes the angle. Is associated with retinal ischemia. Risk factors include diabetes. ***Steroid-induced glaucoma*** occurs in patients who take steroid medications to suppress macular edema, corneal transplant rejection, immune hyper-reactivity and injury-related inflammations. The resulting structural changes in the trabecular meshwork (including the induction of MYOC) increase its resistance to aqueous humor outflow and elevate IOP. Untreated, this induces POAG in 40% of patients ('steroid responders') (37). **Pigmentary glaucoma** typically originates from the "pigment dispersion syndrome" caused by the atrophy of the pigmented epithelial cells in the iris. Dispersal of melanin into the trabecular meshwork impedes aqueous outflow and elevates IOP. The DBA/2J mouse strain, which develops a similar phenotype of chronic glaucoma, has mutations in the *Gpnmb* gene (encoding a lysosomal-related glycosylated protein) and the *Tyrp1* gene (encoding a melanosomal protein with possible enzymatic and structural functions) (38, 39) . **Other types of glaucoma** are associated with cataract formation, certain eye tumors, uveitis (ocular inflammation), myopia and early onset (juvenile glaucomas).

Aging and glaucoma

Aging and cellular senescence represent a central risk factor for progression of glaucoma. We lose 10,000 ganglion cells (0.3 – 0.6%) and 0.58% of TM cells per year – by the age 80, a healthy individual with normal IOP loses about 30% of their RGCs (8). The loss of ganglion cells in aged individuals correlates with the general decline in cognitive, motor and other functions in aged people and bears many similarities to glaucoma, including dendritic remodeling, reduced axonal transport in the optic nerve (which halves during the lifetime of a rodent), decreased quality control mechanisms in ganglion and trabecular cells, and lower recovery rates following injury. 97.6% of patients over 40 have a median age of glaucoma diagnosis of 64 years, with the prevalence rising steeply from 0.2% - 2.7% in individuals aged 50 – 59 years to 1.6% - 12.8% after age of 80 years (40).

While age is a strong predictor of POAG we *don't know what critical stress is communicated to RGCs in older eyes to make them less resistant to elevated IOP*. One possible contributing factor may be the increased stiffness of ocular structures ("ocular rigidity") which may augment trabecular contractility (which elevates IOP) and increase the susceptibility of ganglion cells and glia to pressure-mediated stress. Older individuals may also have deficient ocular metabolism that is accompanied by age-dependent oxidative stress, mitochondrial dysfunction (41) and loss of neuroprotective mechanisms (42).

Intraocular pressure generation in the eye

It is important to note that **IOP reflects the balance between production and outflow of aqueous humor** (Figure 7A & Figure 7B). Details of aqueous humor regulation are discussed in reviews by Accott et al. (2014) (43) and Braunger al. (2015) (26) but it is important to note that this transparent, nutritious fluid is continually generated by the ciliary body (~2.4 µl/min at daytime in healthy adults; black arrowhead in Figure 7A) to feed the nonvascularized lens. Aqueous fluid is drained (white arrows) through the trabecular meshwork (TM; red arrowhead, #8 in Figure 7A). In primates, TM supports ~80-90% of aqueous outflow and thus represents the principal bottleneck for fluid outflow whereas the auxiliary 'uveoscleral' outflow pathway in the ciliary muscle (#1 in Figure 6A) supports the rest. Aqueous fluid outflow is ~50% lower at night compared with daytime, with consequent increased risk for developing acute pressure-induced eye damage during sleep (44). Both abnormal production of aqueous fluid or its deficient drainage through the TM and the Schlemm's canal (a pipe composed of endothelial-like cells that feeds the fluid collected from TM into the venous system) can lead to glaucoma.

IOP-dependence contributes a significant proportion of glaucoma cases. Any level of IOP can contribute to pathology but the risk for contracting glaucoma increases exponentially when chronic IOP exceeds 20 mm Hg (Figure 8). The magnitude and duration of IOP correlate with disease severity, with larger IOP elevations precipitating both disease onset and speed of progression (AGIS 2000). Similarly, the longer the duration of ocular hypertension, the higher the likelihood of developing optic neuropathy (31). Importantly, many individuals with elevated IOP do not develop glaucoma and up to 50% of patients with glaucoma ("normal tension" patients) may not have statistically elevated IOP (45). These patients probably express protective factors that counterbalance morbidity factors that drive neurodegeneration whereas "normal tension glaucoma" patients probably express gain-of-function transducer mechanisms that make them super-sensitive to mechanical stress.

Increased intraocular pressure as a risk factor in glaucoma

The vertebrate eye is a highly dynamic environment where IOP provides the hydrostatic pressure that is necessary for maintaining the shape, growth and optical properties of ocular tissues. Together with old age, increased intraocular pressure (IOP) represents the most important risk factor for the onset and progression of glaucoma (Figure 8). IOP-dependence contributes ~30 – 70% of glaucoma cases (46). The average IOP in

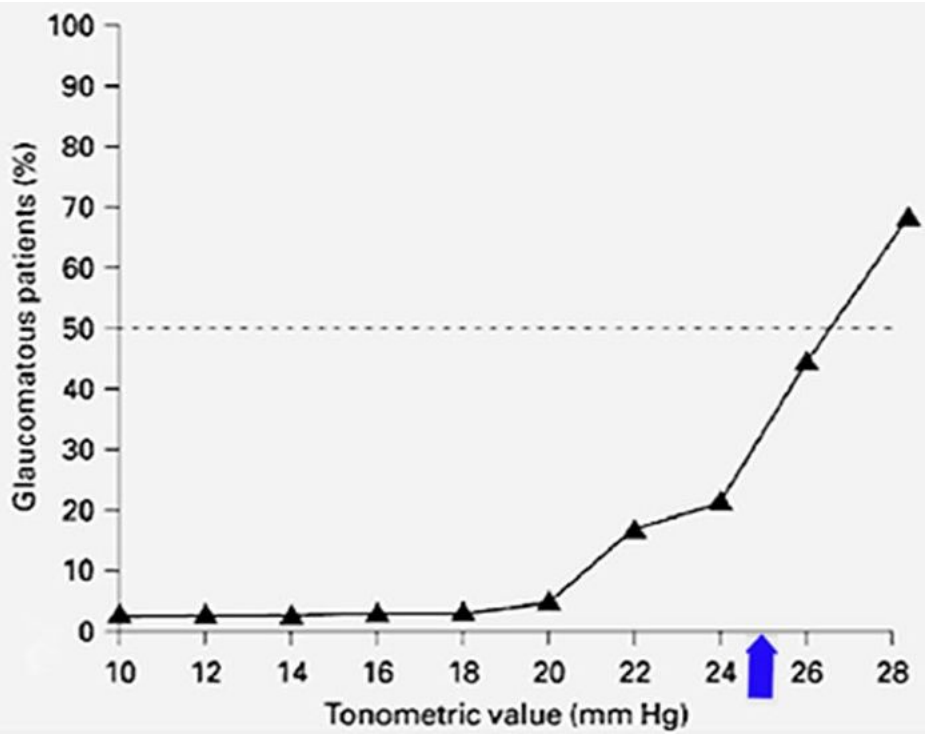

Figure 8. The relationship between IOP, tonometric value (mm Hg) and the diagnosis of glaucoma. Prevalence of 50% of patients is at 27 mm Hg. From Bonomi et al., 2001 (138).

newborn rodents and primates that ranges between 6 – 8 mm Hg, increases to 7 – 15 mm Hg in adults. IOP amplitudes tend to be slightly higher in the right eye than the left but the lifetime variability in IOP amplitude for individual eyes is minuscule (<2 mm Hg) (31). In contrast to the average IOP amplitudes which remain stable across lifetime, IOP is complex in the time-domain, showing pulsatility, circadian periodicity and oscillations (~3 mm Hg at ~1 Hz) (47). Blinking, eye scratching, sneezing, lens accommodation, arterial blood pressure and eye movements all transiently elevate IOP (by up to 200 mm Hg). The amplitude and rhythm of IOP fluctuations are regulated by *Cry1*/*Cry2* clock genes and local release of melatonin, which peaks at night and is more pronounced in glaucoma patients (48). IOP and risk for developing glaucoma may be increased by body position (eg, yoga inversion practices), weight lifting and swimming goggles whereas moderate physical exercise and diet rich in ω3/ω6 polyunsaturated fatty acids can decrease IOP by ~4 - 5 mm Hg. A confounding factor, however, is given the wide assortment of risk factors and glaucoma-associated signaling mechanisms there are no clear IOP threshold values that allow us to consistently identify the patients at risk for optic neuropathy.

Currently accepted treatments of glaucoma are largely limited to IOP lowering, a strategy that usually stops disease progression if pressure can be decreased by ~30–50%. Anti-glaucoma medications target aqueous fluid production in the ciliary body and/or the secondary (uveoscleral) outflow pathway. Because IOP lowering may also reduce the progression of vision loss in patients with 'normal' IOP (8-15 mm Hg) levels (17), glaucoma can be viewed as a **disease that involves increased susceptibility of the eye to mechanical stress at any IOP level**. Unfortunately, the most commonly used IOP lowering agent latanoprost (a prostaglandin $F_{2\alpha}$ analog) does not lower IOP more than 20% in a significant fraction (25-50%) of patients whereas up to 6% of POAG patients are unresponsive or do not tolerate any IOP medications (31, 45). Some treatments that showed efficacy in experimental paradigms, such as cannabinoids targeting the CB1 receptor (49), angiotensin II receptor blockers, melatonin receptor 3, adenosine receptor 1 agonists, TRPV4 channel, TREK-1 channel and endothelin receptor-1 blockers have yet to complete clinical trials. No medications were capable of targeting the main (trabecular) outflow mechanism until 2017, when several Rho kinase (ROCK) inhibitors (e.g., ripasudil) were approved for topical treatment of POAG. Unfortunately, the disagreeable side effects (e.g., hyperemia) may limit

their usefulness to many patients. Developing drugs that target the trabecular outflow component without side effects should therefore be a priority.

Details of the Trabecular Meshwork (TM)

TM cells play a central role in IOP regulation through their control of fluid outflow into the canal of Schlemm (Figure 7A). The cells form three adjacent strata (uveal, corneoscleral and juxtacanalicular) that differ in terms of their gene expression patterns and relative contribution to phagocytosis, fluid filtration, stiffness and resistance to fluid flow (50) but are difficult to pigeonhole from ontogenetic, morphological or functional standpoints: (i) Similar to macrophages, they express histocompatibility and other immune markers, and show phagocyte-like scavenger activity; (ii) Similar to glia, they play important volume regulatory functions and participate in the release of inflammatory cytokines (such as IL-1α and TNFα); (iii) Similar to endothelia, they form a barrier with antithrombotic and antigen-presenting functions; (iv) Similar to fibroblasts, they release extracellular matrix and contribute to contractility yet (v) They express smooth muscle actin (αSMA), a protein typical of smooth muscle cells. Pressure-evoked TM contractions mediated through actomyosin are thought to elevate IOP by increasing the resistance of the outflow pathway to fluid flow (30). **The chronic increase in outflow resistance underlies a positive feedback between elevated IOP, stiffening of the cytoskeleton and increased contractility.** In other words, **cytoskeletal and ECM remodeling underpin both cytological and functional hallmarks of hypertensive glaucoma**. Similar positive feedbacks between mechanical stretch and pathology have been described in other tissues, including lung and heart where cell sensing of small changes in tissue stiffness drives severe, fibrotic remodeling.

At the subcellular level, an increase in pressure induces an upregulation of actin stress fibers, adhesion molecules and remodeling of the extracellular matrix (ECM) in TM cells (Figure 9C & D), together with up/downregulation of hundreds of genes associated with cell adhesion, metabolism, ion transport, inflammation and cell cycle (29). Although not every step of this dynamic response is understood, recent studies showed that mechanical stress induces increases in intracellular calcium concentration $[Ca^{2+}]_i$ of both TM cells (Figure 9A) and ciliary body cells that regulate aqueous fluid outflow and inflow, respectively (51). Calcium in turn regulates almost every aspect of cell physiology, including modulation of contractility, stiffness and increased levels of the cytokine TGF-β, activation of Mitogen-Activated Protein (MAP) kinases, release of metalloproteinases (MMPs) and deposition of ECM molecules such as fibronectin and versican (Figure 9D). The effect of pressure on $[Ca^{2+}]_i$ and cytoskeletal remodeling that is seen in vitro and in vivo models of trabecular outflow and IOP regulation has been broken experimentally by inhibiting stretch-activated TRPV4 channels (Figure 9B), which triggers an immediate IOP lowering (51).

Chronic increases in IOP trigger up- and downregulation of thousands of trabecular and retinal genes, many of which encode signaling pathways associated with glial activation, upregulation of complement genes, endothelial dysfunction and RGC degeneration in animals and humans. A useful online resource that showcases the complexity of these pathways is the Glaucoma Discovery Platform from Jackson Laboratories (http://glaucomadb.jax.org/glaucoma).

Details of retinal ganglion cells (RGCs)

Mammals have >45 classes of RGCs - projection neurons with unique inputs, functional properties and axonal projections to the brain (*G,* red cell in Figure 10). *In vitro* and *in vivo* studies in animal models (mainly non-human primates and mice) have established the disproportionate vulnerability of RGCs to many types of mechanical stress - including IOP, compression, tensile stretch and prolonged swelling (35, 52, 53). The spatial pattern of pressure-induced injury of RGCs correlates with the location of their axons within the ONH whereas other classes retinal neurons tend to be (at least initially) spared from IOP-induced injury (Figure 5) (8, 54). The molecular and cellular changes induced by IOP (altered transcription, organelle function, calcium signaling, neurotransmitter uptake, synaptic organization and cellular architecture) in turn compromise the cells' function

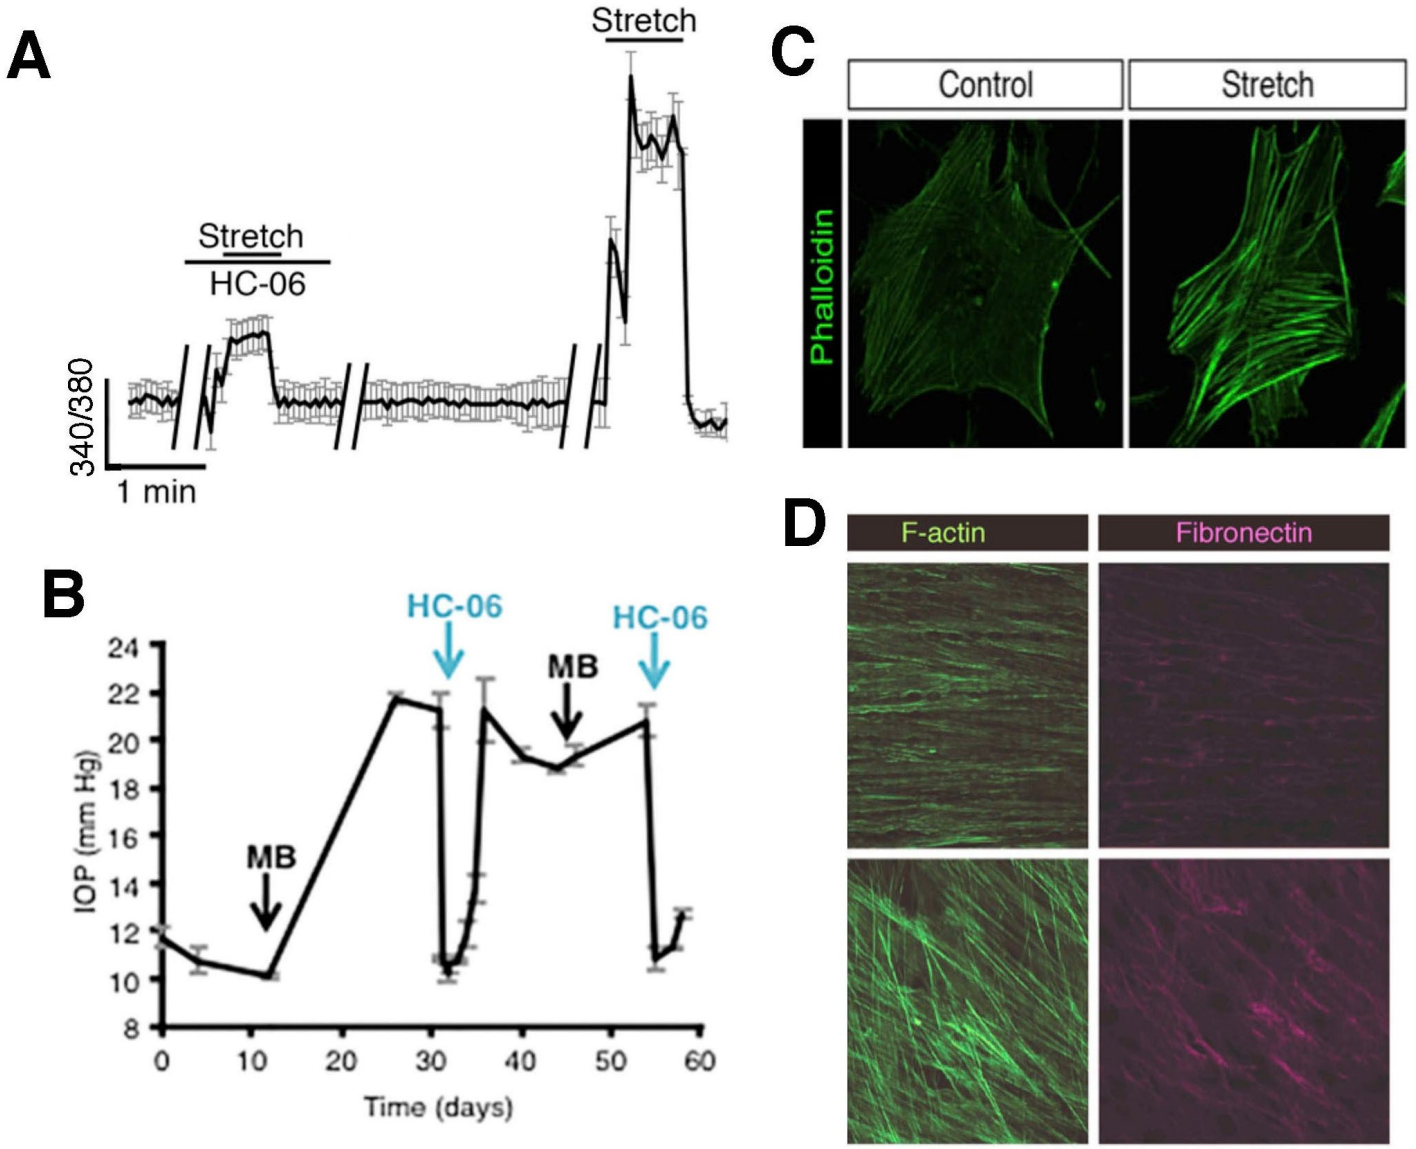

Figure 9. TRPV4 drives mechanically induced calcium signaling, cytoskeletal and ECM remodeling in human TM cells. (A) Substrate stretch (substrate deformation, 6%) elevates $[Ca^{2+}]_i$ in TM cells, an effect that is suppressed by a selective TRPV4 antagonist. (B) Injection of a TRPV4 antagonist into a mouse eye with experimentally elevated IOP results in dramatic IOP lowering. (C) Stretch drives the upregulation of ventral actin stress fibers. (D) *In vitro* model of trabecular outflow using bioengineered 3D nanoscaffolds populated with TM cells. Pressure upregulates actin stress fibers and increases release of fibronectin. This effect is antagonized by TRPV4 blockers (not shown). Adapted from Ryskamp et al (2016) (51).

that is manifested in their light response, synaptic output and survival. **Figuring out *why* and *how* IOP preferentially targets RGCs currently represents a central challenge in glaucoma research.**

Although 'glaucoma' is a late-stage designation of the injured retina, RGCs are remarkably sensitive to acute changes in pressure which result in immediate changes in excitability, loss of spatiotemporal contrast sensitivity and reduced visual acuity (55, 56). Functional dysfunction correlates with the retraction, thinning and reduced complexity of RGC dendrites, loss of synapses and changes in axonal transport (54, 57-60) (Figure 11). Pressure-induced changes in cell firing and dendritic injury are compounded by the obstruction of (anterograde/retrograde) transport of neurotrophic factors and organelles (61) which, if it persists, can contribute to gross structural remodeling at the optic nerve head. Macroscopic remodeling of the ONH tends to be observed months (rodents) or years (primates) after the onset of ocular hypertension, time lags when it tends to be too

late for neuroprotective intervention. Recent studies instead suggest that IOP-induced alterations in dendritic architecture and glial activation (see below) represent better early markers of glaucoma than transport loss. The importance of nonaxonal pressure targets was accentuated in a landmark study by Morgan's group, which demonstrated that *pressure-induced dendritic retraction and RGC loss occur in the presence of intact axons* (62). The studies of early pressure sensitivity and nonaxonal targets (55, 56) thus emphasize the need for early neuroprotective treatment that targets preservation of dendritic morphology and maintenance of synaptic connectivity within the retina.

There are disagreements regarding the onset of pressure-evoked optic nerve damage and pressure sensitivity of RGC subtypes. An early primate study reported RGCs with large perikarya to be disproportionally sensitive to pressure (63) but these results were not reproduced in primates (64) or rodents, where RGC damage appears to be topographic but not subclass-specific (65). IOP-induced RGC loss was not restricted to specific locations in the retina (55) and there seems to be little correlation between perikaryal size and neurodegeneration (58).

To better understand the disease it would be very helpful to know whether particular classes and subtypes of RGCs are disproportionately sensitive or resistant to mechanical stress. Some electrophysiological recordings combined with analysis of reporter-tagged RGCs point at OFF RGCs as more sensitive to elevated IOP from their ON counterparts (55, 58) but another study, employing similar approaches, reached an opposite conclusion (66). Similarly, Ou et al. (54) found IOP-induced dendritic remodeling to be more extensive in OFF cells yet other studies show no apparent differences in pressure-induced dendritic pruning across functional subtypes (67). It is possible these disparities were caused by different ways of inducing ocular hypertension. In any case, it is very possible that early RGC pressure damage in glaucoma reflects molecular/functional, rather than anatomical, parameters (68). For example, susceptibility of OFF-type cells may reflect different responses from local vasculature or glia, and/or altered availability of trophic factors (58). Intrinsically photosensitive RGCs (ipRGCs) tend to resist IOP elevations (69) (see chapter in Webvision on melanopsin expressing ganglion cells), perhaps due to diminished numbers of pressure transducing molecules (70).

John's compartmental model (39) transcends such either/or dichotomies by providing a heuristic framework for the early effects of elevated IOP. The model has profoundly advanced the conceptual disease paradigm by positing that RGCs degeneration in glaucoma involves parallel effects of pressure on molecularly distinct local self-destruct programs in dendrites, somata and axons. A plausible multi-compartmental regulator of pressure-induced damage could be the calcium ion, which drives the remodeling of dendrites, somata and axons through Ca^{2+}-dependent proteases, caspases, MAP kinases, ER stress, autophagy and apoptotic cascades (71-73) (see below). Abnormal autophagy and endoplasmic reticulum (ER) damage, which compromise RGC viability due to intracellular accumulation of misfolded proteins, loss of calcium homeostasis and deficient protein trafficking (73) represent additional early features of pressure-related RGC stress, whereas axonal constriction constitutes both a possible early insult and potential coup de grâce that instigates apoptosis. Consistent with the compartmentalization model, local axonal damage can be ameliorated by reducing oxidative damage, targeting the dual leucine zipper kinase (DLK) enzyme and potentially with exercise. Accordingly, preclinical experimental strategies that aim to increase RGC survival in glaucoma can be separated into approaches that (i) facilitate expression of endogenous protective mechanisms, (ii) supply RGCs with exogenous neurotrophic factors, (iii) target pressure-sensing mechanisms, (iv) prevent downstream remodeling (v) slow down cell death by targeting the final common apoptotic pathway and/or (vi) use pharmacological agents with wide-spread or unclear neuroprotective mechanisms of action. Adult ganglion cells in mammals show little or no regenerative response after pressure injury however their survival can be extended for short periods of time with recombinant and virally expressed delivery of neurotrophic factors (e.g., BDNF, CNTF, NT-4, FGF-2, neurturin) which partially protect RGCs in animal models of glaucoma (59, 74). Degrees of protection have been observed following treatments with Rho kinase inhibitors, endothelin ET-2 inhibitors, erythropoietin, resveratrol, NMDA receptor antagonists, NO donors, antioxidants, α_2-adrenergic agonists (brimonidine), cannabinoids (e.g., Δ^9-THC) and β-adrenergic blockers. Memantine, an antagonist of NMDA receptors, has shielded rodent and non-

human primate ganglion cells from glaucoma (75) but was ineffective in human trials. Enigmatically, exposure to long-wavelength red light (850 – 1100 nm) was reported to be protective (76), and visual (neuronal) activity was proposed to facilitate regeneration of injured RGC axons (77). The multiplicity and variability of protective effects suggests that many therapeutic strategies may have been targeting secondary molecular mechanisms that are downstream from the actual RGC mechanotransducers.

Optic nerve head (ONH)

Degeneration ("cupping" or "excavation") of the ONH is the current diagnostic marker that separates glaucoma from other RGC diseases (e.g., nonarteritic anterior optic neuropathy (NAION), traumatic optic neuropathy, optic neuritis and multiple sclerosis). Cupping correlates with the manifestation of "arcuate scotoma" (loss of sensitivity) in visual testing (perimetry) and correlates with axonal loss observed in imaging studies. Because topology of RGC loss and defects in the visual field (radial in humans, sectorial in rodents) correlate with the position of axons within the ONH (10, 38), the ONH is widely seen to be important in determining the extent of final axonal damage that drives neurodegeneration.

The ONH contains unmyelinated (early) and myelinated (late) parts of RGC axons together with their extracellular matrix ECM/glial scaffolds and the capillary blood supply (Figures 12 & 13) (reviewed in (10, 38)). The biomechanics of this region are affected by the stiffness and thickness of the sclera that surrounds it and by glial deposition of ECM molecules (78). The "papilla" where the optic nerve enters the retina (Figure 12) represents the weakest part of the sclera as the axons (~1.2 million in humans) make a 90^{o} turn to enter the optic nerve through ~200-400 pores of varying sizes that are part of the structure called the *lamina cribrosa*. 12% of axons must squeeze through these collagenous pores. Axons from the peripheral retina pass in the peripheral part of the lamina whereas those from the central retina pass through its center but axons from the same retinal eccentricity may pass at different levels within the optic nerve.

The primate lamina cribrosa is a specialized region of ~10 interconnected ECM beams composed of collagen I, III, IV and elastin. These beams are lined with astrocytes, microglia, fibroblasts and an extensively branched vascular supply all of which may interact. Small ECM-cell adhesions may persist for tens of seconds whereas linkages between focal adhesions, intracellular actin cytoskeleton and ECM proteins (fibronectin, tenascin, collagens, etc.) can form on the scales of minutes-to-hours (78). Mechanical strains experienced at the ONH at normal IOPs (~15 mm Hg) range between 5 and 6% whereas IOP elevations to 50 mm Hg may increase them to 8 – 10% (79). Typically, 5-10% cellular stretch is sufficient to substantially affect calcium levels, cytoskeletal organization and tissue physiology across tissues and organs. Biomechanical modeling and 3D reconstruction studies points at the viscoelasticity of ONH structures as a determinant of the dynamic ONH response to changes in IOP. Cribrosal ECM plates in particular are seen as the weakest contact point for mechanical strain/compression (80). Increases in pressure stiffen the ONH yet it is not clear whether a stiffer lamina is better at countering mechanical stress. A useful analogy may be the hypertrophic (fibrotic, stiffer) heart which allows stronger pumping against high back-pressure, but is ultimately detrimental for cardiovascular health.

It must be pointed out that our understanding of the types of strain that affect RGC axons remains incomplete due to the anisotropy of the ONH and the likelihood that subregions with different geometry experience different tensions in response to the same IOP stimulus (78). The size of the pressure differential between IOP and the optic nerve is unknown and it remains unclear that it is affected by cerebrospinal fluid pressure, whether and how stretch of scleral tissues contributes to RGC injury, whether certain RGC classes (which?) are selectively sensitive/resistant to IOP, why retinal glia are so sensitive to elevated IOP, what (if any) is the role of ischemic compression at moderate IOP elevations and which signaling pathways mediate the acute vs. chronic effects of ocular hypertension. These pathways might be linked via IOP-dependent obstruction of anterograde and retrograde transport of pro-survival growth factors (BDNF, NT-3/4, NGF, CNTF), changes in immune gene expression, local chemotaxis, cell-ECM interactions and mitochondria (81, 82). It is possible if not likely that

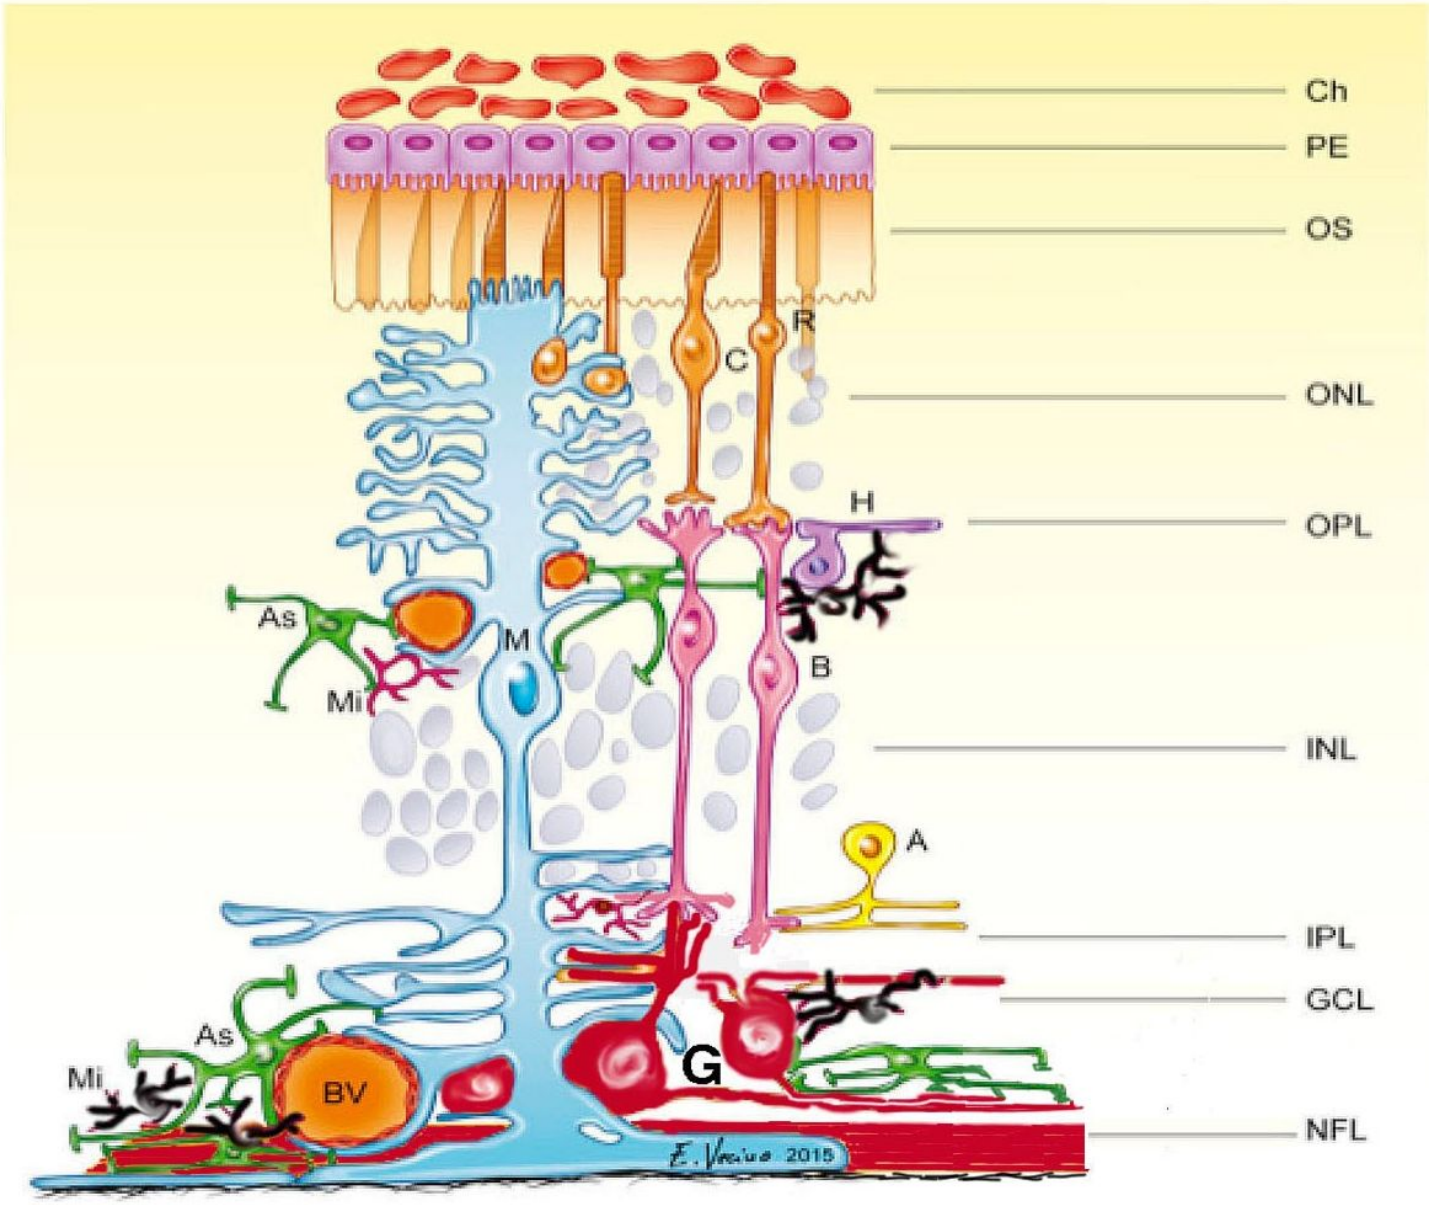

Figure 10. Schematic drawing of the glia and their relationship to neurons, retinal pigment epithelium and blood vessels in a prototypical vascularized mammalian retina. Note the proximity of blood vessels (BV), astroglia, Müller glial endfeet, and neuronal processes. From Vecino et al. (2016) (139). Drawing modified by Helga Kolb. (2018).

pressure affects these manifold processes via mechanotransducer mechanisms (such as mechanosensitive TRPV4 and TREK-1 channels and integrins; see below), which mediate the responses to scleral stretch, ONH compression, tension & shear. Activation of these mechanotransducers in different cell types (RGCs, glia, vasculature) may determine the relative balance of axonal vs. nonaxonal injury and the importance of neuroinflammation between individuals (and species) with glaucoma.

Many of the studies that implicate axonal involvement in glaucoma have been conducted in optic nerve crush models that are not directly relevant to pressure-induced axonal injury. Studies in animal models of primary open angle (microbead-induced) and secondary closed angle (DBA/2J) glaucoma clearly show that pressure

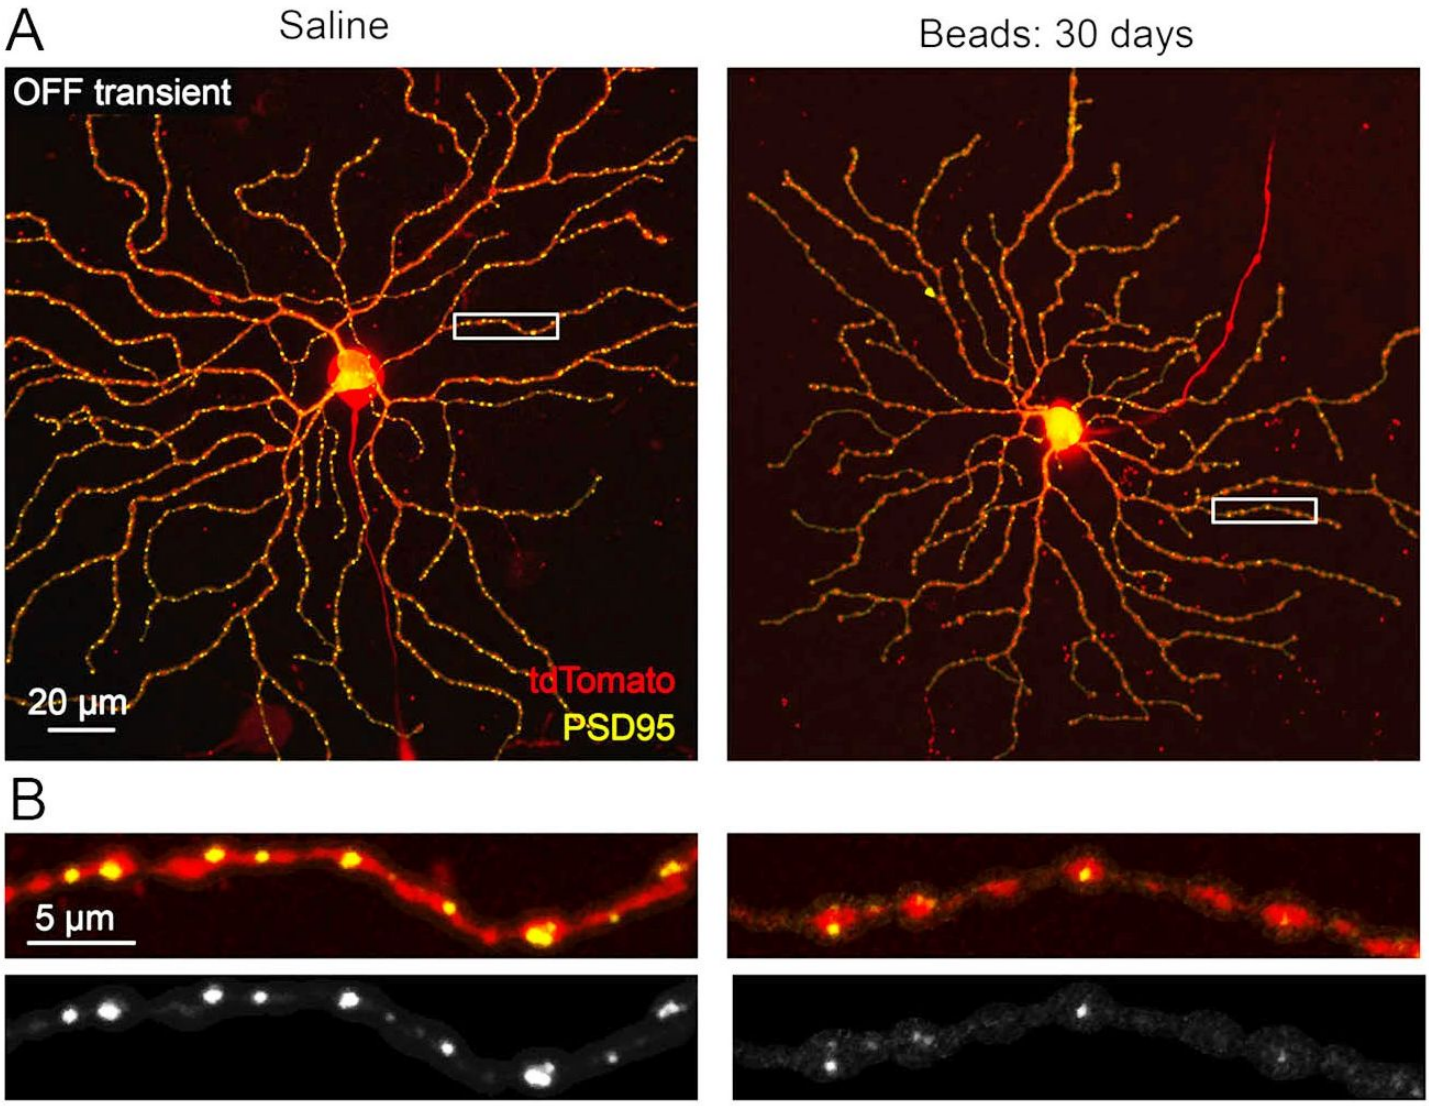

Figure 11. The effect of high intraocular pressure on certain ganglion cells in the mouse model of glaucoma (made glaucomatous by injection of microbeads into the anterior chamber of the eye). (A) immunocytochemical staining of biolistically labeled OFF sustained retinal ganglion cells in microbead injected and in control (saline injected) retinas. The glaucomatous ganglion cell is less robust in dendritic branching and exhibits less synaptic sites (yellow staining spots) than the control ganglion cell. (B) The dendrites are stained by tdTomato, and their synaptic sites by PSD95-CFP. Synaptic sites are more numerous on the control ganglion cell dendrites, but fewer and weakly stained in the bead-injected (high IOP model) retina. From Della Santini et al., 2013 (55).

elevations compromise axonal transport (61) but its importance for neurodegeneration remains to be established given that long-lasting reductions in transport don't impact RGC survival in axonal diseases such as papilledema. Moreover, many types of RGC tolerate loss of transported survival-promoting factors, whereas the lack of sustained RGC survival in retinas supplemented with neurotrophic factors argues against the obligatory consequences of their loss in animals with blocked axonal transport. Furthermore, changes in axonal transport in DBA/2J mice (9-12 months) tend to occur much later (83) than dendritic remodeling (1-3 weeks; (55)), glial reactivity (3-6 months) and defective signaling of the optic nerve (~6 months) (72, 84, 85) . The observation that anterograde transport is compromised before retrograde transport (83) argues against a key role for ONH constriction predicted in most biomechanical models. Instead, recent studies suggest a key role for nonaxonal mechanisms that include physiological deficits in RGC activity (55, 83) and inflammatory signaling (35, 81).

Another important argument against the obligatory role of the lamina cribrosa in glaucoma is supplied by evolution. Laminar ECM plates are well developed in pigs, cats, guinea pigs, tree shrews and dogs but are absent in rodents. In rats and mice, structural and metabolic support to passing RGC axons (~50,000 in mice) is provided by a "glial lamina" composed of astrocytes that form tubes around the axonal bundles (38, 86) (Figure 13). Because these animals still develop glaucoma in response to elevated IOP, neither ECM plates nor the lamina cribrosa are likely to be necessary for pressure-induced axonal loss.

IOP causes neuropathy in the brain

Glaucomatous damage is not restricted to the eye but includes the entire visual pathway from the retina to the brain. IOP increases cause spatial vision loss (87) together with decreases in the size, number and metabolic activity levels in P-, K-and M-layers of the lateral geniculate nucleus (LGN), and cells in magnocellular layers apparently more susceptible to damage compared to parvocellular cells. Furthermore, changes can manifest in layer 4C of the primary visual cortex (88). Hence, regenerative strategies in glaucoma will have to ensure axonal survival and regrowth, perhaps through stimulation of the retinorecipient afferents (89). This will require attention to glaucoma-related changes to RGC axon terminals within the midbrain and retinotopic specificity of ganglion cell projections (61).

Glaucoma effects on the Sclera and Cornea

Sclera is a dense (400-1000 μm thick) connective-like tissue mainly composed of collagen and elastin fiber and populated with ECM-producing fibroblasts. It extends from the cornea to the optic nerve and provides mechanical support of the retina and an insertion for extraocular muscles. It contacts the lamina cribrosa within the "peripapillary" region (Figure 12A) that is expanded by, and thus resists, IOP. The sclera may therefore be considered biomechanically active system that experiences tension due to IOP and muscular contractions imposed by accommodation/convergence that in turn may be transmitted from the sclera to the adjacent lamina cribrosa, optic nerve and the vasculature that feeds the ONH (78, 80). We know that mechanical stress regulates the composition, growth and size of the eye (90) in part through activity of scleral MMP-2/TIMP2 enzymes (91). Similar to ONH and TM tissues, sclera becomes stiffer and thinner with age and in glaucoma, which may compromise its ability to bear IOP-induced stress and protect the more compliant retina and axons.

Increased risk for IOP-dependent vision loss has been correlated with thinner central corneal thickness and viscoelastic damping ("corneal hysteresis") (40). This might suggest that glaucoma involves changes in molecular mechanotransduction and biomechanical properties across all tissues in the eye. Subjective vision loss in glaucoma often results from corneal edema caused by a rapid rise in IOP. Unfortunately, little is known about how corneal epithelial/endothelial cells sense pressure and tensile stretch (40).

Neuroinflammation in glaucoma: the crucial functions of glial cells

Pressure-dependent activation of retinal glia is a central if sometimes underappreciated feature of glaucoma. In healthy retinas, **Müller cells** (Figure 10, M, blue cells) provide essential metabolic, osmotic support and maintain the excitatory-inhibitory balance through removal of extracellular glutamate. **Astrocytes** (Figure 10, As, green) maintain the ONH structure, support axons, and maintain the blood-retina barrier. **Microglia** (Figure 10, Mi, black) regulate proper synapse formation, phagocytosis and immune signaling, whereas **oligodendrocytes** (not shown in Figure 10) myelinate RGC axons from the lamina to midbrain in the optic nerve.

Glaucomatous glial cells exhibit response patterns that mirror the responsiveness of their brain counterparts to neuronal damage from physical trauma, pathological swelling and neurodegenerative disease. IOP elevations evoke profound changes in retinal glial gene expression, gliotransmitter release, and compromise their roles in

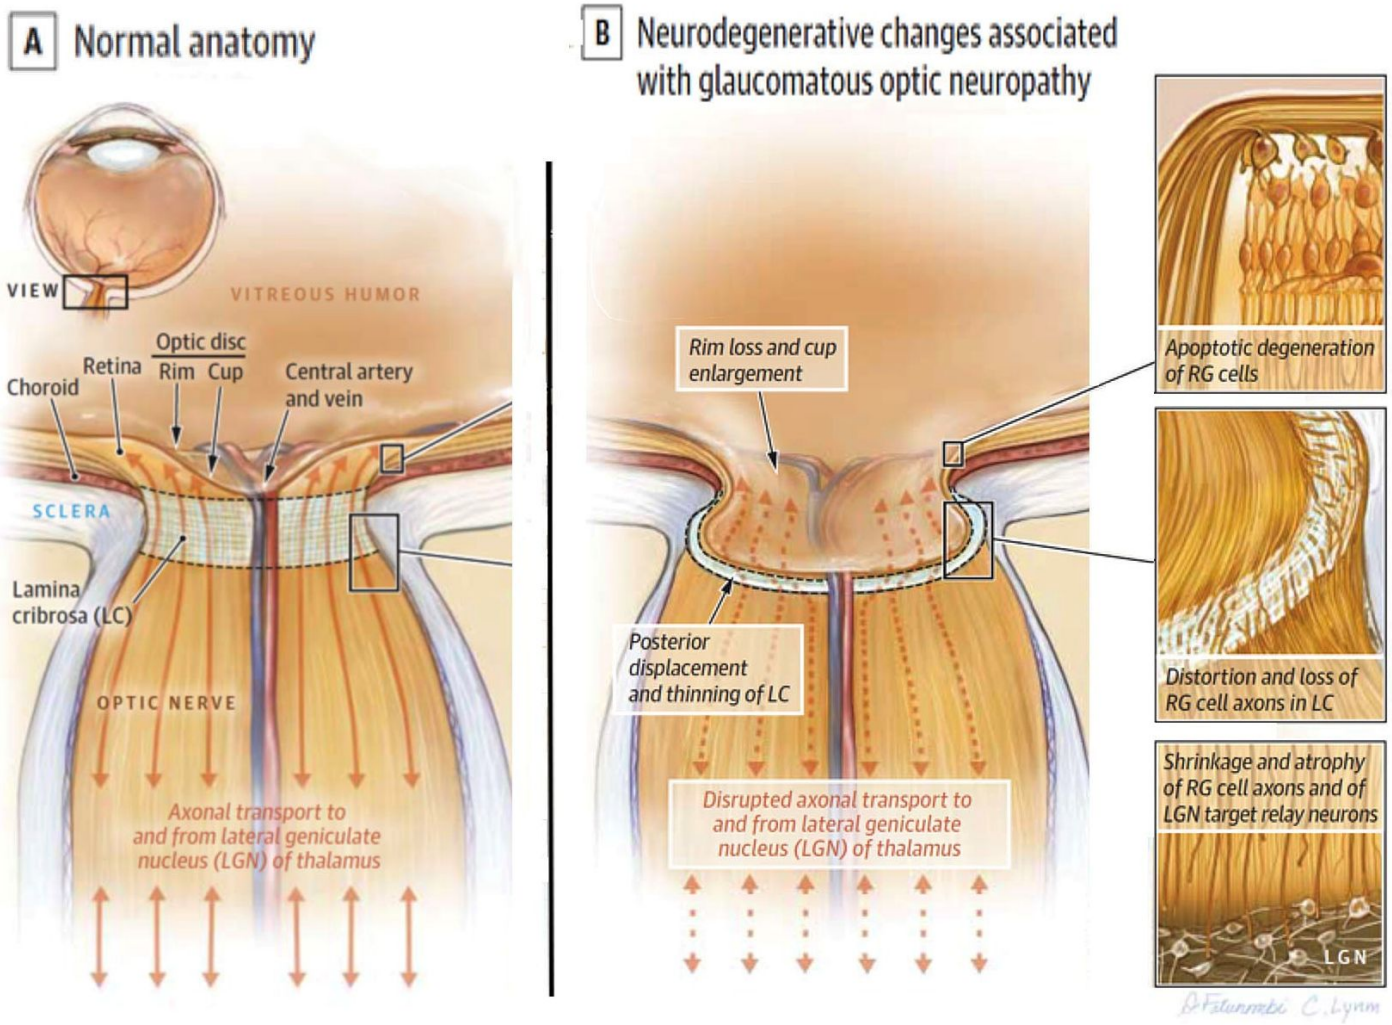

Figure 12. (A) The optic nerve head (optic disk) is composed of neural, vascular, and connective tissues. (A) The convergence of axons of retinal ganglion cells (RG) at the optic disc creates the neuroretinal rim that surrounds the cup, a central shallow depression in the optic disc. RG axons exit the eye through the lamina cribrosa (LC), forming the optic nerve, and travel to relay nuclei for vision within the midbrain (including the LGN). (B) Optic neuropathy in glaucoma involves damage and remodeling of the optic disc and LC that lead to vision loss. Note the displaced and thinned LC that is associated with axonal loss and contributes to the excavation of the cup. Strain placed on the LC causes molecular and functional changes in astrocytes and microglia, remodeling of the extracellular matrix and impairing of local microcirculation. Adapted from Weinreb et al (2014).

nitric oxide, cytokine, chemokine, immune-like molecule (e.g., complement, CX3CL1, TNFα, IL-1β) and reactive oxygen species (ROS) signaling (35, 85). Short and mild increases in IOP may induce reactive activation of Müller cells, astrocytes and microglia prior to significant RGC/axonal damage. One prominent example is glial-dependent changes in cytoskeletal, ECM proteins and structural proteins (the glial acidic fibrillary protein GFAP, vimentin, collagens, laminin and tenascin) and downregulation of proteoglycans (92). Ocular hypertension also underlies metabolomic remodeling in the retinal glia, with includes downregulation of glial glutamate uptake and biosynthesis of glutamine that could impact neuronal excitability and function. A less understood aspect to the yang of pressure-induced proinflammatory glial signaling is the yin of trophic protection from glial release of protective neurotrophic CNTF and/or BDNF factors, and JAK/STAT3 signaling.

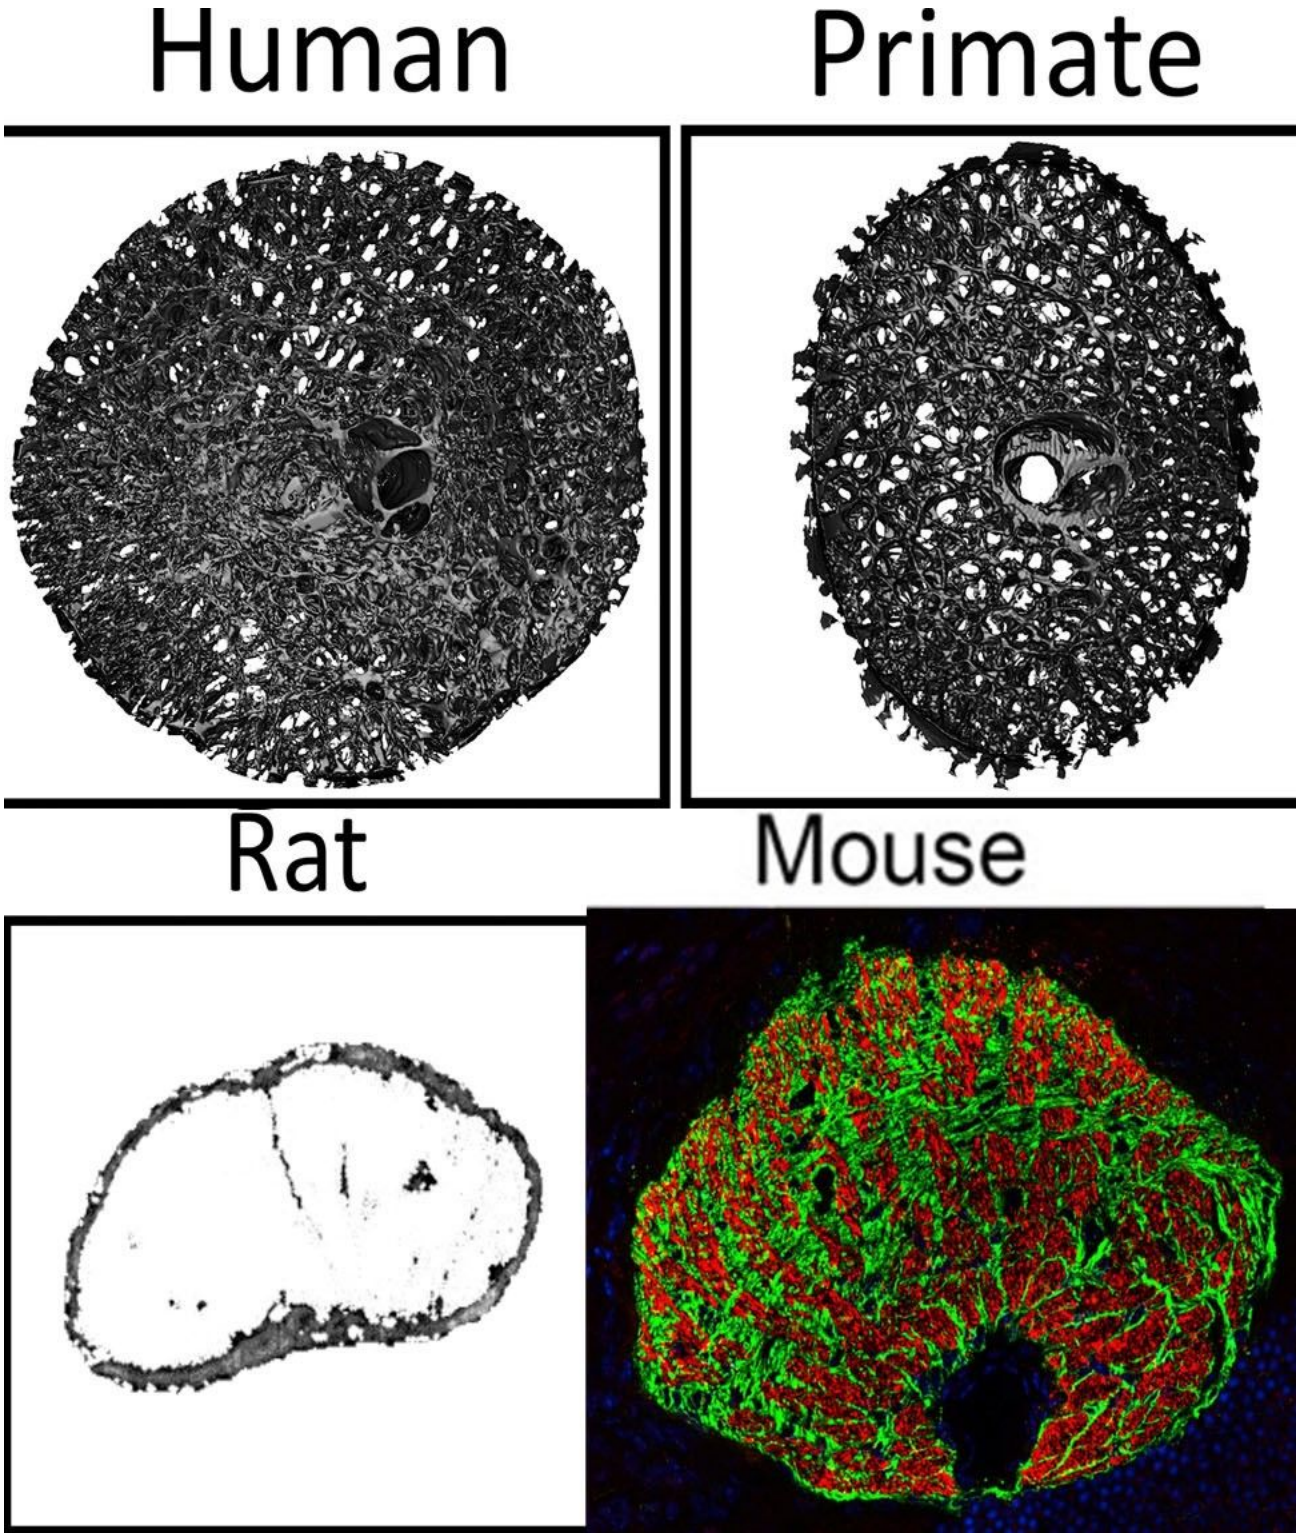

Figure 13. Collagenous lamina are obvious in human and primate, but minimal in rats After Samuels et al., 2018 (140). The lamina in the mouse shows astrocytes (green) between the axons (red). The ophthalmic artery is the hole in all images. From Rudolf Fuchshofer, in Tamm and Ethier, 2017(141).

Astrocytes in the optic nerve head and in glaucoma

Astrocytes are less abundant in the retina than in the brain but still comprise ~50% of cells in the primate ONH. Their retinal functions include maintenance of vascular tone, ECM production and structural support (93).

Astrocytes regulate neuronal activity and neurovascular coupling via ATP, prostaglandin, angiotensin, adenosine and EET (epoxyeicosatrienoic acid) release. Moreover, as the dominant producers of the ECM, astrocytes contribute to the mechanical compliance of the lamina cribrosa and its remodeling in glaucoma. The mammalian retina contains astrocytes with distinct molecular and anatomical signatures. Type I GFAP-positive astrocytes, located in the prelaminar and unmyelinated regions of the human ONH (green in Figures 10 & 14, red in Figure 15A), cover ECM beams and cribrosal pores, ensheath axonal bundles, surround blood vessels and mediate transfer of metabolites between axons and capillaries (green in Figures 10 & 14). Another subtype, the $GFAP^-$negative and α-SMA (smooth muscle actin)- negative Type 2 astrocytes dominate the myelinated postlaminar region of the ONH (94) where they coexist with a subset of recently discovered $GFAP^-$ $\alpha\text{-}SMA^+$ "lamina cribrosa cells" that may weaken the ONH through dysfunctional synthesis of collagens, elastin and fibronectin (95). In rodents, astrocytes are classified using morphological rather than molecular criteria into protoplasmic and fibrous subtypes (92). As in mammals, rodent astrocytes tile the retina to regulate neurovascular function (Figure 10, Figure15B panel E) and send out fine processes that ensheath and compartmentalize axonal bundles. In contrast to the ONH, rodent astrocytes also provide structural support within the "glial lamina" (Figure 13). However, in animals with avascular retinas (such as rabbits), astrocytes are absent from areas that lack blood vessels,

Neighboring astrocytes are coupled through homomeric (e.g., Cx 43) and heterotypic gap junctions that redistribute calcium ions and metabolites across the glial network but also regulate neuronal function via release of neuroactive compounds (96, 97). The cells are a major source of fibronectin, but also upregulate many ECM proteins in response to mechanical stressors (pressure, stretch) under both *in vivo* and *in vitro* conditions (e.g., tenascin, laminin, collagens, elastin and thrombospondin) (e.g., Figure 14) together with genes associated with cell motility and migration (gelsolin, LIMBP1, periplakin) and downregulation of integrin genes (92, 98).

Mechanical stressors dramatically alter the gene expression, morphology and function of retinal astrocytes and push the cells into a reactive state called *astrogliosis* that manifests as the inflammation and fibrosis of the lamina, and correlates with weakened ONH architecture, compromised blood supply and axonal loss (86, 98, 99). Astrocytes in the glaucomatous ONH exhibit thickened processes, calcium-dependent hypertrophy and proliferation (86, 99). The list of genes/proteins associated with IOP-induced astrogliosis comprises hundreds of genes that encode cell cycle proteins, mitogen-activated protein kinases (MAPKs), bone morphogenetic proteins (BMPs), endothelin receptors (ET_A and ET_B), matrix metalloproteinases (MMPs), JAK/STAT3 transcription, cytoskeletal proteins (GFAP, vimentin, collagens, laminin and tenascin), cell adhesion components, signal transduction molecules (NF-kB, STAT5, MCP-1, glypicans), immune/complement systems (C1q, cytokines such as IL-6, LIF), periostin, phagocytosis-related gene *Mac-2,* and/or NF-κB-dependent assembly of the astroglial inflammasome (81, 100, 101). The cytokine TGF-β2 released from retinal astroglia suppresses MMP-dependent ECM degradation while promoting the expression of collagens, elastin and fibronectin (92) that may result in a stiffer lamina and ONH damage. Another hallmark of pressure-activated astrocytes is the migratory response that allows them to crawl out of laminar cribriform plates (102).

While we don't understand how elevated IOP induces astrogliosis, physiological studies show a direct link between mechanical stress and astroglial $[Ca^{2+}]_i$ (97). Physical forces induce transmembrane currents across retinal astrocyte membranes (103), trigger propagation of calcium waves between astrocytes and Müller glia and stimulate release of proinflammatory mediators. Retinal astroglial mechanotransduction is therefore best viewed within the context of feedback loops with adjacent microglia, Müller cells, microvasculature and RGCs (104).

Microglia and monocytes in glaucoma

Glaucoma involves both adaptive and innate immune mechanisms, with retinal microglia - which constitute the innate immune system - as one of the earliest sentinels of mechanical stress. In healthy retinas, microglial processes (*Mi*; black in Figure 10) engage in dynamic surveillance of the local milieu and shaping of local

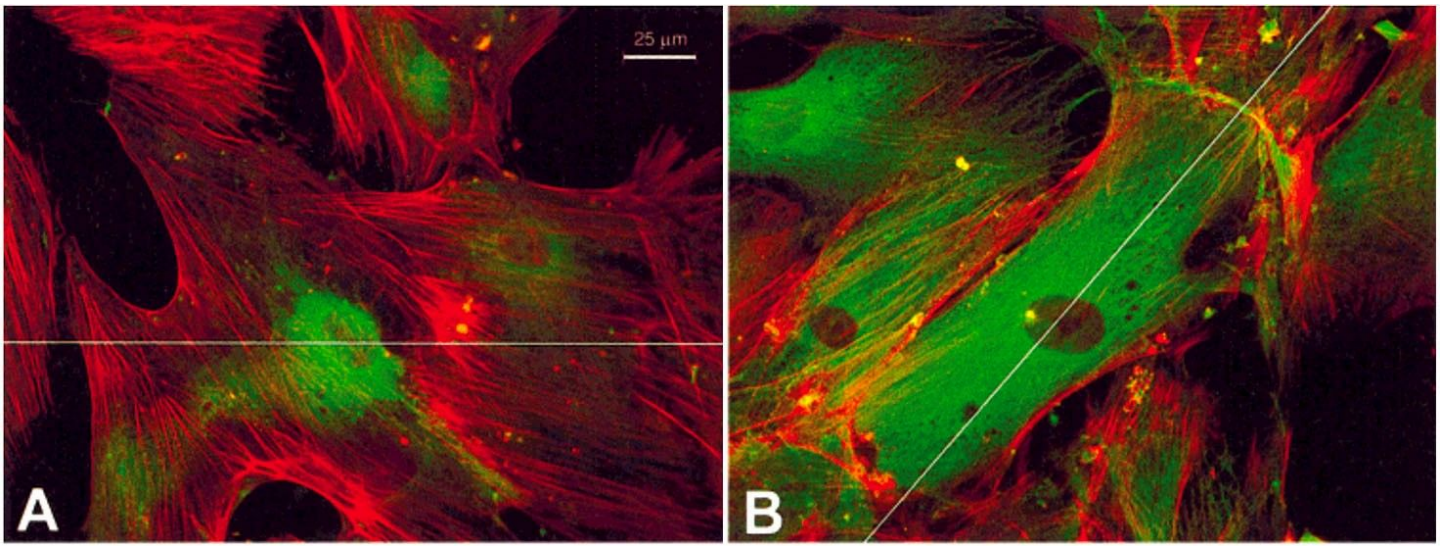

Figure 14. Cultured Type B astrocytes from explanted human lamina cribrosa. (A) Control astrocytes immunostained with tropoelastin (green) and phalloidin (for F-actin, red). (B) Astrocytes exposed to 10 cm H_2O pressure have increased intracellular tropoelastin (green) and displacement of the F-actin filaments (phalloidin, red) to the periphery of the cells. synaptic contacts but this activity is dramatically altered in the proinflammatory phenotype associated with glaucomatous microglia. These cells can be characterized by proliferation, process retraction and upregulation of complement, toll-like receptor (TLR2-4), TNFR1α & β receptors, nitric oxide synthase, heat-shock proteins (HSP27, HSP60, HSP72), chemokine (IL-8) and cytokine (IL-1β, IL-6, CCL2, TNFα) signaling as well as the

suppression of anti-inflammatory TGFβ signaling (35, 105). Release of metalloproteinases (MMP-1-3) may alter and destabilize the ECM early in the disease. An important recent study from the Vetter laboratory recently demonstrated a key role for microglia in selecting the surviving RGCs during development (106). Within the ONH, microglial activation is first detected in the areas of early axonal damage (Figure 15A, Figure 15B), potentially in response to loss of fractalkine (CX3CL1) inputs from RGCs (107) and altered cross-talk with Müller glia (108). Both minocycline, a small-molecule inhibitor of microglial activation, and bosentan, an inhibitor of microglial endothelin (ET1/2) receptors, increased ganglion cell survival in the DBA/2J mouse glaucoma model (81, 109).

Another important feature of immune activation in the glaucomatous retina is the permeability loss of the blood-retina barrier, which allows the invasion of activated monocytes and dendritic cells from systemic circulation (81, 105). Glaucoma has been linked to microglial changes in the classical and alternative complement pathways, with the 'alternative' C1q complex (38) presumably promoting activation of the 'classical' C3 convertase that instigates synaptic pruning and somatic phagocytosis. Another important player are the cytokines IL-1β and TNFα, which promote RGC apoptosis in the glaucomatous retina (105). IOP elevation in one eye triggers microglial activation in both eyes, providing evidence that the involvement of immune mechanisms in glaucoma involves the spread of diffusible systemic factors. Consistent with this, activated microglia form clusters around blood vessels in hypertensive eyes (110) and dendritic and synaptic architecture in rodent glaucoma can be protected not only by inhibiting the C1q protein or deleting its gene, but also by blocking pressure-induced immigration of macrophages/monocytes (60, 81). In addition, microglia may respond to mechanically released chemokines such as the monocyte chemoattractant protein (MCP-1) from Müller glia (111) and fractalkine (CX3CL1) from ganglion cells (107).

Müller cells

Müller cells (*M*; blue in Figure 10) are radial glia that extend from the outer to the innermost retina. They ensheath every neuron and regulate virtually every aspect of retinal function, from energy metabolism to volume regulation, blood flow, uptake and recycling of neurotransmitters and immune signaling (112). Their membrane properties are dominated by potassium channel Kir 4.1-dependent inward rectification, which

drowns the contributions from other ion channels. Müller endfeet contribute to the neurogliovascular unit that maintains the blood-retina barrier (Figure 16, control) and also secrete the basement membrane forming the inner limiting membrane through which the retina interacts with IOP. Endfeet strongly express stretch-activated TRPV4 channels and are therefore very sensitive to tensile stretch, poking and changes in volume (27, 113).

Müller glia are amongst the first retinal cells to respond to elevated IOP (85). Acute and chronic IOP elevations push them into a reactive state (reactive gliosis) that is typically visualized by immunolabeling the retina for the intermediate filament GFAP (Figure 16; chronic and acute glaucoma). Mice lacking GFAP may be more sensitive to mechanical injury (114), perhaps because these cytoskeletal elements resist mechanical stress. In the reactive mode, Müller cells are likely to modulate vascular permeability and neuronal survival via the release of nitric oxide, TNFα/IL-1β/NF-κB/mTOR signaling and release of the cytokine MCP-1 (35, 111). Among other aspects of Müller signaling affected by pressure are the downregulation of glutamine synthesis/glutamate uptake, upregulation of cytoskeletal proteins, and changes in expression of aquaporin AQP4 (water) channels, calcium channels (ryanodine receptors), complement proteins (C1q) and advanced glycation end products (RAGE) (72, 115, 116).

Endothelial cells, pericytes and local blood supply

Blood supply to the ONH originates in the ophthalmic artery which branches into the central retinal artery, perfusing the nerve fiber layer (Figure 10) and two posterior ciliary arteries. Venous blood drains into the central vein that travels in the optic nerve (Figure 12). Large IOP increases induce ischemia, which compromises the diffusion of glucose, oxygen and lactate through capillary compression, however, even small (3-5 mm Hg) elevations in IOP may result in hypoxia, accumulation of reactive oxygen species and hypoxia-induced factors (e.g., HIF-1α and HIF-2α), downregulation of astroglial glutathione content and induction of the autophagosome (117).

Research challenge for the future

The importance of calcium

The past decades have seen intense efforts to determine the final common mechanism(s) in glaucomatous retinal injury. With respect to RGCs, these mechanisms include ER stress, activation of proapoptotic cascades and dysregulation of calcium homeostasis within axonal and nonaxonal compartments (35, 39). Calcium, a 2nd messenger, plays critical functions in cellular physiology and pathology across the body and it is not surprising that virtually every cell type associated with glaucoma, and every stage of the disease, appear to involve Ca^{2+} dysregulation. The sources and pathways associated with pathological Ca^{2+} homeostasis in glaucoma may include ion channels within the plasma membrane and calcium release from intracellular compartments such as the endoplasmic reticulum (ER), mitochondria and lysosomes. It is not inconceivable that such changes in $[Ca^{2+}]_i$ promote TM contractility, drive inflammatory activation of retinal glia and facilitate the susceptibility of RGCs to secondary insults.

Experiments *in vitro* have demonstrated that mechanical stress triggers $[Ca^{2+}]_i$ elevations in retinal ganglion cells, microvascular endothelial cells, nonpigmented cells of the ciliary body, glia and the trabecular meshwork (51, 113, 118-120) whereas Ca^{2+} removal from the external medium or calcium chelation block stretch- and swelling-induced Ca^{2+} influx and stretch-induced remodeling of the cytoskeleton. There is evidence that $[Ca^{2+}]_i$ increases in glaucomatous RGCs occur in dendrites and somata (121), which might account for the increased ER stress and Ca^{2+}-dependent signals (immediate early genes (c-fos, JNK2/3, CREB), proteases, caspases and MAP kinases) in glaucomatous RGCs. Another Ca^{2+}-dependent mechanism involves constitutive activation of calpains, Ca^{2+}-dependent enzymes that promote caspase activation and protein degradation. Inhibition of calpains was protective in models of rodent ganglion cell injury, presumably through the Ca^{2+}-activated

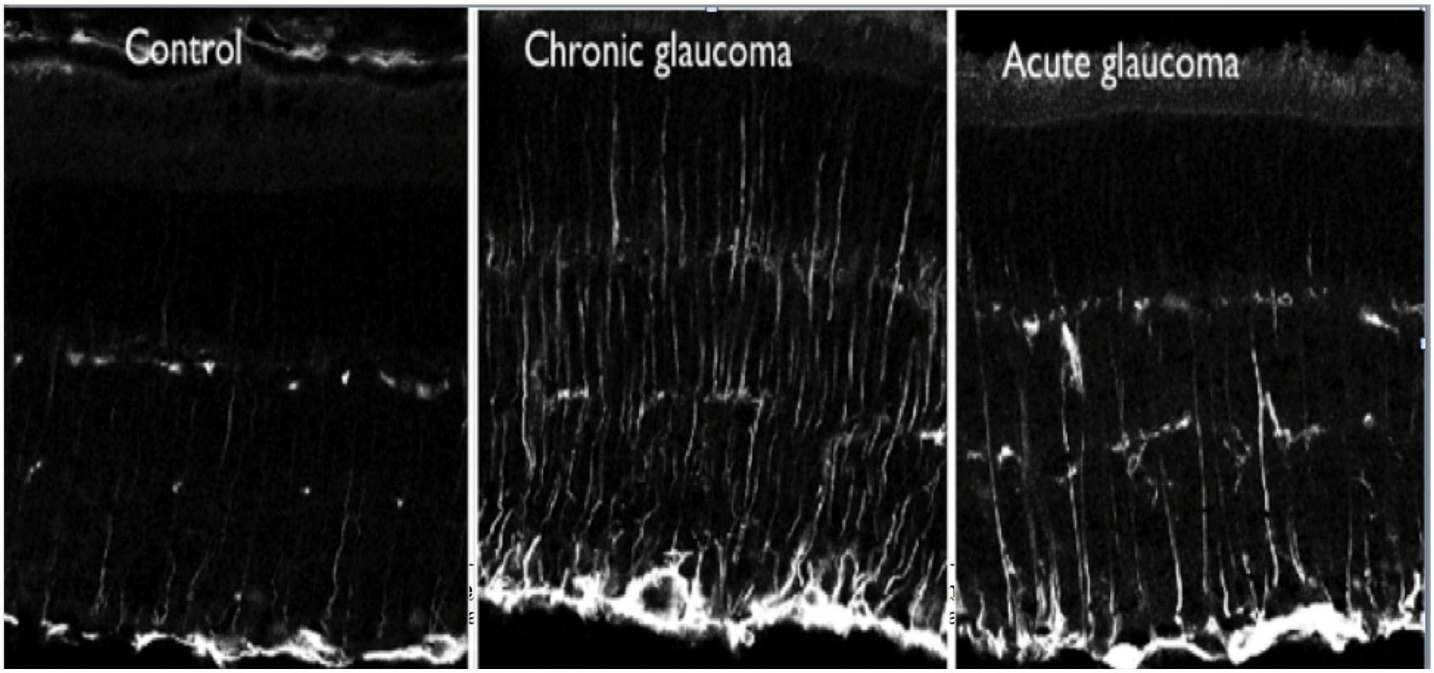

Figure 16. Reactive Müller gliosis in chronic (DBA/2J) and acute (microbead) mouse models of glaucoma. IOP elevations are associated with pressure-dependent upregulation of GFAP (glial fibrillary acid protein) in endfeet and radial processes (Krizaj laboratory, unpublished data).

phosphatase calcineurin (71). It is also possible, however, that the calcineurin-calpain pathway may contribute to axonal regeneration (122).

The findings described above suggest that targeting pressure-induced calcium influx might help alleviate retinal pathology. Such protective effects were seen under non-physiological conditions (optic nerve transection/crush), with the blockade of voltage- and glutamate-dependent calcium influx conferring largely protective effects on RGC survival and axonal degeneration. We hypothesize that blocking calcium-permeable channels that are sensitive to pressure or its biomechanical corollaries (such as tensile stretch) might result in even more significant injury amelioration in hypertensive eyes.

Importance of mechanotransduction

A crucial requirement without which glaucoma in animals and humans cannot be understood, is to define the molecular links between ocular pressure sensing, aqueous humor dynamics and neurodegeneration. To achieve this, we need a better understanding of actual sites of mechanical impact within the eye and identification of mechanical stressors (tensile strain, shear flow, compression etc.) that are sensed by cells in both the anterior and the posterior eye. Studies in animal models of glaucoma and in isolated cells show that most glaucoma-relevant cell types (trabecular meshwork cells, retinal glia and RGCs) respond to pressure with fast onset electrical and calcium signals (~milliseconds to ~seconds), whereas sustained exposure to mechanical stressors tends to evoke phenotypes that are characteristic of glaucomatous injury. In addition to characterizing the pressure transducer molecules, it will also be important to determine how ocular cells ignore steady-state IOP, and how they respond to and compensate for transient IOP fluctuations triggered by blinking, coughing, eye rubbing, circadian periodicity, swelling, ocular trauma, and exercise (e.g., swimming goggles, yoga practice). To identify the molecular mechanisms, we can now build on the vast trove of information available from investigations of cellular mechanosensing.

Mechanobiology is an emerging field that combines biology and bioengineering to study how physical forces and changes in mechanical properties of cells contribute to cell development, differentiation, proliferation and disease. Its common theme is that every cell converts mechanical inputs into electrical or biochemical signals by using specialized proteins that govern the mechanical stability and mechanical signal transmission at virtually every level of organization, from the nanoscale to macroscale (123, 124). These mechanotransduction machines impose regulatory constraints at the level of cell-cell and tissue-tissue networks but some cells are better at mechanotransduction than others, and therefore more sensitive to mechanical forces and dysregulated in disease. Often cited examples of mechanotransduction gone awry are hearing and balance diseases caused by mutations in mechanosensitive proteins, but there are many other examples of bone, cartilage, lung, bladder, immune system, heart and eye diseases caused by increased pressure and stretch (125). Glaucoma and myopia, for example, can be considered as mechanotransduction diseases that reflect the dysfunctional response of cells in the eye to specific types of local mechanical stress.

Many protein families respond to mechanical forces with conformational changes. Mechanosensitive proteins include focal adhesion proteins, cell-cell adhesion, integrin and ECM proteins, receptor tyrosine kinases, G-protein-coupled receptors, cytoskeletal proteins and, importantly, ion channels that are activated by minute changes in membrane curvature and stretch in the absence of chemical ligands (124-126). These m*echanosensitive channels* evolved for sensing submicrometer displacements of the plasma membrane but show huge differences in primary structure, ion selectivity, conductance and pharmacology (Figure. 17). They have been classified into Na^+-permeable (ENaC/degenerins), K^+-permeable (TREK, TRAAK) and nonselective cation (TRP and piezo) channel families, which show isoform-specific mechanical thresholds, time courses, adaptation to sustained stimulation as well as differences in how they tether to the cytoskeleton and respond to posttranslational modulation.

Conceptually, mechanochannels function as bandpass filters that can transmit specific amplitudes and types of mechanical stress (i.e., compression, tension, swelling, shear flow etc.) that range from gentle touch, pressure, texture, vibration, sound, shear flow to physical trauma and pain. Recent studies show that glaucoma-relevant tissues in the eye (TM, ciliary body, neurons, glia, cornea, endothelial cells) express multiple types of mechanosensitive TRP, piezo and tandem pore K^+ channels (27, 127-129). Pharmacological suppression and genetic ablation of these channels ameliorate the inflammatory and degenerative retinal phenotypes associated with ocular hypertension (119), suggesting possible roles in glaucoma.

Figure 17 illustrates the basic topology of vanilloid TRP (TRPV) and TREK (TWIK-1 related K+) mechanotransducers. TRPV4, a member of the vanilloid TRP family mediates influx of Na^+ and Ca^{2+} ions in response to a wide variety of mechanical and chemical stimuli (130, 131) that include pressure, stretch, swelling, poking and body temperature (34 - 37^{o}C). It is expressed in ~60-70% of mouse RGCs, 100% of Müller cells (Figure 18A) and the majority of trabecular and corneal epithelial cells (70, 113, 132), with some RGCs sharing TRPV4 expression with the cognate TRPV1 channel (Figure 18B) (70, 128). Interestingly, the channel appears to be absent from neuronal classes that are less sensitive to glaucoma (photoreceptors, bipolar, amacrine cells; Figure 10) and mice lacking TRPV4 show no deficits in outer retinal function (Figure 18C). TRPV4 channels are often integrated into cells' cytoskeleton network through ankyrin repeats in the N-terminus (Figure 17A) and are linked to ECM networks through α2 integrin molecules and focal adhesions. They are sensitive to pressure (129), drive stretch-induced cytoskeletal remodeling and may contribute to the loss of tensile homeostasis during chronic IOP elevations (51).

Many ocular manifestations of glaucoma (IOP changes, calcium overloads, reactive gliosis, cytokine release, microvascular dysfunction, actin upregulation, fibronectin secretion and RGC apoptosis) can be mimicked pharmacologically by stimulating TRPV4 channels in RGCs, glial, endothelial, ciliary body and trabecular meshwork cells (27, 111, 127, 133). TRPV4-induced phenotypes include RGC degeneration (133), reactive gliosis (27), glial swelling (113) and increased permeability of the blood-retina barrier (127, 134) whereas mice

lacking the TRPV4 gene seem to be protected from some types of mechanical and nociceptive stress (130) and do not appear to develop glaucoma (51). Cholesterol and polyunsaturated fatty acids - potential risk factors in glaucoma - also modulate TRPV4 activation (135).

How is mechanical homeostasis in the healthy eye maintained in counterpoint to TRP and piezo channel activation? A possible mechanotransducer candidate that opposes excessive TRPV4 activation might be the K^+-permeable TREK-1 channel. TREK-1 is eerily sensitive to stimuli that gate TRPV4 (membrane stretch, swelling, body temperature, and arachidonic acid) and is often co-expressed with TRPV4 (O. Yarishkin, F. Vazquez-Chona and D.K., unpublished observations). Mice lacking TRPV4 channels are less sensitive to mechanical stress (131) whereas mice with ablated TREK/TRAAK channels are hypersensitive to mechanical forces and local pH changes (136). According to this model, the tensile homeostasis of at least some ocular tissues might be maintained by concomitant activation of TRPV4/piezo vs. TREK-1 (and its cognate TRAAK) channels.

Summary and Conclusion

Glaucoma is a leading cause of irreversible blindness worldwide. There are multiple forms of the disease, but all involve dysfunctional signaling in the anterior eye that is linked to optic neuropathy. There is no cure and at present there is no way to regain sight that had been lost. This is a problem, because glaucoma is often asymptomatic until very late stages and many people with the disease do not realize they have the disease until it is too late for effective treatment. It is therefore important that patients with risk factors (i.e., elderly individuals with family history and/or African ancestry) are screened at regular intervals. After diagnosis, treatment will be lifelong but requires vigorous compliance with the treatment regimen (IOP-lowering eye drops).

What is glaucoma? The clearest answer is that we still don't know, as pathology can reflect a multifactorial pathology and/or a collection of diseases with a similar final common pathology. Interestingly, mechanotransduction in aged individuals and those with glaucoma appear to be compromised across all tissues of the eye (cornea, sclera, TM, retina), suggesting broad dysfunctions in the cells' ability to generate and process mechanical forces. Most forms of glaucoma appear to be hereditary, but it is likely that in order for the pathology to manifest, mutations/alterations in multiple proteins and/or lipids are required and identification of causal genes and mutations will immensely advance the diagnosis and treatment. For now, only 5-10% of cases have been linked to specific genes.

IOP lowering - currently the main treatment - begin with eye drops, with refractory or advanced cases relegated to laser procedures and incisional surgeries. At this time, anti-glaucoma agents largely target a secondary pathway that mediates a minuscule fraction of fluid outflow and there is much scope for improvement, especially in targeting trabecular outflow. Another priority is to protect retinal neurons and glia from pressure, which necessitates the elucidation of molecular/cellular mechanisms that sense and transduce mechanical stress. Specifically, improved treatment requires research scientists, clinicians and biomedical engineers to (i) Determine the quantitative relationships between risk factors, genetic susceptibility and molecular mechanisms that underlie cellular interactions in the front and the back of the eye, (ii) Develop standardized tests to define where the optic neuropathy in a particular patient falls in the spectrum between 'normal' aging and glaucoma, (iii) Develop novel technologies (such as optical coherence tomography) for early diagnosis (iv) Improve the efficacy of pharmacological agents that target TM while eliminating side effects and (v) Protect the pressure sensitive targets within the trabecular meshwork, retinal ganglion cells and glia. This requires investment into neuroprotective treatments, which has been discouraged by disagreements among scientists about RGC mechanotransduction mechanisms, the prohibitive expense of clinical trials, and recent pricey failures of putative neuroprotection drugs.

A main goal for future treatments must be to lower IOP together with the protection from pressure-dependent inflammation and neurodegeneration, an approach that may include direct targeting of the pressure sensing proteins themselves. Unfortunately, at this moment there seems to be - despite decades of intense research - no

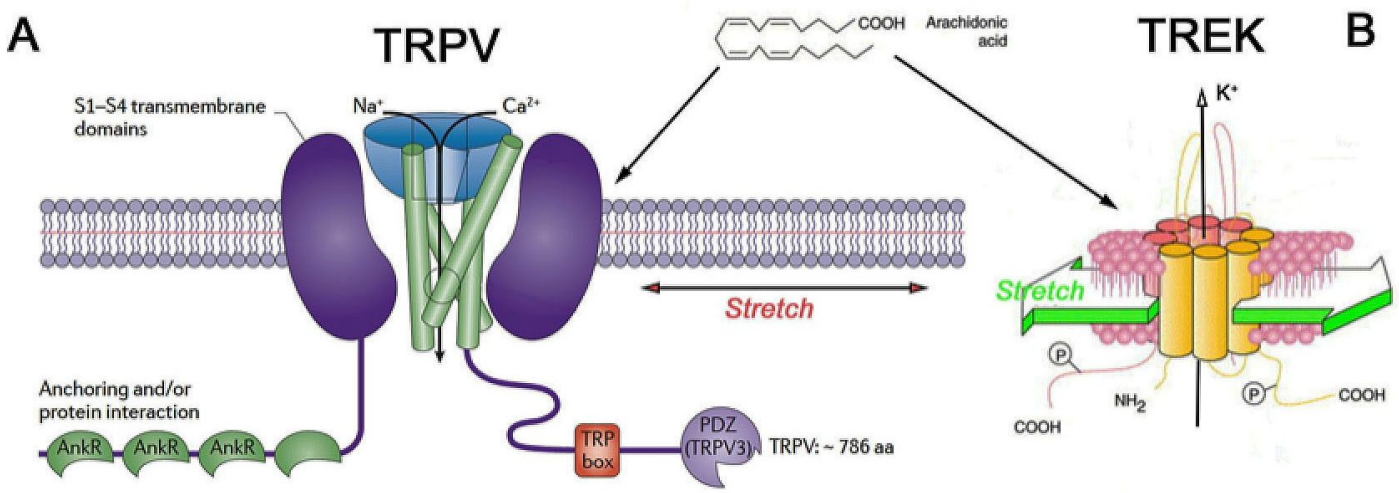

Figure 17. Schematic representation of mechanosensitive vanilloid TRP (TRPV) and tandem-pore TREK/TRAAK channels. (A) TRPV channels include amino terminal ankyrin repeats (AnkR), the TRP box which is thought to be involved in channel gating, and a PDZ/PSD95 domain that may regulate cytoskeletal interactions. (B) TREK and TRAAK channels are formed by two loop-forming (P) subunit tetramer domains which dimerize to form the functional channel. Adapted from Moran et al., 2011 (143) and Patel and Honoré, 2001 (144).

consensus regarding the early retinal targets of IOP (dendrites? somata? axons? glia? blood vessels? ONH?). It is becoming obvious, for example, that glia are amongst the earliest responders to elevated pressure and that neurodegeneration can continue long after IOP is stabilized. Therefore, any attempts at neuroprotection must take into account IOP-independent vascular, glial and scleral mechanisms. Very possibly, prevention of glaucoma will improve with better understanding of molecular, circadian, caloric restriction and exercise parameters that are increasingly viewed as relevant to ocular health. Another innovative front will definitely be on the technology side, as patients are equipped with real-time telemetric devices, noninvasive ONH measurements become routine, and diagnoses are provided by deep learning (artificial intelligence) algorithms (46). We live in exciting times that, having unveiled the key likely components and patterns of visual damage in glaucoma and old age, can only lead to glorious future where mechanotransduction mechanisms in individuals at risk for disease onset are understood, targeted and used for early diagnosis.

About the author

David Krizaj received his B.A. at the University of Ljubljana (Slovenia), Ph.D. in Physiology & Biophysics at New York University and completed postdoctoral studies in Retinal Neurobiology at University of California San Francisco. He took a position at the Moran Eye Center at the University of Utah School of Medicine where he holds the John Frederick Carter Endowed Professorship in Ophthalmology. Dr. Krizaj's interests include intracellular signaling pathways with a focus on calcium homeostasis, synaptic transmission and mechanotransduction, and the last 5 years his lab has been actively engaged in studying the roles of mechanosensitive TRP, tandem-pore and piezo channels in the regulation of intraocular pressure. Another main thrust is to define the molecular mechanisms of pressure sensitivity of trabecular meshwork cells, retinal neurons and glia, and how its dysregulation contributes to diabetic retinopathy and glaucoma. Dr. Krizaj can be contacted at david.krizaj@hsc.utah.edu.

Visual Prosthesis

Introduction to Visual Prostheses

Eduardo Fernandez, M.D.[1,*] and Richard Normann, Ph.D.[2,†]

Created: March 9, 2016.

"The best and most beautiful things in the world cannot be seen or even touched – they must be felt with the heart." Helen Keller.

1. Introduction

Loss of vision affects millions of people worldwide and poses extraordinary challenges to individuals in a society that relies heavily on sight. Although in recent years the techniques of molecular genetics have led to a rapid identification of a great number of genes involved in visual diseases (see https://sph.uth.edu/Retnet/sum-dis.htm for an update of genes and loci causing retinal diseases), the nervous system once damaged is capable of little functional regeneration and currently there is no effective treatment for many patients who are visually handicapped as a result of degeneration or damage to: 1) the retina, 2) the optic nerve, or 3) the visual parts of the brain.

While pharmacological interventions provide therapeutic solutions to many physiological problems, a pharmacological approach to the mechanisms of blindness has not been discovered. Furthermore, there remains the pervasive question as to how these molecular approaches will actually restore functional vision after it is completely lost in a given individual. Therefore, there are compelling reasons to pursue the development of sophisticated microelectronic prostheses as a viable rehabilitative and therapeutic options to substitute, and ultimately, restore limited, but useful sight. Such assistive devices have already allowed thousands of deaf patients to hear sounds and acquire language abilities and the same hope exists in the field of visual neurorehabilitation.

Essentially all visual prosthesis efforts share a common principle of providing focal electrical stimulation to intact visual structures (including the retina, optic nerve, lateral geniculate nucleus (LGN) and occipital visual cortex), evoking the sensation of discrete points of light called phosphenes. Figure 1 shows the possible perception of phosphenes generated by stimulating simultaneously 3 electrodes arranged as a triangle.

It is expected that the neural plasticity of the visual system can contribute to an ever-improving correlation between the physical world and evoked phosphenes. Figure 2 shows an example. Immediately after implantation, the evoked phosphenes are likely to induce a poor perception of an object (the letter "E" in this example). However, appropriate learning and rehabilitation strategies will contribute to provide concordant perceptions.

2. The History of Neural Stimulation

Electrical phenomena and some of the effects of electricity upon man were known in ancient times, but it was not until the eighteenth century that a connection was made between electricity and the neural system. In 1791 Luigi Galvani, an Italian physician (Figure 3), observed that dissimilar metals, attached to a frog's leg and connected together can induce the frog's skeletal muscles to contract (1).

These observations lead to the conclusion that nerves and muscles could produce electricity and utilize it to produce function. Subsequent studies led to a further understanding of the nerve impulse and synaptic transmission and to the development of new therapies based on the application of electrical fields.

The first and most successful example of a neural stimulation device is the cardiac pacemaker that has become a standard therapeutic approach to improve cardiac function in millions of patients. Technology partially achieved during the development of the pacemaker has been used successfully for rehabilitation of sensory and/or motor functions in patients with neurological diseases. Thus deep brain stimulators have been implanted successfully in patients for pain management and for control of motor disorders such as Parkinson's disease (2-4), and cochlear implants are being used for restoring auditory function (5-9). Moreover advances in artificial limbs and brain-machine interfaces are now providing hope of increased mobility and independence for amputees and paralyzed patients (10-14), and there is preliminary data showing that electrophysiological methods can be used to extract neural information about the volitional intent of the subjects to move their distal musculature and then translate these signals into models that are able to control external devices (10, 14-20). As more and more patients have benefited from this approach, the interest in neural interfaces and visual prostheses has grown significantly.

In terms of restoring lost sensory function, cochlear implant research has arguably been the most successful, and has been translated into a viable therapeutic option for many profoundly deaf patients (3, 21-23). Simply explained, a wire electrode bundle is surgically inserted into the inner ear thus serving as an electronic replacement for damaged hair cells. A microphone and speech processor picks up and decodes sounds from the environment and the coded signals drive, in turn, the electrodes that stimulate the nerve fibers of the cochlea, and create the sensation of hearing (Figure 4). In conjunction with intense rehabilitation programs that are tailored to the individual, deaf individuals can learn to comprehend and in some cases, even acquire speech. The same hope exists in the field of visual prostheses.

This field is still in its infancy but is experiencing great interest in both academic and commercial sectors. The possibility of merging different technologies and focusing them on a common target is allowing us to develop new systems, devices and interfaces to the nervous system with greater complexity than could have been imagined only a few decades ago. Further, our understanding of the function and dysfunction of the nervous system has improved to the point that, in many cases, researchers have suggested plausible interventional routes whereby neuroprosthetic systems can be expected to be efficacious.

3. The Case for Artificial Vision.

The possibility to restore visual perceptions in blind individuals has a long history in biomedical engineering. A German neurosurgeon, Forester, was the first to expose the human occipital pole under local anesthesia and to electrically stimulate it. In 1929 he noted that electrical stimulation induced the perception of points of light, called phosphenes and usually described as 'stars in the sky', 'clouds' and 'pinwheels', that were dependent on where the stimulation probe was placed. These findings together with the studies of Wilder Penfield and co-workers during the course of neurosurgical interventions for the treatment of epilepsy (24, 25) established the physiological basis for the present efforts to develop a visual prosthesis for the blind.

Subsequent experiments by the group of Giles Brindley in England (26-28), William Dobelle at the University of Utah (29-32), Pollen (33) and others (34) showed that simultaneous stimulation via arrays of electrodes placed on the surface of the brain allowed blind volunteers to recognize simple patterns, including letters and Braille characters.

The results of these studies supported the premise that patterned electrical stimulation of the visual cortex can evoke patterned percepts. However, these early efforts did not culminate in the restoration of a useful visual sense. Problems with this early work were associated mainly with the large surface electrodes that were used to evoke phosphenes. Such large surface area electrodes required relatively high electrical currents to evoke phosphenes and when multiple electrodes were stimulated, these large currents could interact in a non-linear fashion, evoking phosphenes with unpredictable spatial properties. Furthermore, they also found that a visual prosthesis based on relatively large surface electrodes implanted subdurally would have limited usefulness because of occasional elicitation of pain due to meningeal or scalp stimulation, and also the risk of inducing

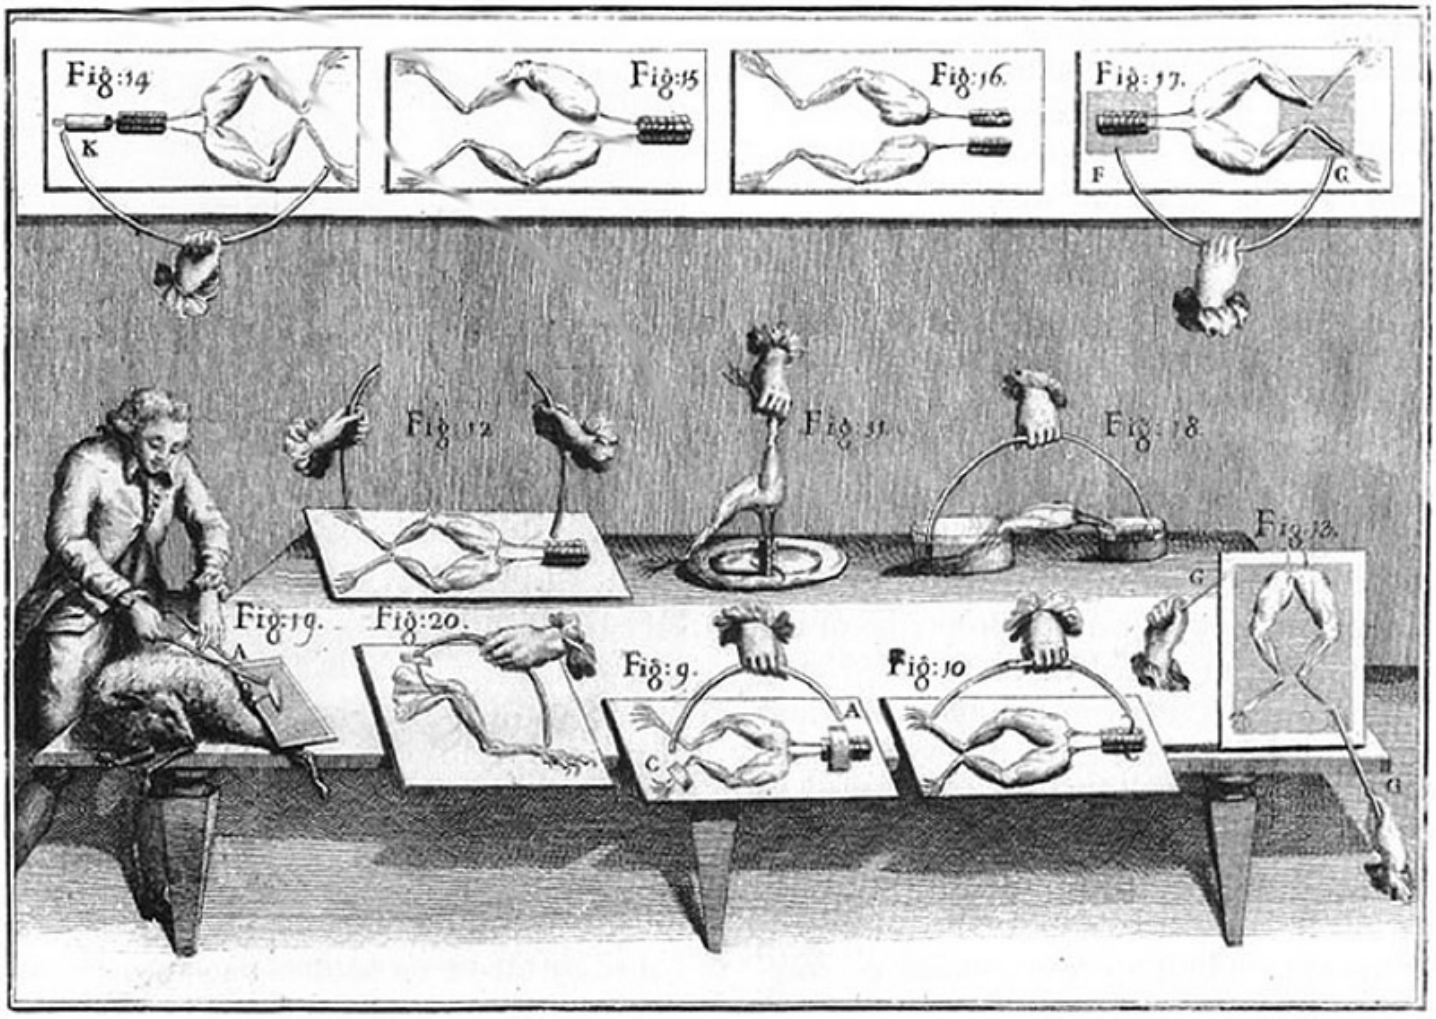

Figure 3. Woodblock engraving of some of Galvani's experiments on animal electricity (from Galvani, 1791).

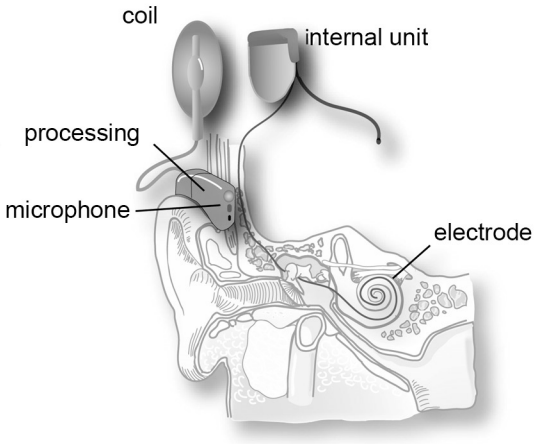

Figure 4. Cochlear implant.

epileptic seizures. This body of work suggests that relatively large surface electrodes may not be a tenable approach to stimulation of the visual cortex, and led a number of investigators to develop a visual prosthesis that

could be implanted directly into the retina, the brain or other parts of the visual pathways. One of the pioneers in this field was Tassicker, an Australian researcher who in 1956 was the first to patent a method of implanting a light-sensitive selenium cell in a blind person's retina (Figure 5) to transiently restore the patient's ability to perceive the sensation of light (35, 36).

4. Visual Pathways: From Real Vision to Visual Neuroprostheses

The concept of artificially producing a visual sense in blind individuals is founded on our present understanding of the structure of the mammalian visual system, its processing elements, and the relationship between electrical stimulation of any part of the visual pathways and the resulting visual sensations (37).

Our entire experience of the external visual world derives from the concerted activity of a restricted number of retinal ganglion cells. These retinal ganglion cells have to send their action potentials through the "bottleneck" optic nerve to the brain (Figure 6).

The retina is essentially a piece of brain whose 150 million photoreceptors get direct stimulation from the outside world's lights and images. Visual input to the retina consists of a stream of photons, which can be unequivocally quantified in space and time. The retina performs spatial, temporal, and chromatic processing of visual information and converts it into a compact "digital" format composed of neural impulses (38). In addition, starting at the retinal level, vision is an active process and eye movements are essential for information processing (39, 40). Thus our entire experience of the external visual world derives from the concerted activity of a restricted number of retinal ganglion cells, which have to send their information, via the one million optic nerve fibers, to higher visual centers. The representation has to be unequivocal and fast (within a few hundreds of milliseconds), in order to ensure object recognition for any single stimulus presentation (41-43). Therefore, the question of how the information about the external world is compressed in the retina, and how this compressed representation is encoded in spike trains is an important challenge for the success of any visual prosthesis.

The next processing center is the lateral geniculate nucleus (LGN), which begins to integrate information from both eyes into a binocular representation of visual space (Figure 7). Once retinal signals arrive within the LGN, they are in a position to be influenced by a wide variety of other inputs as well as the complex feedforward and feedback circuits to and from higher visual centers. These inputs include not only visual information, but also nonvisual information that comes from cortical areas, superior colliculus, pretectum, parabigeminal nucleus, reticular nucleus and other brain stem pathways (44). The number of synapses provided by these non-retinal inputs greatly outnumbers the number of inputs coming from the retina, but their function is not fully understood.

The LGN neurons mainly project to the primary visual cortex (also known as the striate cortex or V1), which was the first cortical area clearly identified in the human brain by Gennari in 1782 (45). Area V1 (Figure 7) is located at the back of the head, in the occipital lobe, and from here the information is distributed to a number of higher cortical centers for further processing (46). The main point, as stated by Hubel and Wiesel, is that the primary visual cortex is in no sense the end of the visual path (47, 48). It is just one stage, probably an early one in terms of the degree of abstraction of the visual information processing (47, 49-51).

Retinal ganglion cells are not themselves homogeneous, but form several parallel and physiologically-distinct pathways from retina to brain (Figure 8). While ON and OFF pathways are well known in vertebrate retinas (52), primate retina makes a further subdivision into magnocellular and parvocellular pathways, or M and P pathways. These are named after the diameters of cell bodies within sublayers of the primate lateral geniculate nucleus, where ganglion-cell axons project. P-cells are color cells, M-cells are low-contrast-sensitive, non-color cells (53).

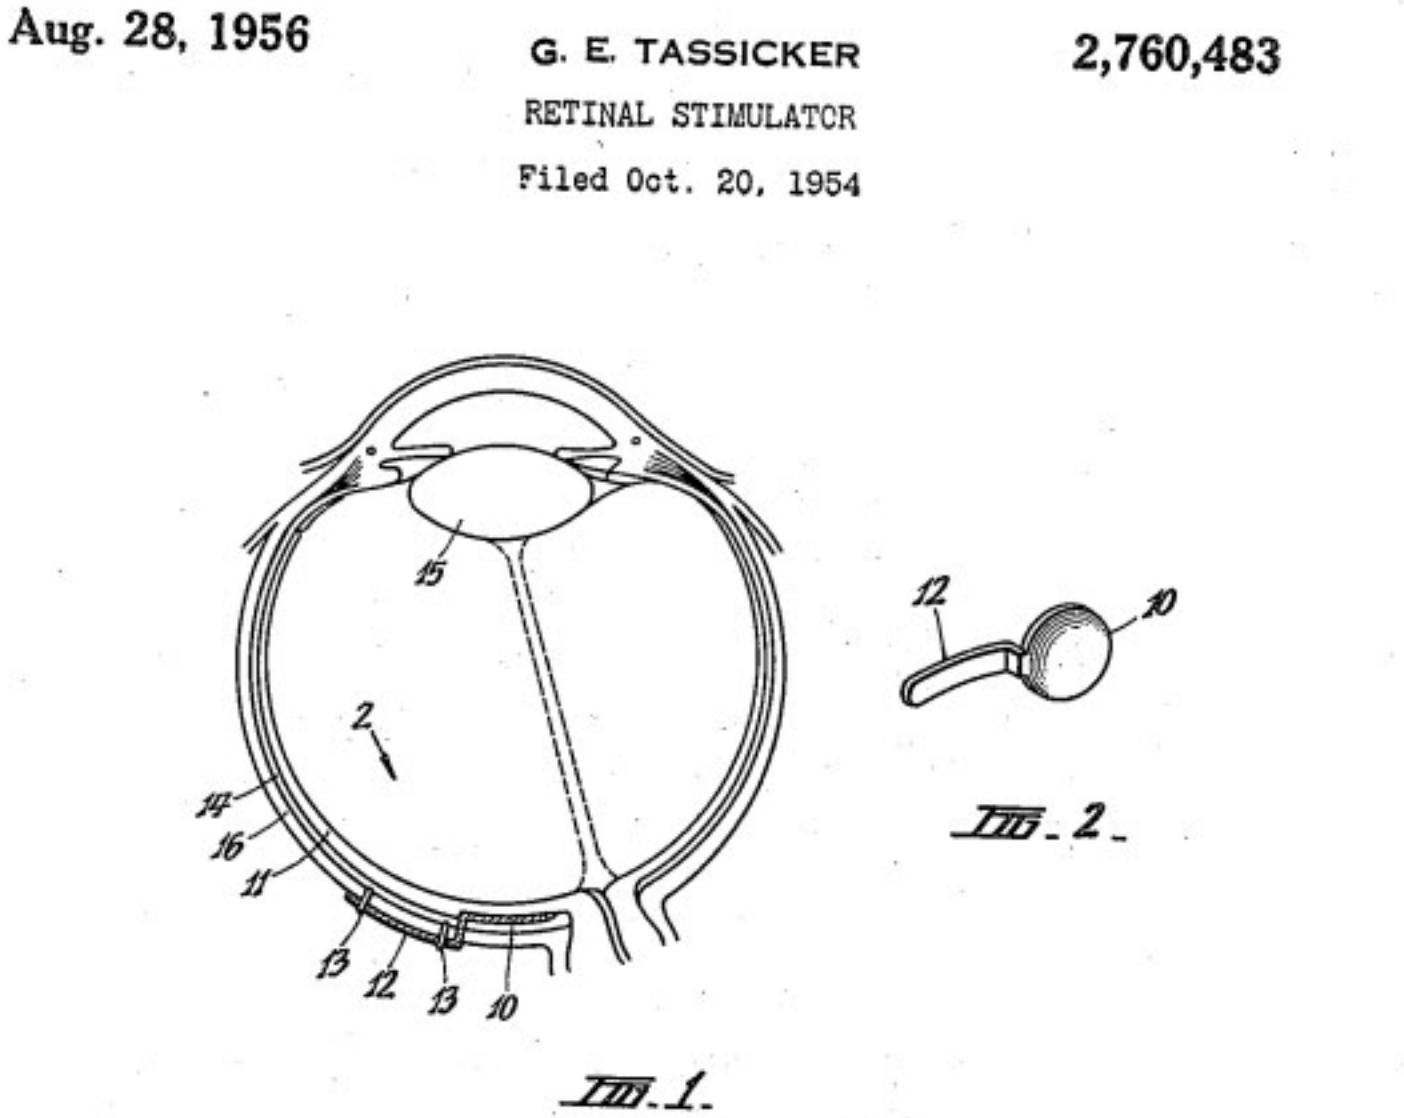

Figure 5. Retinal stimulator comprising a disc which is dished to conform to the curvature of the retina and which is adapted to be inserted surgically into the eye.

Blindness results from an interruption in the normal flow of signals along the visual pathways; a visual prosthesis has to excite the neurons of the pathway at some point after the damage site (54, 55) . The only requirement is that the device should contact still functioning neural elements.

5. Current Approaches to a Visual Prosthesis

Figure 9 shows the main approaches for the design of a visual neuroprosthesis. Since retinal diseases frequently reduce visual acuity and result in non-curable blindness, several groups worldwide are working on the development of different prostheses designed to interact with the remaining healthy retina (36, 56-59), optic nerve (60, 61) and LGN (62-64). However, the output neurons of the eye, the ganglion cells, often degenerate in many retinal blindnesses (65-69), and therefore a retinal, optic nerve or LGN prosthesis would not always be helpful. This extensive degeneration usually spares the neurons in the higher visual regions of the brain, which suggest the enormous potential of a cortical prosthesis designed to stimulate cortical neurons (54, 70-72). Due to

Figure 6. Cross-section of the human retina. Photoreceptors are at the top and ganglion cells at the bottom. Light enters the retina from the bottom and travels through the thickness of the retina to stimulate the photoreceptors at the top in this view. (Drawing courtesy of Helga Kolb).

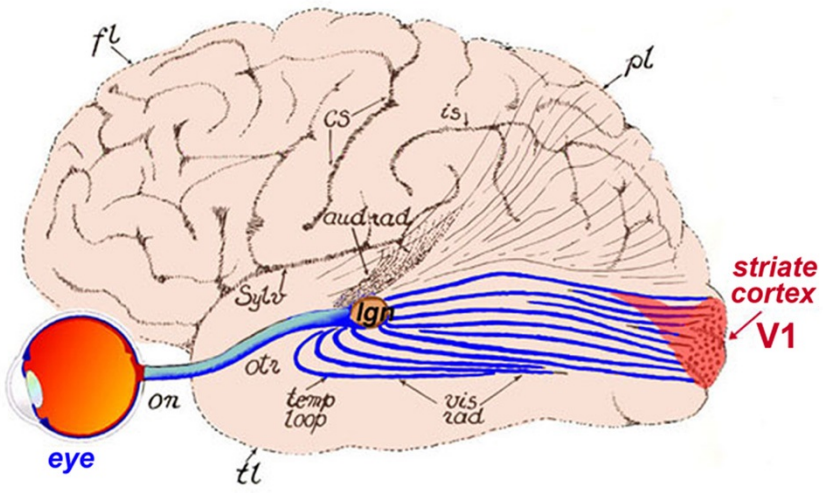

Figure 7. Human visual pathway.

complexity of the interconnectivity and the receptive field characteristics, visual areas beyond V1 have not been proposed as sites for vision prostheses.

Retinal Stimulation

Retinal prostheses are being developed to apply electrical stimulation to the retina in order to restore vision in patients with age-related macular degeneration and retinitis pigmentosa. More than five groups are already pursuing human clinical trials of various retinal prostheses (73-76).

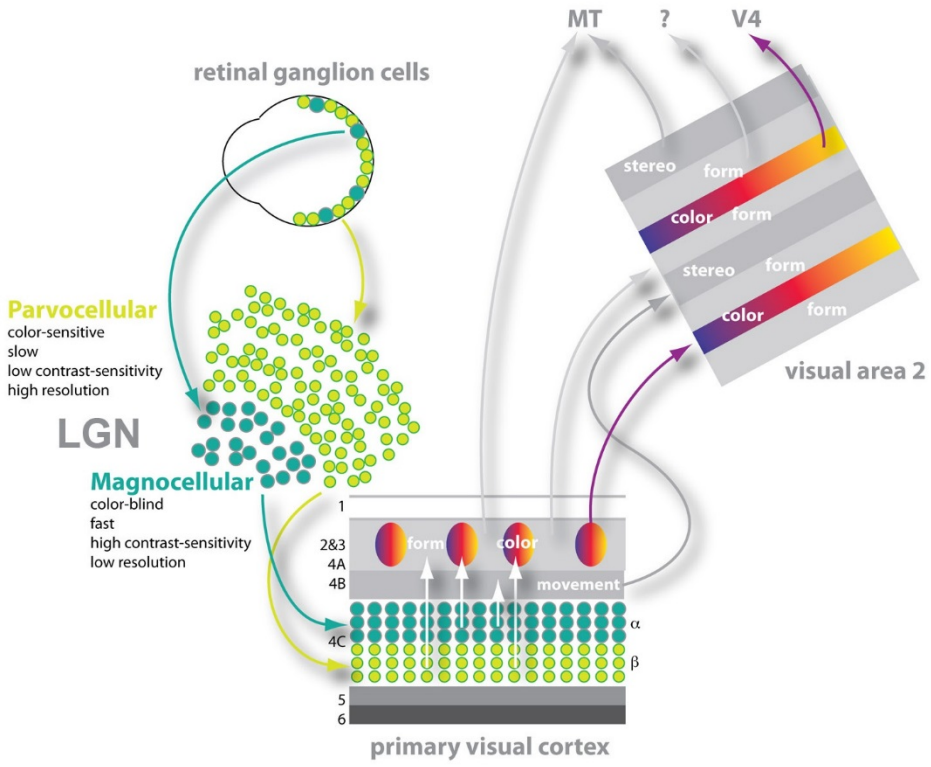

Figure 8. Functional segregation of the visual system, presenting the projection of large retinal ganglion cells to the magnocellular layer of the LGN and further to layer 4Ca of the primary visual cortex. (Image courtesy of Markus Bongard.)

There are significant advantages to the retinal approach as it is less invasive and the implants are lower in the visual pathways, which means that they are closer to the photoreceptors and have more opportunities for natural processing of the visual information. Further, the retinal approach has the advantage that no camera is required to encode the visual world: the optics of the eye provide this function. However there are also some problems related to encapsulation of the device, fixation of the implants, power dissipation and the production of sufficient currents (71, 77). Furthermore for a retinal visual prosthesis to work, there must be a population of functional retinal ganglion cells, and therefore these systems are not capable of treating very advanced retinal degenerations (78, 79).

Currently there are mainly two kinds of retinal implants under development: subretinal and epiretinal. Furthermore some groups are studying the efficacy of the suprachoroidal-transretinal stimulation to generate focal excitation in retinal ganglion cells (80-85). The latest experimental photostimulation approach involves re-engineering retinal ganglion cells or bipolar cells to become light sensitive by incorporation of artificial opsins (86-90). This novel approach is based on laboratory studies in fish or mouse and are nowhere near ready for human application.

Subretinal Implants

As some of the neural retina, with the exception of the photoreceptors layer, is preserved in both age-related macular degeneration and retinitis pigmentosa a reasonable approach to the restoration of vision under these pathologies is the replication of the function of the photoreceptors (36, 74-76, 91). One of the main advantages of this location is that the remaining retinal cells in the outer plexiform layer (vertically running bipolar cells and horizontally oriented horizontal cells) may be utilized to stimulate the amacrine and ganglion cells directly.

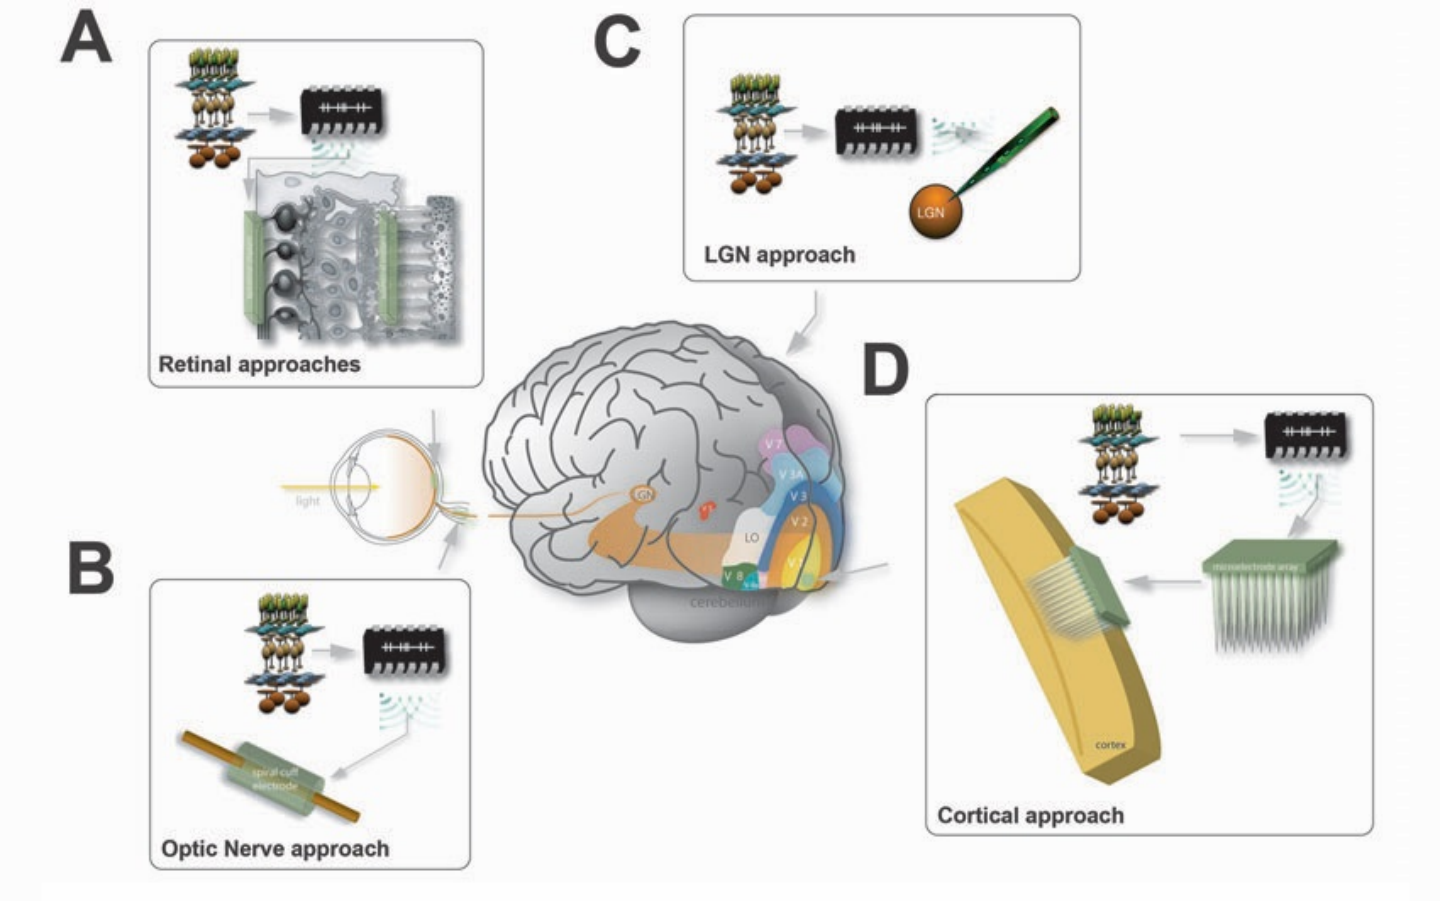

Figure 9. Main approaches for the design of a visual neuroprosthesis.

In a general sense all research groups that have focused on the subretinal approach have proposed a similar method. Thousands of light-sensitive microphotodiodes equipped with microelectrodes are assembled on a very thin plate and placed in the subretinal space. The subretinal device or microphotodiode array (MPDA) is implanted between the pigment epithelial layer and the outer layer of the retina, which contains the photoreceptors. Light falling on the retina generates graded currents in the MPDA that stimulate the dendrites of the bipolar cells in the outer plexiform layer to induce a visual sensation.

The schema is tantalizingly simple. Furthermore, the photodiodes can be tailored to provide either positive or negative current in response to illumination, with the intention of mimicking the function of ON and OFF bipolar cells. However, the success of this approach depends upon three assumptions. First, the bipolar cells of the dysfunctional retina should persist and function in a somewhat physiologically normal manner. Second, the MPDA must generate enough current under normal illumination levels to stimulate the remnant bipolar cells. Third, the electrodes can be placed in close enough proximity to the bipolar cells. Encouraging progress has been reported in each of these areas.

Epiretinal Implants

As an alternative approach to stimulate the retina, other research groups have proposed placing the stimulating electrodes in close proximity to the retinal ganglion cells. This approach attempts to stimulate the remaining retinal neurons of patients who are blind from end-stage photoreceptor diseases and relies on significant numbers or retinal ganglion cells surviving in pathologies such as age-related macular degeneration and retinitis pigmentosa (92, 93).

Both the epiretinal and subretinal approaches imply the use of implanted multielectrode arrays (MEAs) and transcutaneous telemetry to transfer data and power to the implanted MEAs. To date, a number of experiments performed in sighted and blind human subjects have demonstrated the potential for epiretinal electrical stimulation to provide patterned visual perception. One such device, the Argus II epiretinal implant developed by Second Sight (Sylmar, California, USA) has already obtained regulatory approval for marketing in Europe and the United States and has shown improved reading and motion detection in several patients (73, 94, 95). There are, however, issues relevant to the epiretinal approach that need to be solved. The epiretinal devices have to be firmly affixed in place in order to efficiently stimulate the retina and provide a consistent visual perception. Other issues of concern are power dissipation, cross-talk between electrodes, and the long-term viability of the tissues under the implant.

LGN Stimulation

The lateral geniculate nucleus (LGN) is the primary processing center for visual information, meaning that the neural signals encoding visual information have not yet been extensively processed. The LGN receives information directly from the retinal ganglion cells and projects mainly to the primary visual cortex. The LGN holds promise as a target for electrical stimulation for artificial visual percepts since it has been demonstrated that LGN microstimulation in monkeys produces predictable visual percepts (62-64). Therefore, a visual prosthesis based on LGN stimulation could be helpful to restore sight to those who have become blind because of trauma to the eye, or diseases such as glaucoma, macular degeneration, or retinitis pigmentosa.

One possible disadvantage of this approach is the limited number of electrodes that can be inserted in the LGN and hence the limited visual resolution capable with this approach. Moreover, the neurons in the LGN are too close together to be stimulated individually, which would be important in trying to reproduce natural vision. Furthermore, most of the projections to the LGN are from primary visual cortex making it difficult to create complex visual percepts.

Intracortical Stimulation

If primary visual cortex neurons can be stimulated with visual information in a format somewhat similar to the way they were stimulated before the onset of blindness, a blind individual could use this stimulation to extract information about the physical world around him/her (54, 55, 71, 72). Thus in more recent years an intracortical approach with penetrating microelectrodes has been introduced. Penetrating electrodes can activate populations of neurons with greater spatial specificity and lower levels of stimulation than is possible with larger electrodes on the surface of the brain as in the original Brindley and Dobelle experiments. The Utah Electrode Array (96) is an example of such a penetrating microelectrode array that could be used to stimulate many neurons in the visual cortex (Figure 10). The active regions of the electrodes in this electrode array are coated with iridium oxide to facilitate the transfer of charge flowing in the conducting silicon from which the array is made, and the size of these active regions is on the order of 50 µm. Such small electrodes abut small populations of cortical neurons, and electrical currents on the order of 10-30 µA can excite these neurons (this is three orders of magnitude smaller than the currents required with large surface electrodes). The electrodes are 1.5 mm in length and when implanted in visual cortex they reach down to layer 4, the layer of the cortex that receives normal input from the retina (Figure 10). In order to restore useful vision, visual cortex would have to be tiled with from 5-10 UEAs (97).

In 1966, Schmidt et al. (70) described the implantation of 38 floating microelectrodes within the right visual cortex of a 42-year-old woman who had been blind over 22 years. 34 of the microelectrodes were able to elicit phosphenes for a period of 4 months, and most of the microelectrodes had stimulation thresholds below 25 mA. Unfortunately, these microelectrodes were not well suited for long-term application. Thus, due to the breakage of lead wires early in the experiment, only limited tests could be done to evaluate recognition of simple patterns of stimulation. Nevertheless, taken as a whole the results suggested that passing electrical currents through an array

of electrodes inserted into an appropriate location in the visual pathway, is able to produce the perception of phosphenes, and that these phosphenes could be appropriate for restoring some limited but useful sense of vision to the profoundly blind. This intracortical approach requires penetrating electrodes with exposed tips located in layer 4 and with sizes that are of the same order of magnitude as the neurons that are intended to be stimulated.

This approach would be the most viable treatment for complete blindness caused by glaucoma, optic atrophy or diseases of the central visual pathways, such as brain injuries or stroke. Several groups worldwide are presently working on it (55, 71, 72, 98-100).

6. Engineering a Visual Neuroprosthesis

Regardless of the differences in the approaches, all vision prosthesis (with the exception of subretinal prostheses and the photostimulation approach) share a common set of components (37) which are illustrated in Figure 9. One or two cameras provide image acquisition. These visual signals are then processed by a bio-inspired retina-like encoder in order to transform the visual world in front of a blind individual into electrical signals. This first stage performs a multichannel spatio-temporal filtering, to extract and enhance the most relevant features of the scene and also to re-encode this information into a neuromorphic stream of electrode addresses (101). The second stage serializes the information and transmits it through a radio-frequency link to the implanted device. This telemetric transmission provides a wireless transfer of power and data to the internal system. The implanted electronics package must decode the signals, identify the target electrodes and generate the stimulation signals applied using multiple microelectrodes.

Most of the devices include a bio-inspired visual information block (artificial retina) to extract and enhance the most relevant features of the visual scene. A coding block that translates the retina-like output into pulses modulated with different cadences and temporal lags and whose projection onto the electrode matrix must be fully configurable. A radio frequency block provides a wireless transfer of power and data to the implanted electronics package which must decode the signals, identify the target electrodes and conform the voltage shape (D/A converter) of the final waveforms to be applied to the electrodes located near the target neurons (see Figure 11).

These transformations must take into account many issues that are normally performed by the retina. For example, sampling across the retina is not uniform and therefore retinotopic gradients and magnification factors have to be introduced to match image representation. On the other hand, it is clear that several streams of information are processed in parallel from any retinal point by several dozens of interneuronal subtypes before contrast, brightness, orientation movement and color are finally coded as modulation of ganglion cell action potential series (102). While chromatic information is not of utmost priority, a differential characterization will nevertheless be required when designing “achromatic” processing modules for basic representation of image components. The goal of developing such a bio-inspired retinal encoder is not to simply record a high resolution image, but to transmit visual information in a meaningful way to the appropriate site(s) in the retina, optic nerve, LGN or brain.

Although it is not the purpose of this chapter to present a detailed study of the problem of coding/decoding of retinal images by ensembles of retinal ganglion cells, increasing evidence suggests that the retina and the brain utilize distributed codes that can only be analyzed by simultaneously recording activity of multiple neurons (103-106). Far from a simple transducer of light into electrical neural impulses, the retina performs a locally-computed spatio-temporal contrast enhancement function, and a very efficient compression of visual information. These tasks are essential to provide a high adaptation capability to very different lighting conditions, high noise immunity, and to efficiently communicate the visual information by means of a limited number of optic nerve fibers. Thus, our entire experience of the external visual world derives from the concerted activity of a limited number of ganglion cells in the retinal output layer. They have to represent all the features of

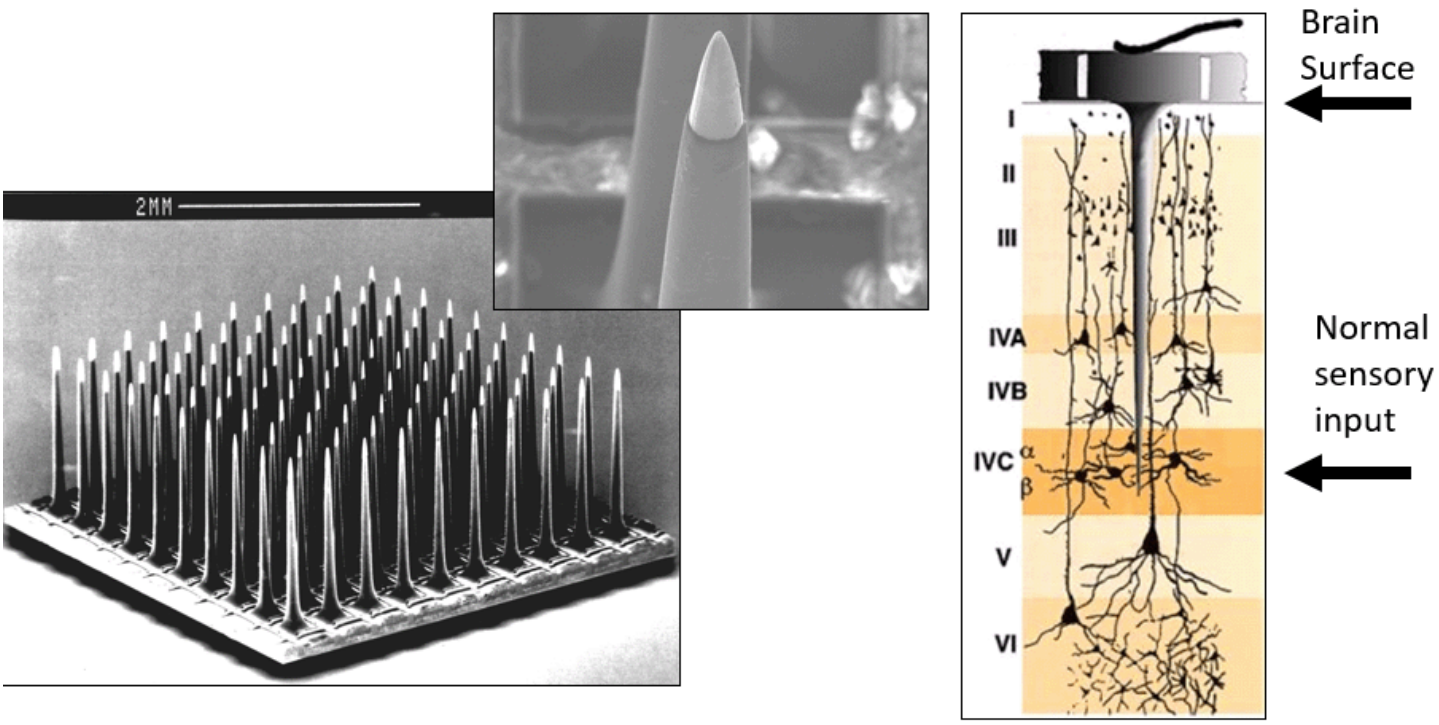

Figure 10. The Utah Electrode Array contains 100, 1.5 mm long penetrating microelectrodes that reach down to layer 4, the region of normal cortical input from the retina.

objects in the visual world, namely their color, intensity, shape, movement, and the changes in these features in time. This representation has to be unequivocal and fast (within a few hundreds of milliseconds) in order to ensure object recognition for any single stimulus presentation.

The development of a bio-inspired visual encoder poses therefore an information processing challenge without parallel in neuroscience, computer science or communication technologies. Consequently, several research programs are developing complex retina encoders for visual implants (107, 108).

Figure 12 summarizes the basic architecture of a typical bio-inspired retinal model. It is based on information about the photoreceptor distribution within the human/primate retina and on electrophysiological recordings from populations of retinal ganglion cells. Through a set of parametrized filters and functions, that simulate the complex operations of the neural retina, a portable model is obtained that can be easily translated into a hardware description for automatic synthesis using the appropriate tools.

The input images are captured by a photosensor array (preferably a logarithmic response camera that has a similar response to the human visual system and can reduce saturation in high contrast visual scenes). These visual signals are processed by a set of separate spatial and temporal filters that enhance specific features of the captured visual information. The model can take into account the irregular distribution of photoreceptors within the human retina: a high density of pixels and smaller receptive field sizes in central areas; lower density and bigger receptive fields in peripheral areas. A gain factor can be specified for every individual channel as well as a global gain. The next stage reduces the information to the resolution of the electrode matrix, with the option of defining specific receptive field shapes and sizes. Finally, a mapping and neuromorphic coding (into output charge-balanced pulses that can be sent to each electrode) is carried out and feeds the radio frequency link that goes to the microelectrode array. Thus the continuously varying input video stream is converted into neuromorphic pulse-coded signals through a circuit that emulates the function of retinal neurons (Figure 13) (55, 108).

The implementation of the model in digital hardware provides a flexible design, achieving a high performance with response times several orders of magnitude lower than that of biological systems. The present version of the whole system is able to work properly up to 40 MHz (55, 71, 101). This means that 40,000 electrodes could be stimulated with an inter-spike temporal resolution equal to or lower than 1msec. The use of reconfigurable circuitry (FPGA) permits one to adjust or even change the spiking model easily (101, 108). Furthermore, this technology can be used for psychophysical experimentation in order to determine the best image processing strategy, and to get insights into the optimal number of electrodes, grey levels and grid size (109, 110).

Finally the output of the bio-inspired retina has to be transmitted to a remote stimulating device that electrically connects with the implanted microelectrode array (Figure 6). Ideally this should be done telemetrically (i.e. without the need of attached wires) to reduce the risk of infections and an opto-coupling stage should be incorporate to protect the patient against electrical risks. Furthermore, for a durable system, the materials used in the implanted system must be biocompatible, and electrical-charge displacements must be within margins of capacitive work, never in an irreversible-faradaic working zone (111).

Several factors should be taken into account, especially safety, size and power consumptions. Thus, this stimulating device should be able to operate in real-time for a high number of electrodes, have low power requirements and be flexible enough to generate different waveforms and adapt to different stimuli and image processing conditions. Basically it should be able to solve the problem of transmitting data and power to multiple microelectrodes having, simultaneously, the possibility of remote control and sensing of microelectrode status. It implies a compromise between the power level requirements of the stimulation circuits and the signal bandwidth requirements (101, 112).

7. Safe and Effective Stimulation of Visual Pathways through Multiple Micro Electrodes

Any visual neuroprosthetic system must be implanted into the retina, optic nerve, LGN or visual cortex and remain fully functional for periods that may eventually extend to many decades. Therefore, these devices must be highly biocompatible and be able to resist the attack of biological fluids, proteases, macrophages or any products of metabolism. Furthermore, it is necessary to take into account the possible damage of neural tissues by continual charge injection and the most effective means of stimulating the visual pathways. On the other hand, although there are no major safety concerns stemming from the pilot studies carried out to date, the risks of the surgical procedures involved are not negligible. All these considerations place unique constraints on the architecture, material, and surgical techniques used in the implementation of visual prostheses interfaces (55, 71, 113-117).

An important problem reported with all available microelectrodes to date, is long-term viability and biocompatibility. Recent studies of the response of neural tissue to stab wound have shown that there are acute and chronic inflammatory reactions which affect both the neural tissue and the surface of the microelectrodes (118-125). These reactions often result in damage to neurons and microelectrodes and lead to the proliferation of a glial scar around the implanted probes which prevents neurons being recorded or stimulated (126-128). The reasons for the inflammatory response lie in molecular and cellular reactions at foreign surfaces (120, 129). These responses can be controlled and one of the big challenges in this field is to create new, more biocompatible surfaces. The solution may involve coating the electrodes with bio-active molecules that are slowly released into the surrounding neural tissue (117).

8. Selection of Suitable Subjects for a Visual Prosthesis

The selection of a specific person for a visual implant is not straightforward. There are no strict standardized criteria for accepting or rejecting a candidate, nor for the best rehabilitation procedure for every type of

Fig 11. Functional blocks of a visual neuroprostheses

blindness. Generally, a choice should be made between different approaches and/or rehabilitation procedures depending on availability, efficacy or rejection of invasive methods (78, 130, 131). But a pre-surgical protocol and improved methods for predicting success with a visual neuroprosthesis need to be developed (55, 110, 132).

In general, it is considered crucial, at least in these preliminary stages, that the subject should have no residual vision and have had no significant benefit from a conventional visual aid. However, these seemingly straightforward criteria do not always work well in practice and there are different definitions of "residual vision" and "significant benefit from a visual aid". Needs and wishes of individual subjects are also significant variables for implant candidacy. This issue is further complicated because it is not possible to predict success with a visual implant in a specific person. Clearly, our knowledge regarding visual system anatomy and function may allow for crude bio-inspired models and strategies of stimulation. However, what has not been discussed is how the type, onset, duration and temporal profile of an individual's visual loss may have repercussions on the success of the device. To decide what time is the most suitable for intervention is a difficult double-faced ethical decision (130).

Recognizing these limitations, it is generally acknowledged that previous visual experience is necessary for the patient to interpret and recognize the visual patterns that are generated. In this context, it has been presumed that if blindness occurs after the age of ten years of age (i.e. after the critical period), visual pathways should have developed normally and thus remain excitable (78, 130).

Improved networking among research groups would clearly help in developing a common body of standardized test and standardized selection criteria (110). According to Merabet et al (132) the criteria for potential users of a visual neuroprosthesis should include:

- Visual function criteria and pre- and post-implantation testing. Indications in favor of a cortical visual implant could include profound and bilateral visual loss, but more objective and quantitative criteria should be developed. These studies need to incorporate a more quantifiable means of estimating risk and benefit for a given candidate.
- Electrophysiological criteria. Measurement of electroretinogram (ERG) as well as visual evoked potentials (VEP) should be a basic component in candidate selection. Improved methods for predicting success with a visual implant need to be developed. These methods could include a test using data from transcranial magnetic stimulation of visual pathways and new imaging techniques such as functional magnetic resonance (fMRI).
- Medical, anatomical and surgical criteria. The ideal candidate should be a healthy adult. The medical history should include the onset and evolution of the blindness, physical examination, and laboratory tests to include or exclude candidates and to assist the implant team in planning a total program, including post-implant training.
- Evaluation of the risks and limitations associated with the surgery and every specific approach. These are usually small for persons in good general health but increase with age and other pathological conditions.
- Quantitative evaluation of the subjects' needs and performance using standardized psychophysical and behavioral methods.
- Psychological testing to discard psychiatric disorders and other possible mental status that could affect the success of the visual prosthesis.

There are other important issues that should be taken into account and case studies of surgical sight restoration following long-term visual deprivation provide relevant insights (133, 134). For example, following ocular surgical procedures aimed at regaining some degree of functional vision, patients, blinded for many years, experience profound difficulty in various visual tasks, particularly those requiring the identification and recognition of objects. Interestingly, if patients are allowed to explore the same object through touch, they can recognize it immediately as to register their newly acquired visual percepts with their existing senses. These findings demonstrate that even when vision reaches the brain physiologically, visual perception remains nonetheless impaired. Thus, the simple restoration of a lost sensory input may not itself suffice in reconstituting the sense it normally provides. Active visual rehabilitation may be necessary to maximize the adaptation and get the most from these devices. Moreover some form of spatial remapping between the bio-inspired encoder and the stimulation pattern delivered to the array of electrodes implanted in the visual cortex is highly recommended (55, 104, 107, 112, 135). As a result, the right learning, remapping and rehabilitation strategies could potentially help to modulate the plasticity of the brain and contribute to ever-improving performance and more concordant perceptions.

9. Conclusions and Future Perspectives

The field of visual prosthetics is rapidly emerging and requires extraordinary diverse, lengthy and intimate collaborations among basic scientists, engineers and clinicians. Significant challenges to the development of a successful visual prosthesis include limitations to the number of electrodes, biocompatibility, encapsulation, electrode degradation, power interference, signal and imaging processing, interference with residual vision,

functional evaluation and training. Despite all these issues several research groups are developing sophisticated microelectronic devices designed to stimulate viable neuronal tissue in the hopes of generating functional vision artificially.

To date, at least 23 different devices are under development, several groups are pursuing human clinical trials either with acute or chronic implantation of neurostimulating devices and increasing numbers are expected within the next years (136). Thus this type of technology is clearly expanding and ophthalmology has emerged as one of the more interesting areas of research in the neurostimulation field. However, even the most advanced of these experimental devices has only been able to provide evidence that such an approach is feasible. What remains to be conclusively demonstrated is whether or not the visual percepts produced by implanted microelectronic devices can create meaningful visual perceptions that can be translated into functional gains such as the recognition, localization and grasping of objects or skillful navigation in an unfamiliar environment.

The greater impediments to future progress in visual neuroprosthesis approaches are not only the technical, engineering and surgical issues that remain to be solved, but also the development and implementation of strategies designed to interface with the visually deprived brain specifically tailored for an individual patient's own needs. This would particularly involve an improved patient selection and a "custom-tailoring" of visual prosthetic devices to the subject. A key issue in this context that has often been utterly underrated is the role of neural plasticity. Thus, these strategies should take into consideration not only standardized methods and employ current clinical and technological expertise, but also consider newly emerging developmental and neurophysiological evidence. For example, there is considerable evidence that adaptive and compensatory changes occur within the brain following the loss of sight (7, 55, 137-141). These studies have shown that in some patients the occipital parts of the brain that sighted subjects use to process visual information are transformed and utilized to process tactile and auditory stimuli. This plastic change in the brain probably allows blind subjects to extract greater information from touch and hearing, thus improving quality of life and enhancing the integration of the blind in the social and working environment of a sighted society. The modulation and understanding of these neuroplastic processes is crucial for the success of any visual neuroprosthesis and can therefore provide the neuroscientific foundation for improved rehabilitation and teaching strategies for the blind.

Hopefully the advances in medicine, ophthalmology and genetics will be able to devise new ways of preventing diseases of the retina and visual pathways or in transplanting neurons that have been lost. However genetic science and treatment will not help in injuries due to trauma and probably will not eliminate all the visual impairments due to ageing. Therefore, progress in vision prosthesis technologies is regarded as a necessity for the future. We hope that progress in medical technologies, material science and bioengineering, together with the increase of intelligence in these visual neuroprosthetic devices will improve the quality of life of people that are affected by visual impairments, and encourage further development of custom-tailored devices for restoring functional sight in the blind.

About the authors

Dr. Eduardo Fernandez was born in Elda (Spain) in 1962. He received an M.D. degree from the University of Alicante (Spain) in 1986 and a Ph. D. degree in Neurosciences with honors in 1990. His collaboration with Dr. Helga Kolb and Dr. Richard Normann, began with a stay from 1990 to 1991 under a postdoctoral fellowship of the Spanish Government (FPI program). He is currently Director of the Department of Histology and Anatomy of the University Miguel Hernández (Spain) and Director of the Biomedical Neuroengineering Research Unit of the Biomedical Research Networking Center on Bioengineering, Biomaterials and Nanomedicine (CIBER-BBN, Spain). His main interest is to develop innovative interfaces with the human nervous system and to develop a two-way direct communication with neurons and ensembles of neurons, which could enhance the life of the disabled. He is also working on the development of new therapeutic approaches for retinal degenerative diseases in order to preserve eyesight and slow disease progression. In recent years he has been working in close collaboration with Dr. Normann on the development of a cortical visual neuroprosthesis that will be able to provide a limited but useful sense of vision to profoundly blind people.

Richard A. Normann received BS, MS and Ph.D. degrees from the University of California, Berkeley, CA, USA. His original interests were in retinal physiology elucidating photoreceptor adaptation and horizontal cell function. After a 6-year stint in the Neurophysiology lab at the National Institute of Neurological Disorders and Stroke (NINDS), National Institutes of Health, Bethesda MD, USA, he moved to the University of Utah, Department of Bioengineering. His research interests changed from intracellular recordings in retina to a neuro-engineering bent. Dr. Normann invented the Utah Electrode Array originally for use as a cortical neuroprosthesis for the blind. Since then his research has spearheaded the use of the UEA in sensory and motor physiology, and as an interface to the central and peripheral nervous systems. He is presently a Distinguished Professor (emeritus) in the Departments of Bioengineering and Ophthalmology, University of Utah.

Retinal Prostheses

Ethan D. Cohen, Ph.D.[1,*]

Created: March 19, 2018.

Abstract

Retina prostheses try to reactivate the residual circuitry in a blind patient's retina to produce a synthetic form of usable vision. Using an array of stimulus electrodes or light-sensitive proteins, the neurons in the degenerate retinal network are activated to elicit a series of light percepts termed "phosphenes". If the patient's phosphenes act as independent spatial percepts in their visual field, a crude type of form vision may be achieved. This form vision could improve a visually impaired patient's ability to orient to landmarks in foreign visual environments, avoid obstacles, and improve social interactions. While most retinal prostheses in the current clinical trials rely on stimulation by electrical pulses from electrode arrays to locally excite the patient's retinal neurons, several research groups are also trying more biologically compatible stimulation methods termed "optogenetics" which deploy viruses to transduce light-activated stimulator protein genes into select groups of retinal neurons which when expressed modulate their neural activity. Each technology presents different challenges and benefits for biological integration into the blind patient's degenerate retina. Coupling and replacing the lost retinal neurons in the central fovea remains a challenge for both electronic and optogenetic combination therapies. There are many common issues involved in the real-world assessment of patient visual benefit from these novel medical technologies. Given the heterogeneity of RP as a disease, the availability of multiple therapies may be useful for patients, each offering different advantages for their type of retinal degeneration and its degree of progression.

Introduction

Retina prostheses try to reactivate the residual circuitry in a blind patient's retina to produce a synthetic form of usable vision (Figure 1). Using an array of stimulus electrodes or light-sensitive proteins, the neurons in the degenerate retinal network are activated to elicit a series of light percepts termed "phosphenes" (Figure 2). If the patient's phosphenes act as independent spatial percepts in the patient's visual field, a crude type of form vision may be achieved.

This form vision could improve a visually impaired patient's ability to orient to landmarks in foreign visual environments, avoid obstacles, and improve social interactions. All prosthetic designs to date rely on the same general image encoding strategy to produce vision. The lost photoreceptor mosaic is replaced with an artificial array of silicon photosensors located in a pair of glasses or a photodiode chip (Figure 3). Photoreceptor adaptation is replaced by an electronic automatic gain control. To simulate the antagonistic center-surround contrast enhancement of the ganglion cell receptive field by horizontal and amacrine cells, a video processor chip scales and edge enhances the viewed image. Neural encoder circuitry then transforms the down-sampled image into a limited set of discrete stimulation levels suitable for activating the retinal network (i.e., modulating spike frequencies for ganglion cells or graded potentials for inner retinal neurons) within its usable dynamic response range. Finally, the stimulator uses this level information to alter the firing patterns of retinal ganglion cells whose action potentials propagate up the optic nerve to generate phosphene patterns in the visual areas of the brain. While most retinal prostheses in the current clinical trials rely on stimulators producing electrical pulses from electrode arrays to locally excite the patient's retinal neurons, several research groups are also trying more

* About the author

biologically compatible stimulation methods termed "optogenetics" which deploy patches of light-activated stimulator proteins expressed in groups of retinal neurons to selectively modulate their neural activity. To be effective, a retinal prosthesis must not only improve visual acuity on eye charts, but also improve visual performance in real-world uncontrolled lighting environment tasks, such as finding doors, navigating streets, socializing, and other activities of daily living. Patient performance test guidelines for these prosthetic devices are currently being formalized by the HOVER consortium to allow better device outcome comparisons (3). For descriptions of earlier retinal prostheses see reviews (4-6).

The retinal prosthetic patient

A patient group commonly involved in visual prosthetic clinical trials has a severe form of a retinal degeneration termed "retinitis pigmentosa" (RP). With time, the patient's peripheral rod and then cone vision is gradually lost resulting in a narrow central visual field some 3–10° in diameter. Upon funduscopic examination, pigmented lesions with the appearance of 'spicules' begin to appear in their peripheral retinae due to RPE cell migration into the retina. Disease progression in RP is highly variable, however a smaller cohort of patients progress to what is termed "late-stage RP", characterized by nearly complete degeneration of both rod and cone photoreceptors resulting in bare or no light perception (10-12). Currently, patients from this late-stage RP group are the main retinal prosthesis users.

RP is a genetically heterogeneous group of diseases, which include rod-cone dystrophies, Usher's syndrome, and Leber's congenital amaurosis. The number of mutations involved in RP is very large, and a significant number of patients may clinically present with unknown genetic variants (13). The types of RP inheritance can be autosomal dominant, X-linked, recessive, and simplex, from roughly 100 different gene families (RetNet, 3/2017). This heterogeneity presents a severe challenge to personalized gene therapies such as autologous stem cell transplants, CRISPR-Cas9 gene excision technology, or the recently approved biallelic RPE65 retinal dystrophy gene therapy which may require timely defect identification and selective treatment of each affected individual. Studies of gene therapy in dog models of some RP subtypes suggest an early genetic intervention is desirable, as the retinal degeneration may continue even after the gene therapy is delivered (14). In contrast, retinal prosthetic (electronic and optogenetics) therapies are not disease gene mutation dependent, which could potentially benefit a larger prosthetic patient cohort.

The end stage retina in RP patients also shows significant remodeling and reorganization of the anatomical organization, receptors, and function in the retinal network (See Marc et al Webvision entry for more details) (15, 16), which presents a challenge for prosthetic therapies replacing lost photoreceptors and foveal cones (17-19). Bipolar cell dendrites retract their processes from the synaptic endings of dying central photoreceptors (5, 16, 19-22). Bipolar and amacrine cells in the inner nuclear layer often survive by making abnormal synaptic contacts. RP patients experience on average a 30% decline in their number of retinal ganglion cells, whose axons are critical for sending phosphene-evoked spikes to the brain through the optic nerve (23). Since all retinal prostheses rely on the presence of functioning retinal ganglion cells, prosthetic candidates are often evaluated for ganglion cell function using a corneal stimulation electrode to induce electrically-evoked phosphenes termed the "electrically-evoked response" (EER) (24-26). Currently, there are two main classes of retinal prostheses: electrical and optogenetic.

Table I.

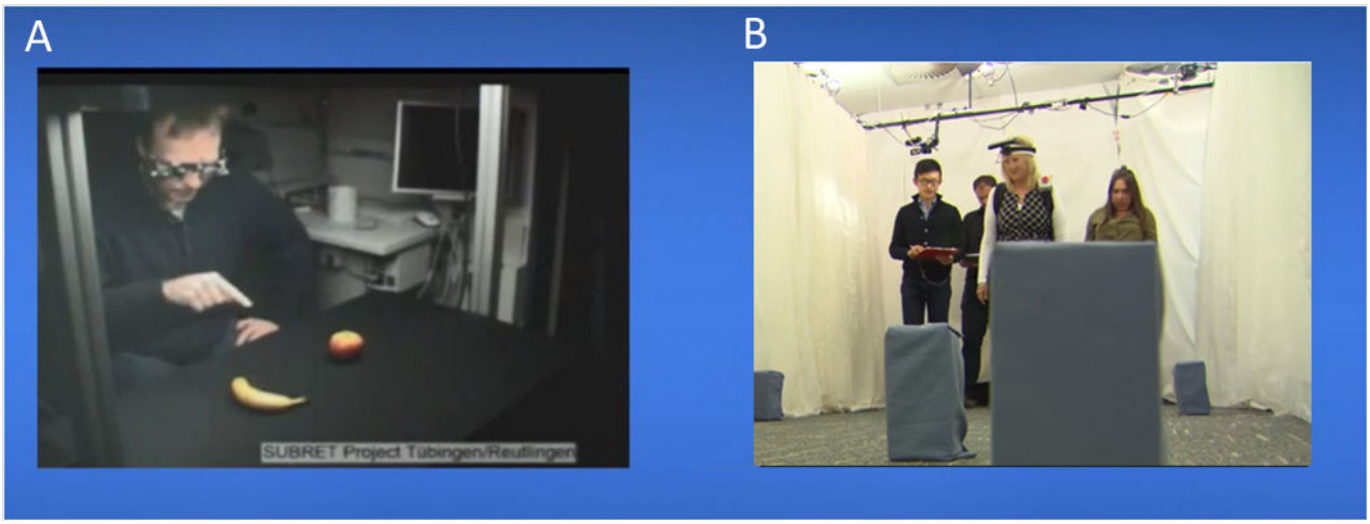

Figure 1. Patients testing retinal prosthetic implants in human clinical trials. A. Subretinal implant patient using the Alpha IMS in a common object identification task. (Retinal Implant AG, retrieved from https://www.youtube.com/watch?v=WSdmWbItsvU). B. Suprachoroidal Australian retinal implant patient negotiating an obstacle avoidance course (Bionic Vision Australia, retrieved from https://www.youtube.com/watch?v=6EmleCs0KGY).

Figure 2. Early examples of electrical phosphenes images resulting from gross stimulation of the eye. Drawings of self-induced phosphenes reported by Purkinje (1823), (1) resulting from direct current stimulation across the eye between conductors in his mouth and forehead (Subfigures 15,16 inside Fig. 3.2). Similar electrical phosphenes evoked by transient current stimulation of the conjunctiva were also self-reported by Volta (1800) (2).

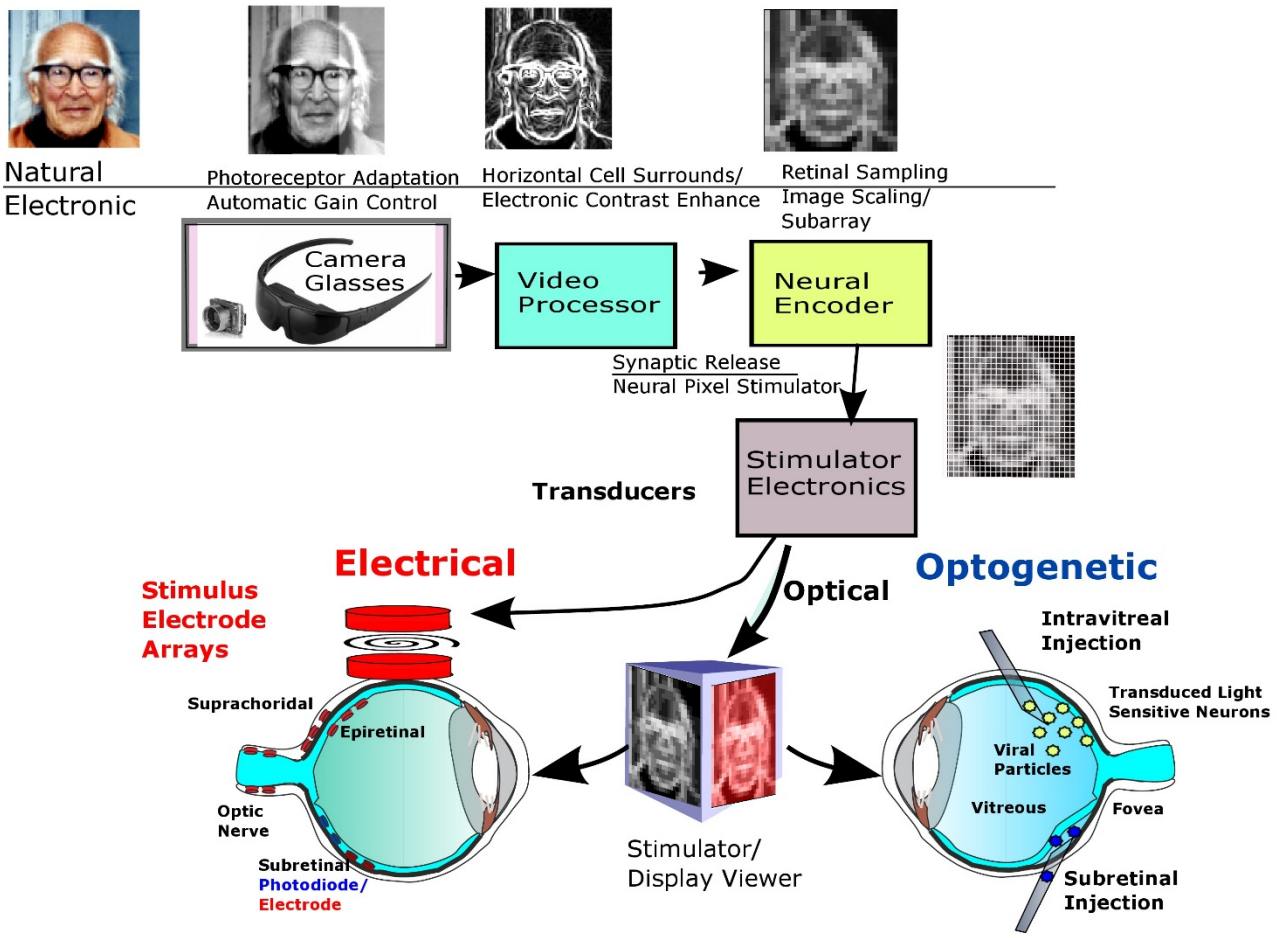

Figure 3. Retinal prosthetic image encoding and stimulation schemes. The image boxes show the natural retinal mechanism and its prosthetic replacement. An example is shown of the conversion of a 250 x 250 pixel color image of a face for retinal stimulation using contrast enhancement methods. The camera-sampled color image is converted to a 256 grayscale b/w image, edge-detected with a Sobel algorithm (8), descaled to a 125 x 125 pixel image, reduced to a 25x25 pixel stimulus pattern with 10 brightness levels similar to the abilities of Argus II patients,~6-10 levels (9), and sent to stimulate the retinal neurons using either external pulses of electrical current (via photodiode or electromagnetic coupling), or pulses of light on a display, activating exogenously expressed photosensitive ion channels in transduced neurons (optogenetics). Image of George Wald (Nobel Prize for discovering the mechanism of rod and cone phototransduction, 1967) kindly provided by Elijah Wald.

Retinal prostheses using electrical stimulation

A large group of retinal prostheses elicit vision in blind patients by using electrical current pulses to depolarize and activate neurons in the retinal network. Retinal implants using electrical stimulation are classified according to the location of their stimulating electrodes in the eye. The prosthesis electrodes can be placed at the inner retinal surface or inner limiting membrane (ILM) (epiretinal), or in the subretinal space (subretinal), or in the sclera behind the choroidal vasculature (termed “suprachoroidal or episcleral”), or on/in the optic nerve (optic nerve) (Figure 3). Each implant electrode location has different advantages and disadvantages for stimulating the retinal circuitry (Figure 4).

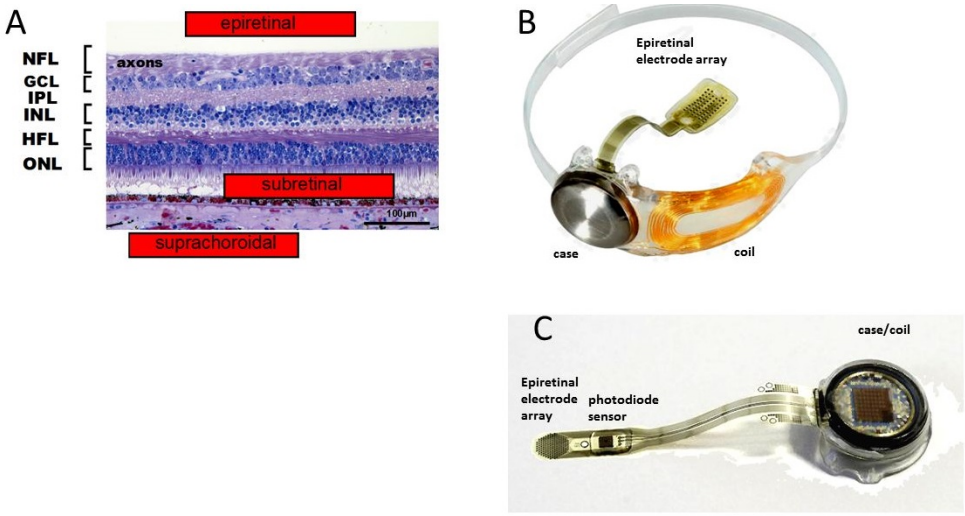

Figure 4. Locations of electrically-stimulating prosthetic electrode array, and examples of epiretinal prostheses. Epiretinal Electrode Prostheses

Epiretinal prostheses electrodes are placed on the inner limiting membrane of the retina, to locally stimulate the underlying retinal ganglion cells and inner retinal neurons. Through an incision in the ora serrata, the surgeon implants a flexible stimulus electrode array close to the ILM surface, where it is held in place with one or more retinal tacks. The array is connected by a cable to the stimulator case and coil, which is sutured on the outside of the globe, and held in place by scleral bands. Telemetry coils mounted on the arm of the patient's camera glasses deliver wireless power and data signals to the implant coil. A pocket visual processor/battery unit allows user-selectable viewing modes. The first epiretinal prosthesis in a clinical trial, the Argus I used a modified cochlear implant stimulator and had a 4 x 4 array of 250-500µm diameter platinum (Pt) epiretinal electrodes (27). For visual scale of electrode size at the retina, 1 degree visual angle is about 280µm on the retina. This is the visual field size of the nail of the index finger held at arm's length (28). Other early epiretinal prosthesis designs clinically tested included the Epi-Ret (29) and the IMI retinal implant (30). The "Argus II Retinal Prosthesis System" is currently the only retinal prosthesis legally marketed in the U.S. It was approved by the U.S. Food and Drug Administration (FDA) in 2013 as a humanitarian use device, and was CE marked (EU) in 2011.

The Argus II uses a 6x10 array of 200µm diameter Pt disc electrodes placed against the inner retinal surface (diagonal visual field of ~20°) (Figure 2, B) (31,32). Most Argus II subjects (~70%), can follow a white line on a black floor, and ~55% were able to find a black door on white wall (HDE FDA report, 2013), while a few (10%) are able to slowly read large white letters on black backgrounds (33).

A newer epiretinal prosthesis, the IRIS II sends event-based camera encoded images of visual scenes to a hexagonal array of 150 stimulus electrodes and in 2017 was implanted in 10 patients in EU clinical trials (Figure 3, C). To avoid the data bottleneck of sending each electrode stimulus level as a radiofrequency (RF) signal through a magnetic coil, the IRIS II uses an IR LED mounted on the patient's glasses to transmit the stimulation signal directly through the patient's lens to a photodiode sensor decoder mounted on the intraocular cable of the implant's stimulus electrode array.

Performance of epiretinal electrode prostheses

The advantage of epiretinal prostheses is that they are minimally invasive to the retina, do not occlude the retinal vasculature, and are easily monitored through the patient's lens using a funduscope or optical coherence tomography (OCT). In animal models, short current pulses (0.1-0.5msec) tend to activate action potentials directly at the ganglion cell. Longer duration pulses may produce delayed spikes due to synaptic transmission from activated bipolar or amacrine cells (35-37). Epiretinal electrode stimulation excites both ON- and OFF-center ganglion cells non-selectively. For Argus II users, phosphene thresholds to biphasic 0.45msec pulses averaged 206.5μA (93nC) (32). Argus I subjects reported phosphene percepts from single stimulated electrodes as elliptical blobs (~4 x 10°), or thin (1°) arcs some 7-15° in length (38, 39), and Argus II subjects have reported similar shaped percepts (40). Phosphene brightness perception of Argus II subjects is limited to some 6-10 stimulus current steps (9). The Argus II's camera glasses are fixed to the patient's head but the electrode array is fixed on the retina in the eye. However, the brain maps the phosphenes induced by epiretinal stimulation electrodes based on the patient's eye gaze position, so if the eyes move so do the phosphenes. Argus II subjects also report a perceptual fading of stimulated phosphenes due to a Troxler-like effect, in some cases in under 0.5 sec, so they often use head scans to study an object of interest (41).

For epiretinal prostheses, close conformation of the stimulus electrode array to the inner retinal surface is necessary to provide uniformly focused stimulation across the electrode array. While stimulus array electrodes near the retinal tack region lie directly against the retina, the proximity of stimulus electrodes of Argus II patients averaged 179.6μm from the retinal surface (32). Incomplete contact could be caused by residual vitreal cortex fibers, posterior hyaloid/epiretinal membranes, patient/gender differences in the retinal curvature, and a lack of conformation to the curved fovea. The closest structures to epiretinal stimulus electrodes are often arcuate nerve fiber bundles under the inner limiting membrane from the axons of peripheral retinal ganglion cells, which course around the fovea, and converge on the optic nerve head (20, 42, 43). The thickness of the perifoveal nerve fiber layer bundles average 80 -120μm (44), and the nerve fiber layer near the macula averages 33.9μm (45). Using submillisecond stimulus pulses, subjects often report seeing arc-like phosphene percepts to electrode stimulation (39, 40, 46, 47). Recent stimulation strategies using long sinusoidal current pulses 10-20msec in duration may reduce this nerve fiber activation which could improve spatial percepts by individual electrodes (47-48).

Subretinal electrode prostheses

Subretinal prostheses place electrode arrays in the subretinal space between the pigment epithelium and the degenerate photoreceptor layer (Figure 5). This places the stimulus electrodes in close proximity to activate the remaining bipolar and amacrine cells of the blind patient, which theoretically could excite the remaining retinal circuitry in a more natural fashion than epiretinal prostheses. Early subretinal devices tested included an ambient light powered 5,000 microphotodiode-stimulator chip, which performed poorly in US clinical trials (51). However, actively-powered photodiode-based subretinal stimulator chips have been more successful in clinical trials with some patients able to read large letters (5-10°) (52-53). A second generation 40 × 40 stimulus electrode/photodiode array (1600 electrodes) termed the Alpha AMS was CE marked in the EU in 2016 with improved durability (53-55). This polyimide-encapsulated combination photodiode and stimulation electrode based chip (3.2 x 4mm, 70 m thick) allows subjects to use natural eye scanning with a synthetic visual field of ~13^{o} to analyze objects. Active power to the AMS chip is provided by a cable from a coil-powered case sutured onto the skull, similar to a cochlear implant. Patients with functional implants had grating acuities which ranged from 0.1 - 3.33 cycles/degree (55). Several other subretinal stimulation implants are in active development by US/EU groups. Recently, the light-powered photodiode stimulation electrode chip concept has been revived by the Palanker group, using a chip whose pixels contain multiple photodiodes in series with a central-stimulus electrode. When actively illuminated, each pixel generates enough voltage to excite the retinal network, which altered ganglion cell firing in animal models (50). Termed the "PRIMA" implant, a camera/view-screen

stimulator goggle generates IR light pulse "images" to power the implant chip array in the blind retina. A clinical trial for the PRIMA is currently started in the EU (11/2017). Other subretinal implant designs include a 256-electrode array by the Rizzo group with a more conventional globe-mounted titanium case/coil and camera glasses (56).

Performance of subretinal electrode prostheses

The advantage of subretinal prostheses is that their electrodes stimulate the remaining neurons of the outer retina such as the bipolar cells. This could provide a more coordinated visual circuitry activation in blind patients, which would propagate through the retinal network. In many subretinal designs, the photosensors are also located directly over the stimulation electrodes. An intraretinal mount allows blind subjects to use natural eye movements to scan objects of interest, and helps prevent the perceptual fading reported for static retinal stimulation (57). However, subretinal chips may also partially block oxygen diffusion from the choriocapillary bed, and some Alpha IMS implant patients exhibit mild leakage of the retinal vessels when studied with fluorescein angiography (58, 59). Subretinal implantation devices need a thin package to fit in the subretinal space, and a durable near-hermetic encapsulation of the implant electronics.

Suprachoroidal electrodes

Suprachoroidal (or episcleral) prostheses place their stimulus electrodes in a scleral pocket directly behind the choroidal blood vessels (Figure 5, C). A suprachoroidal electrode array of 49 bullet shaped stimulus electrodes (0.5-mm diameter) was implanted behind the temporal retina in three subjects in Japan (Fujikado) (49). The array was connected to a multiplexing stimulator case (similar in form to a cochlear implant) which was surgically attached to the patient's temporal bone, and controlled by a camera/processor. Using biphasic pulses (0.5msec duration), large phosphenes extending ≥10 degrees visual angle were reported (60). A second suprachoroidal design developed by the Bionic Vision Australia Consortium used a smaller array of 20 Pt electrodes (400-600um diameter), which was implanted in the temporal suprachoroidal space near the fovea in 3 RP subjects. The cable ended in a percutaneous connector for interfacing with an external camera and stimulator (61). Using either anodic or cathodic first biphasic pulses, 2 subjects reported phosphene shapes with average diameters of 8.4 and 9.0 degrees of visual angle, respectively (62).

The advantages of suprachoroidal prostheses are that minimal surgery is needed for electrode array implantation which causes less risk of retinal detachment, and there is reduced risk of infection, as the vitreal cavity of the eye is never entered. While suprachoroidal electrodes are located behind the retinal pigment epithelium/choroidal vessels, which can spread the stimulus pulse currents at the retina, subjects can perceive simple phosphene shapes, suggesting these devices may have clinical utility for regaining peripheral vision commonly lost in most RP patients. However, strong electrical phosphene stimuli can occasionally evoke a tingling sensation in the trigeminal choroidal nerve (60).

Optic nerve prostheses

Historically, a few groups have investigated stimulating the optic nerve, largely with surface electrodes (63), however each electrode appears to activate large numbers of axons, resulting in multiple phosphene percepts in the patient's visual field. The optic nerve innervates the visual thalamus, or lateral geniculate nucleus, which in turn innervates the occipital lobe of the visual cortex. These are also targets for visual prosthesis, particularly relevant to blindness resulting from ganglion-cell loss, or optic nerve injury. These prostheses are reviewed in the companion Webvision chapter "Introduction to Visual Prosthesis' by Eduardo Fernandez and Richard Normann.

Neurotransmitter-releasing retinal prostheses

The amino acid glutamate is the major excitatory neurotransmitter used in synaptic transmission from photoreceptor- to-bipolar-cell, and bipolar-to-ganglion-cell synapses. In theory, glutamate released onto bipolar cells would depolarize OFF-bipolar cells, while simultaneously hyperpolarizing ON-bipolar cells (OBCs). Conceivably, if a glutamate-releasing prosthesis could be placed at the level of the missing photoreceptor endings in RP patients, communication with the remaining bipolar cell dendrites could propagate the visual signal to ganglion cells. Several glutamate-releasing prosthetic designs have recently been proposed; one using optical waveguide uncaging of neurotransmitter near retinal neurons (65), and another using microfluidic neurotransmitter release through miniature orifices (66,67). The Pepperberg group has proposed stimulation using tethered neurotransmitters (68). However, it is unclear how these devices can attract the dendrites of retinal neurons, and replenish released neurotransmitter.

Retinal prostheses using optogenetic stimulation

Optogenetics is a newer prosthetic stimulation technology that relies on viral expression (transduction) of light-sensitive ion channels in blind retinal neurons, enabling subsequent excitation of these neurons by light. This molecular technology has the potential to improve cellular targeting, increase spatial resolution and provide better coupling of the light stimulus to cellular excitation. Optogenetics originates from an 1865 observation by Ferdinand Cohn (69) that certain unicellular algae exhibit phototropism to blue but not red light. Mast in 1916 localized this algal light behavior to an orange eye spot (70) (Figure 6). Suction electrode recordings by Sineshchekov (71, 72) showed that light rapidly activated a current (submsec latency) in the algal membrane, with faster kinetics than rhodopsin. Hegemann and Nagel's group expressed these algal membrane proteins in Xenopus oocytes and found one that acted as a direct light-activated mixed cation channel (73), which they

termed “Channelrhodopsin 2” (ChR 2). Boyden and Diesseroth expressed the ChR2 protein in mammalian neurons and found they could evoke action potentials by single pulses of blue light (74).

Given the large number of genetic mutations involved in RP, a disease-independent gene therapy such as optogenetics could benefit many blind patients. Currently, a variety of optogenetic protein stimulation technologies are currently being evaluated for modulating neurons including light-activated ion channels, ion pumps (ex. bacteriorhodopsin, halorhodopsin), and G-protein-coupled receptors (ex. melanopsin, rhodopsin). Optogenetic proteins all incorporate a vitamin A /retinal analog in the binding pocket of their protein side chains (either all-trans 14-retinal or 13- retinal) (75). Other light-activated proteins also under investigation include: N-ethyl maleimide modified glutamate channels (LiGluR) (76), adenyl/guanyl cyclases (77), phosphodiesterases (78), and IR light-gated G-proteins (ex. snake TrpA1, often termed thermogenetics) (79). However, it is not currently clear whether these mechanisms have the fast kinetics and higher quantal sensitivity needed for activating the retinal network.

All optogenetic proteins currently in development express the optoprotein solely in the neuronal membrane, which severely reduces the quantal catch in comparison to retinal photoreceptors. For example, a foveal cone photoreceptor contains 1000-1200 photopsin-filled membrane infoldings which amplifies quantal catch some 1000X (80, 81), and a similar number of rhodopsin-filled discs are found in rods (82). Therefore, an intense light source is often required to supply the high irradiances ($>10^{15\text{-}17}$quanta/cm^2/sec) needed to adequately activate ChRs in the membrane to depolarize the retinal ganglion cells to action potential threshold (83-85). Because these irradiance levels are rarely encountered in the office environment, most optogenetic prostheses are thought to be combination product technologies that rely on cameras and artificial light sources (i.e. projector glasses) for delivering high flux retinal activation, light adaptation, and scene contrast enhancement (Figure 2). Research is also progressing on the optical stimulus encoder paradigms for delivery of effective light stimuli for the ChR therapy to activate natural retinal network function (Yan and Nirenberg) (86).

Light-activated depolarizing channels for optogenetic therapies

ChR2 was first virally transduced into blind rd1 mouse and rat inner retinal neurons by Bi et al. in 2006 (83). They used an adeno-associated virus (AAV) vector construct coupled to a powerful nonselective promoter to express the ChR2 GFP tag construct (Figure 7). Injected into the vitreous humor, the AAV2 construct transduced many mouse and rat retinal ganglion cells and some inner retinal neurons. Blue light stimuli caused transduced retinal ganglion cells to depolarize and fire action potentials, which could be monitored as visual evoked potentials (VEPs). Currently, an early feasibility clinical trial of a ChR2 therapy has started in the US as of (8/2015), where it has been recently reported (11/17/2017) that some patients can sense the location of windows in rooms (87). Red-shifted ChRs termed "ReaChR" or "Chrimsons" are also being explored in primate and human retinas for blindness indications, also using a non-selective CAG promoter (88). A 2017 EU clinical trial for retinitis pigmentosa patients used the optogenetic combination product “ChrimsonR” ChR and biomimetic “Visual Interface Stimulating Glasses” (NCT03326336 Clinicaltrials.gov).

Like ChR2, OBCs normally produce a sustained depolarization to center light stimulation. In rodents. OBCs can be genetically targeted using the Grm6 promoter (89). Lagali et al. in 2008 used in-vivo electroporation to transfect OBCs with a ChR2 lentiviral gene construct in the eyes of rd1 blind mouse neonates (84). The transfected mice had a measurable optomotor response to moving gratings of up to 0.26 c/degree. Bipolar cell response thresholds as measured by ganglion-cell firing to blue light stimulation were ~3x10^{15} quanta/cm^2/sec. Doroudchi et al in 2011, used AAV Grm6 ChR2 constructs to transduce OBCs in a series of blind mouse lines (rd1, rd10, rd16) (85). They showed that ChR2 expression was stable for up to one year, and found ganglion cell firing thresholds to blue light ~4×10^{16} quanta/cm^2/sec. Transduced blind mice were able to discriminate escape platforms illuminated with blue light in a Morris water maze test (90).

Light-activated hyperpolarizing channels for optogenetic therapies

Optogenetic hyperpolarizing mechansims are also useful for mimicking the light response of photoreceptors and OFF-center bipolar cells, which normally hyperpolarize to light. Several pumps and channels that produce hyperpolarization have been discovered: 1. Halorhodopsin, a yellow-light activated chloride pump hyperpolarizes cells; 2. Light-activation of proton pumps such as Chief or bacteriorhodopsin cause acid-sensing ion channels to open and hyperpolarize cells (91-93); 3. A family of true light-gated chloride channels has recently been discovered, with increased light sensitivity and a green shifted activation spectrum (GtACR1) (94); and 4. The chloride ChR, IC++ has been developed (95). The Pan group transduced inner retinal neurons in rd1

blind mice with a viral combination construct of halorhodopsin and ChR2 for a dual blue light excitatory and yellow light inhibitory ion channel control of these neurons (96).

Degenerate cones have been known to survive in some blind mouse strains. Because halorhodopsin activation hyperpolarizes neurons, similar to the light-evoked hyperpolarizations of photoreceptors, a second application for halorhodopsin was to restore the light response of degenerate cone photoreceptors. (See also Marc et al chapter in Webvision). Busskamp et al, in 2010 used a halorhodopsin EYFP construct and cone-specific promoters to transduce expression in two strains of blind mice (97). Yellow-light stimuli caused the transduced cones to hyperpolarize and synaptically activate the retinal network. Both ON- and OFF-center retinal-ganglion-cell light responses could be recorded in halorhodopsin-transduced cone retinas at thresholds of 10^{14}quanta/cm^2/sec. Improvements in cone-specific promoter transduction for primate and human foveal cones have recently been reported (98).

Light-activated G-protein gated mechanisms for optogenetic therapies

The use of G-protein gated opsins for retinal prostheses, such as rod rhodopsin or melanopsin, employ energetically favorable biochemical amplification mechanisms which significantly increase light sensitivity compared to direct light-gated ion channel ChR counterparts. Early work by Kim et al in 2005 showed light activation of G-protein chimaeras of rhodopsin could be coupled to adrenergic receptors (99), while Qiu et al. in 2005 showed transfection of melanopsin caused light to depolarize kidney cells in culture (100). The first retinal application by Lin et al. 2008 used an AAV cytomegalovirus (CMV) promotor-melanopsin construct to transduce retinal ganglion cells in rd1 blind mice (101). The transduced blind mice were now able to detect light in a 2-channel water maze test.

Currently the ON-center bipolar cell (OBC) is an active target area for optogenetic, G-protein-gated, blindness therapies, due to the abundance of ON-center parafoveal rod and foveal cone bipolar cells, and the dependence of the ON-response on G-protein activation of TrpM1 cation channels (102). Recently, several groups found that transduction of melanopsin (G_q G-protein) or rhodopsin (G_t G-protein) in OBCs could promiscuously activate the mGluR6 metabotropic receptor (G_q) G-protein. This foreign mechanism in the OBCs reverses the closure of the normally open TrpM1 excitatory channels to light, and causes the TrpM1 channel in the OBC to have a light-response which operates in reverse from normal. Van Wyk et al, in 2015, used an AAV-Grm6 melanopsin-mGluR6 chimera construct termed “Opto-mGluR6” to activate the TrpM1-gated excitatory ion channels in OBCs in Rd1 blind mice (103). In Opto-mGluR6 Rd1 blind mice, light thresholds for ganglion cell activation were ~1000X lower than in their Rd1 ChR2 transduced littermates, and both light-ON- and OFF- retinal network responses appeared (Figure 8). A similar increase in light sensitivity in Rd1 blind mice was found using an AAV2-Grm6 rhodopsin construct by Gaub et al in 2015, and by Cehajic-Kapetanovic et al in 2015, who showed a behavioral increase in running distance when presented with a swooping owl movie (104-105).

Performance of the optogenetic therapies

Optogenetic stimulation therapies have the advantage over electrical stimulation of being able to deliver photosensitive stimulation at near cellular resolution to a large retinal area, and to better spatially couple to the blind patient’s neurons in a retinal prosthesis. However, the injection of viral capsids into the central retinae of primates has revealed some unforeseen issues with the transduction of retinal neurons, particularly in the fovea, which is critically used for normal vision in humans. Foveal bipolar and ganglion cell bodies are displaced ~2° from cone photoreceptor inputs in the center (5, 21). In the blind patient, viral transduction of ChRs into these surrounding bipolar and ganglion cell bodies when activated by light may elicit phosphenes that seem to originate from their central cones.

Finally, the primate retina has a series of membrane barriers that currently impede viral transduction, particularly to intravitreal injection of viral construct, which is the preferred method in patients with advanced

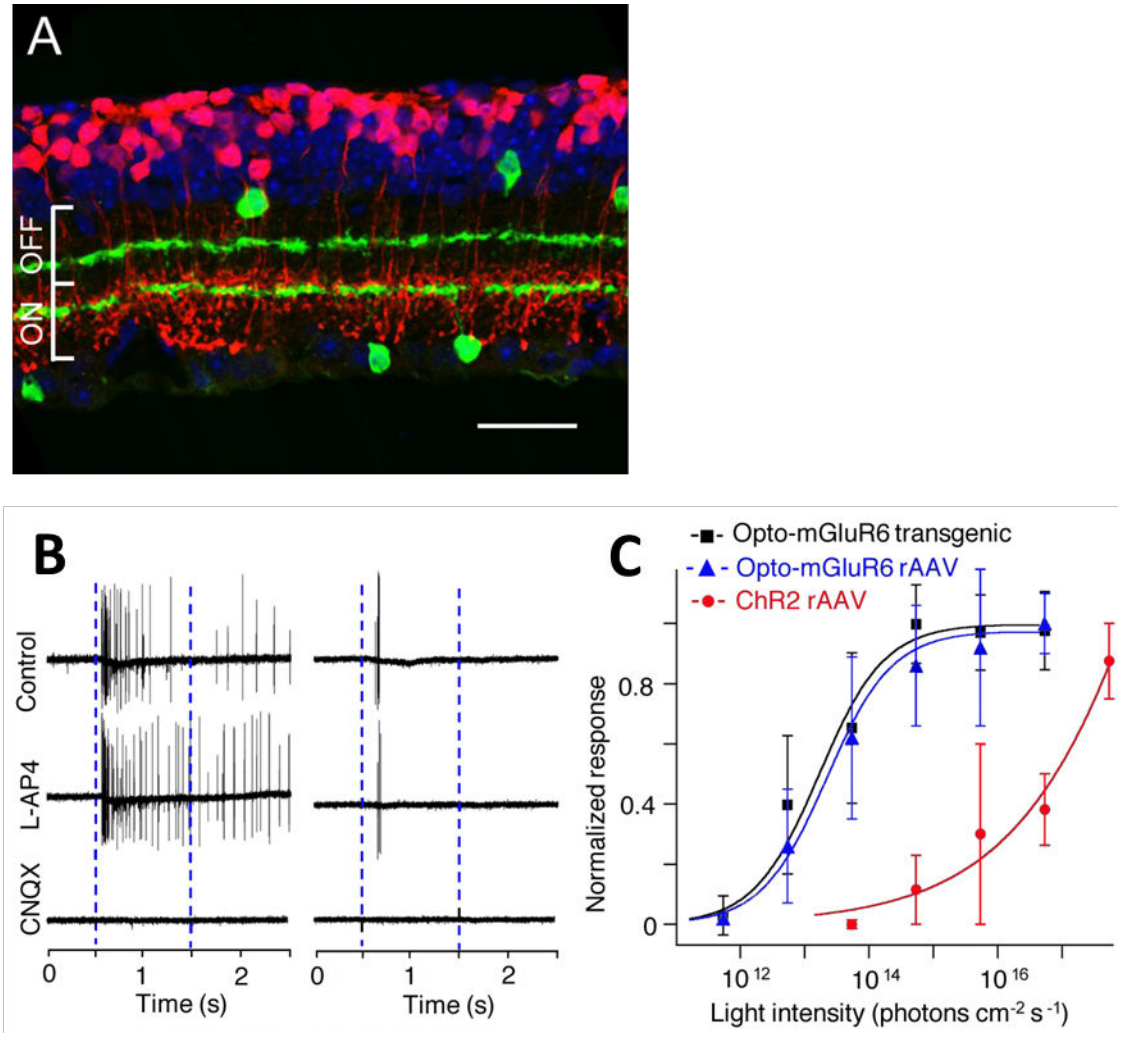

Figure 8. Transduction pattern and light sensitivity of a melanopsin chimaera AAV construct targeted to ON-bipolar cells in a blind mouse model. (Scale bar 20μm) B: Light stimulation causes melanopsin-mediated firing increases in an extracellularly recorded ganglion cell that is not blocked by APB (blue bars denote light onset/offset). C: Comparison of light-evoked ganglion cell firing thresholds of blind mice transduced with melanopsin chimaeras vs. ChR2. AAV melanopsin, (blue), melanopsin transgenic, (black), ChR2 (red). The G-protein gated opsin constructs are significantly more sensitive to light. From ref (103) with permission from PLOS.

RP. Transduction of some AAV capsid constructs may be reduced in efficacy in primates when compared to mouse models (106,107). There may also be a modest host immune response to the viral capsid and or fluorescent protein tags, (108, 109). The ILM/Müller glia end feet play a complex role in viral transduction, first by preventing diffusion of AAV viral proteins into the retina, but also by providing binding sites for viral attachment for retinal entry. In primates, the ILM appears to be thinnest near the perifovea and in the retinal periphery (110). The ILM is a basement membrane composed of several extracellular matrix proteins (laminin, agrin, perlecan, nidogen, collagen), nucleases and several heparin sulfate proteoglycans (111,112).

Yin et al in 2011 and 2014, and Ivanova et al in 2010, both intravitreally injected AAV2-gene-GFP constructs with actin-based promoters in primate eyes and found that viral transduction of ganglion cell bodies was largely limited to a thin ring-like zone centered 2 degrees around the fovea where the ILM was thinnest, and also to a few isolated spots in peripheral retina (Figure 9) (21, 106, 113, 114). A similar ring-shaped foveal transduction pattern has also been reported with intravitreal injected constructs targeting bipolar cells in primates (107). To reduce the ILM AAV diffusion barriers seen in old world primates eyes, injections of vitreolytic enzymes,

vitrectomies, with or without inner limiting membrane peels have been proposed (113, 115,116); however, these treatments may also reduce AAV construct attachment. This has caused others to advocate limited subretinal injections (<100μL) of AAV constructs (117, 118); however, these injections these may not be suitable for RP patients with advanced retinal disease (106). However even effective optogenetic transduction of the parafoveal retina could provide significant visual benefit in severely blind patients.

Gene expression patterns in a degenerate RP retina may differ from normal, resulting in ineffective AAV therapies. RP patients experience long periods of gradual visual loss that may take many years, unlike most blind rodent models. (See Webvision chapter on retinal degeneration). Although RP has traditionally been represented as a disease that causes loss of photoreceptors, these retinal degenerations also induce retinal remodeling and synaptic reorganization of many inner retinal neurons (119, 120). Inactive gene DNA may be methylated (121-123), which in the degenerate retina may produce gene inactivation/degradation in cells; reducing AAV promoter transduction efficiency, or cause off-target cellular gene expression (103, 124). This is particularly true of AAV therapies for OBCs, where in cultured human retinal explants, transduction by an 4XGrm6 promoter construct was not OBC specific (124). More specific OBC promoters may be required for transducing human retina (107). How these promoter expression patterns change in OBCs in degenerate human RP patients is currently unknown, and may only be revealed by clinical trials.

Table II.

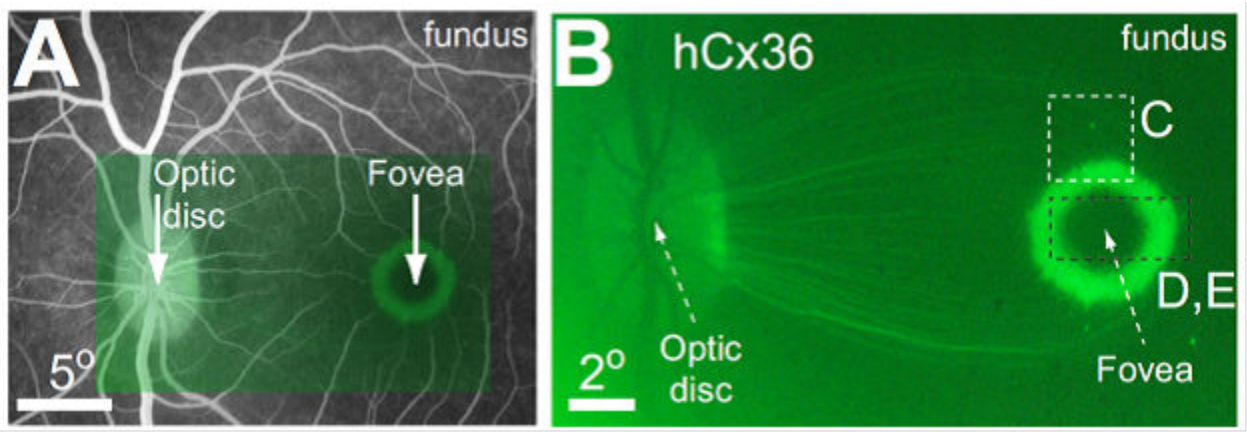

Figure 9. Viral transduction pattern by an intravitreal injection of an AAV capsid in the primate eye. A. Fluorescein angiogram showing retinal location of fluorescent image in B. Transduction of the AAV2/2 hCx –GFP labeled construct occurs in inner retinal neurons especially the ganglion cells. A ring-shaped transduction pattern is observed as the perifoveal inner limiting membrane (ILM) is thin, allowing better capsid entry (Connexin 36 (hCx) from Yin et al. 2011 IOVS) (113) (with permission).

Retinal prosthetic stimulation safety

Patients using retinal prostheses in daily life expose their retinal tissue to chronic stimulation conditions. There are limits to the amount of electrical current and light that can be safely tolerated by the retinal tissue. A variety of methods have been developed to assess the retina under stimulation electrodes and to study retinal function by using funduscopes, fluorescence, optically transparent stimulus electrodes and/or optical coherence tomography (125-127). Excessive electrical stimulation can cause electroporation of retinal neurons and glia cells. Overstimulation near the epiretinal surface can cause swelling of the Müller cell end feet lining the ILM, and ganglion cell death (Video 10, Figure 10) (125). However, chronic electrical stimulation damage limits (Hrs.) for the retina are less well defined, may be location specific, and sensitive to tissue proximity (126-129).

For prostheses using light stimulation to excite retinal neurons, standards exist to limit the retinal exposure of normally sighted patients to excessive UV and blue light. RP patients often complain of being sensitive to excess light and glare, while the retinae of RP animal models are very sensitive to light injury by long funduscopic illumination (130). Many earlier ChR-based optogenetic therapies rely on high retinal fluxes of short wavelength light by the camera-projector glasses to provide adequate ChR channel activation of the transduced retinal neurons. However, newer ChRs and G-protein opsins have been developed with sensitivities shifted to longer wavelengths and with higher light sensitivity (Figure 8, C).

Light can damage the retinal layers both thermally and photochemically. Standards for safe levels of illumination of healthy retina at different wavelengths were based on primate eye exposure data by Ham (131, 132), and earlier studies by Noell in rats (133). These studies and others have been adapted into a series of international standards (ANSI Z80.36, ISO15004, ISO 60825 , Rp27.1) among others for ophthalmic devices. Most of these light safety studies relied on photoreceptor-induced light injury as the damage endpoint (134,135). It is currently unresolved how much light can be safely tolerated by the remaining retinal neurons in end-stage RP animal models and patients, with their degenerate photoreceptors and pigment epithelium cells.

Conclusions

There are exciting new developments in retinal prosthetic therapies that use electrical and optogenetic stimulation that have the potential to provide better form vision and improve the quality of life for the severely visually impaired. Each technology presents different challenges and benefits for biological integration into the blind patient's degenerate retina. Coupling and replacing the lost retinal neurons in the central fovea remains a challenge for both electronic and optogenetic combination therapies. There are many common issues involved in the real-world assessment of patient visual benefit from these novel medical technologies. Given the heterogeneity of RP as a disease, the availability of multiple therapies may be useful for patients, each offering different advantages for their type of retinal degeneration and its degree of progression.

About the author

Dr. Cohen received his Ph.D. in the retina lab of Dr. Peter Sterling at the University of Pennsylvania in 1987. After postdoctoral training in physiology at the University of Minnesota with Dr. Robert Miller, and at the UCLA Jules Stein Eye Institute with Dr. Gordon Fain, he joined the faculty of the Department. of Ophthalmology at Yale University Medical School as a retinal neurophysiologist in 1992. In 2000, he was a visiting professor in the Department of Molecular and Cellular Biology at Harvard University with John Dowling. Since 2003, he is a research scientist at the Office of Science and Engineering Labs at the Center for Devices and Radiological Health at FDA. His research interests include devising new methods to evaluate the safety and effectiveness of visual neurostimulation devices and improving the detection of neurotoxic drugs.

Facts and Figures Concerning the Human Retina

Facts and Figures Concerning the Human Retina

Helga Kolb

Created: May 1, 2005; Updated: July 5, 2007.

Size of the Retina

- 32 mm from ora to ora along the horizontal meridian (1) (Kolb, unpublished measurements).
- The area of the human retina is 1,094 square mm (Bernstein, personal communication), calculated from the expectations that the average dimension of the human eye is 22 mm from anterior to posterior poles, and that 72% of the inside of the globe is retina (2). See also Penkhus (3).

Size of Optic Nerve Head or Disc

- 1.86 × 1.75 mm (Fig. 1)

Degrees and Distance in Micometers

- One degree of visual angle is equal to 288 µm on the retina without correction for shrinkage (4).

Foveal Position

- 11.8° or or 3.4 mm temporal to the optic disk edge

Cross Diameter of the Macula

- 3 mm of intense pigmentation, surrounded by a 1-mm-wide zone of less pigmentation (5).

Cross Diameter of the Central Fovea from Foveal Rim to Foveal Rim

- 1.5 mm (5)
- 1.2-1.5 mm (Ahnelt and Kolb, unpublished data) (Fig. 2a and Fig. 2b)

Cross Diameter of Central Rod-free Area

- 400-600 µm (5)
- 750 µm (6)
- 570 µm (7)
- 250 µm (8)

Vertical Thickness of the Fovea from Inner Limiting Membrane (ILM) to ELM

- in the foveal pit, 150 µm (7)
- foveal rim, 400 µm

Central Region of Fovea Where There Are No Cone Pedicles

- 250 µm (7)
- 200 µm (6)

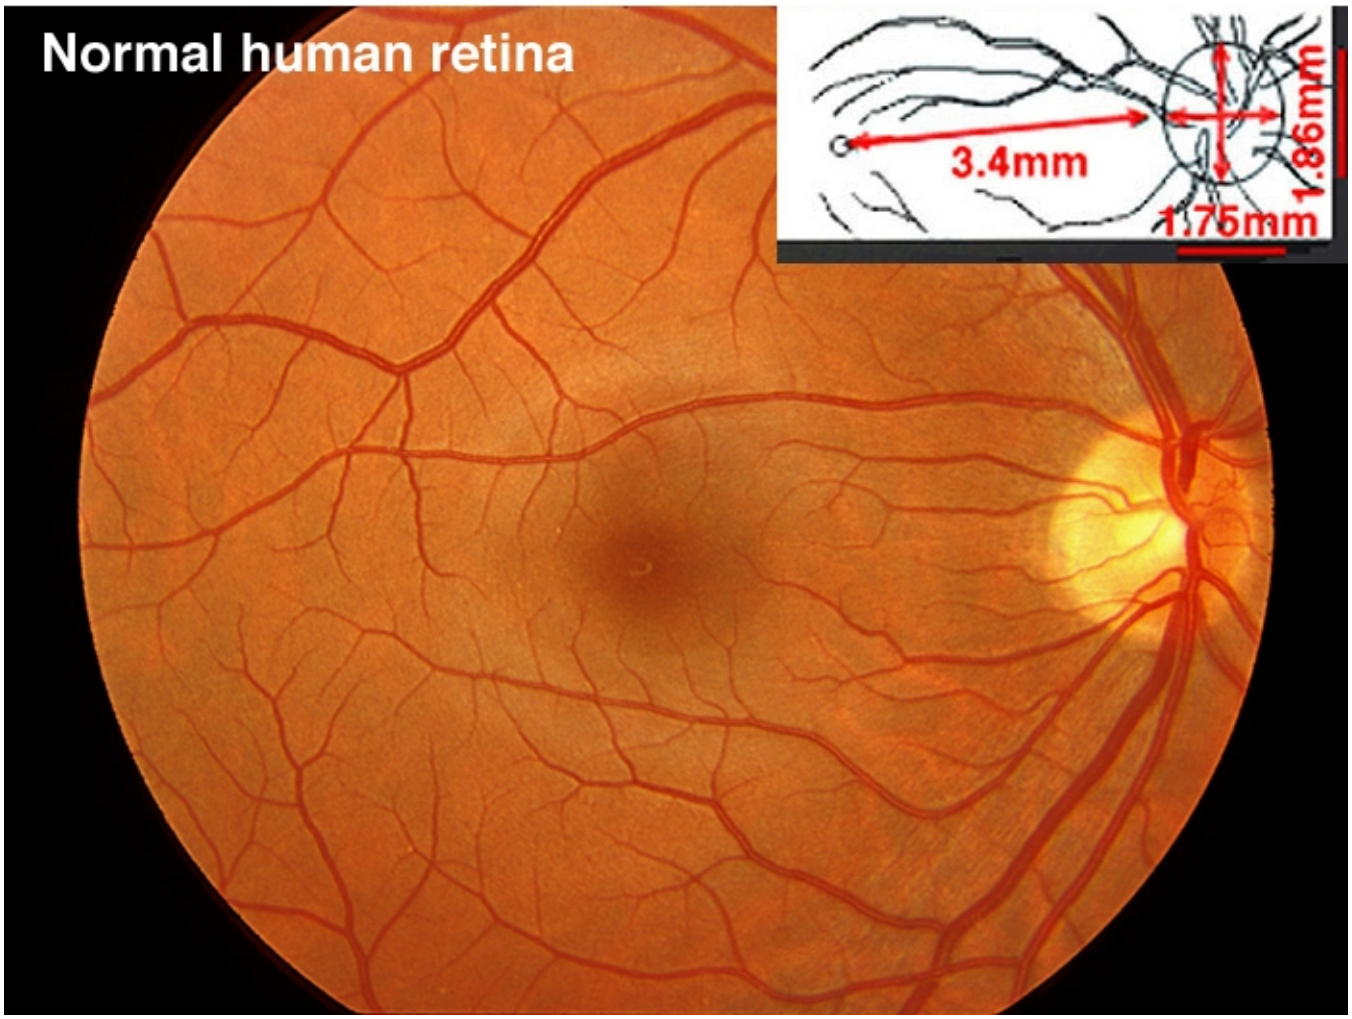

Figure 1. Topography and dimensions of optic nerve and fovea.

- 300 µm (9)

Length of Foveal Axons (Henle Fibers)

- 150-300 µm (9)

Vertical Thickness of the Retina in Different Areas

The vertical extent of the retina across the horizontal meridian at different eccentricities is shown in Fig. 3. This is taken from data given by Sigelman and Ozanics (20). The small black numbers are the originals from Sigelman and Ozanics which were measured in typical histological preparations where there is a great deal of shrinkage. The figures in red are those recently measured by Ahnelt (personal communication) in well fixed EM quality material where there is little or no shrinkage. Hence the latter numbers are larger. The numbers are in mm.

Age When Fovea Is Fully Developed

- not before 4 years of age (6)

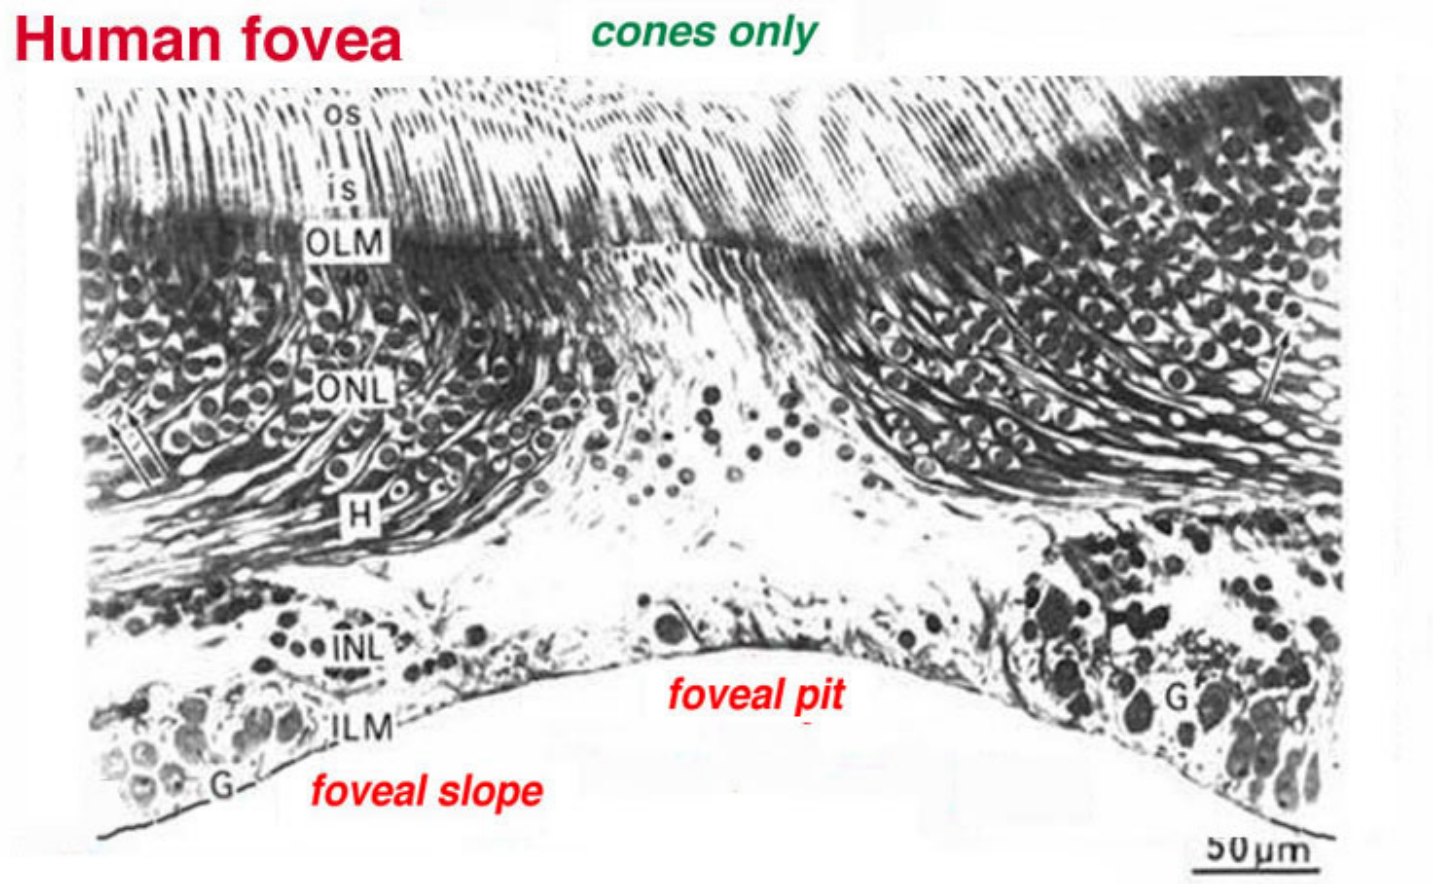

Figure 2a. Vertical section of the human fovea. os, outer segments; is, inner segments; OLM, outer limiting membrane; ONL, outer nuclear layer; H, Henle fibers; INL, inner nuclear layer; ILM, inner limiting membrane; G, ganglion cells. From Yamada (7).

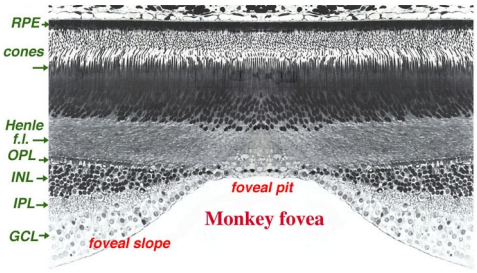

Figure 2b. Vertical section of the monkey fovea. From Hagerman and Johnson (19).

Highest Density of Cones at Center of the Fovea (50 × 50 µm)

- 147,000/mm^2 (10)
- 178,000-238,000/mm^2 (8)
- 96,900-281,000/mm^2; mean, 161,900/mm^2 (11) (Fig. 4)

Total Number of Cones in Fovea

- approximately 200,000. 17,500 cones/degree^2. Rod-free area is 1°; thus, there are 17,500 cones in the central rod-free fovea.

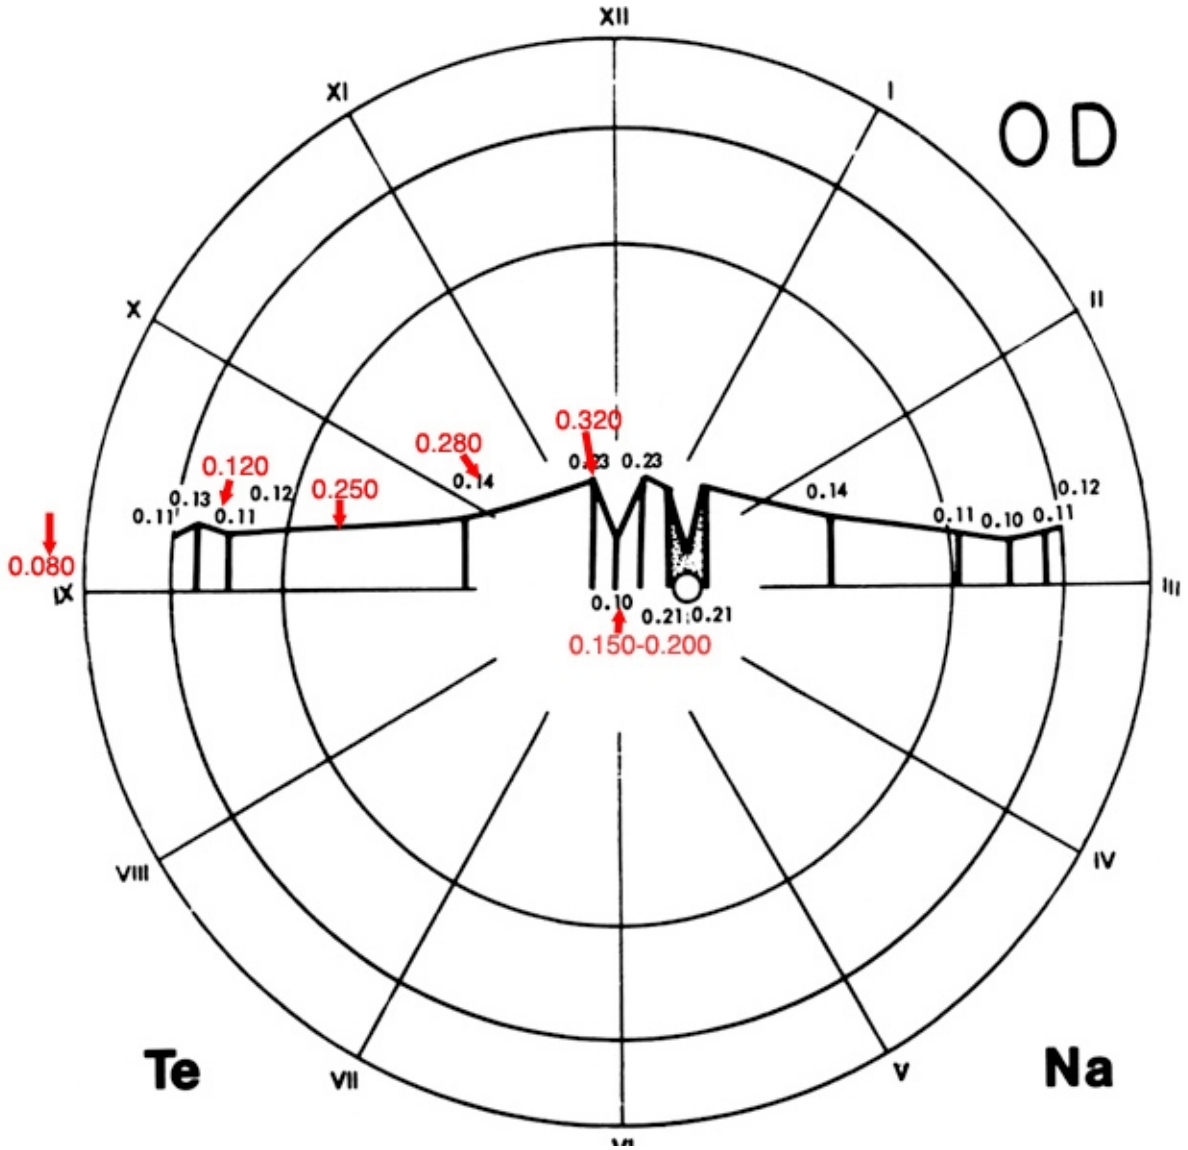

Figure 3. The retinal thickness shows greatest variations in the center. The retina is thinnest at the foveal floor (0.10, 0.150-0.200 mm) and thickest (0.23, 0.320 mm) at the foveal rim. Beyond the fovea the retina rapidly thins until the equator. At the ora serrata the retina is thinnest of all (0.080 mm).

Total Number of Cones in the Retina

- 6,400,000 (10)

Total Number of Rods in the Retina

- 110,000,000 to 125,000,000 (10)

Rod Distribution

- Rods peak in density 18° or 5 mm out from the center of the fovea, in a ring around the fovea at 160,000 rods/mm^2
- No rods in central 200 μm
- Average 80-100,000 rods/mm^2.

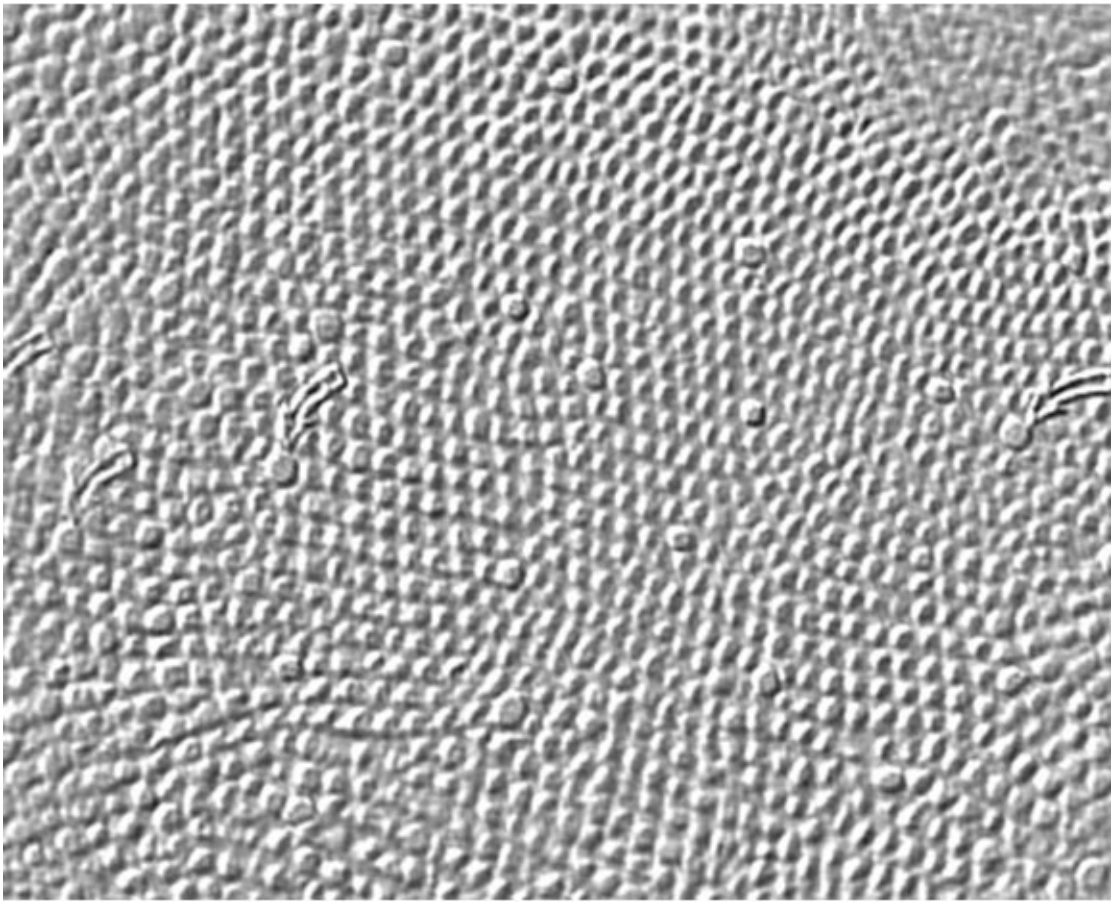

Figure 4. Tangential section through the human fovea. Larger cones (arrows) are blue cones.

- Rod acuity peak is at 5.2° or 1.5 mm from foveal center, where there are 100,000 rods/mm^2 (12) (Fig. 5)

Number of Axons in the Optic Nerve

- 564,776-1,140,030 (13)
- 800,000-1,000,000 (5)
- 1,200,000 (14, 15)

Number of Cones to Ganglion Cells in the Fovea

- 1 cone to 2 ganglion cells out to about 2.2° (16)

Number of Cones/Retinal Pigment Epithelial Cell (RPE)

- 30 cones/RPE in fovea (17)

Number of Rods/Retinal Epithelial Cell (RPE)

- in periphery, 22 rods/RPE cell
- in rod, peak (4-5 mm from foveal center), 28 rods/RPE cell (17)

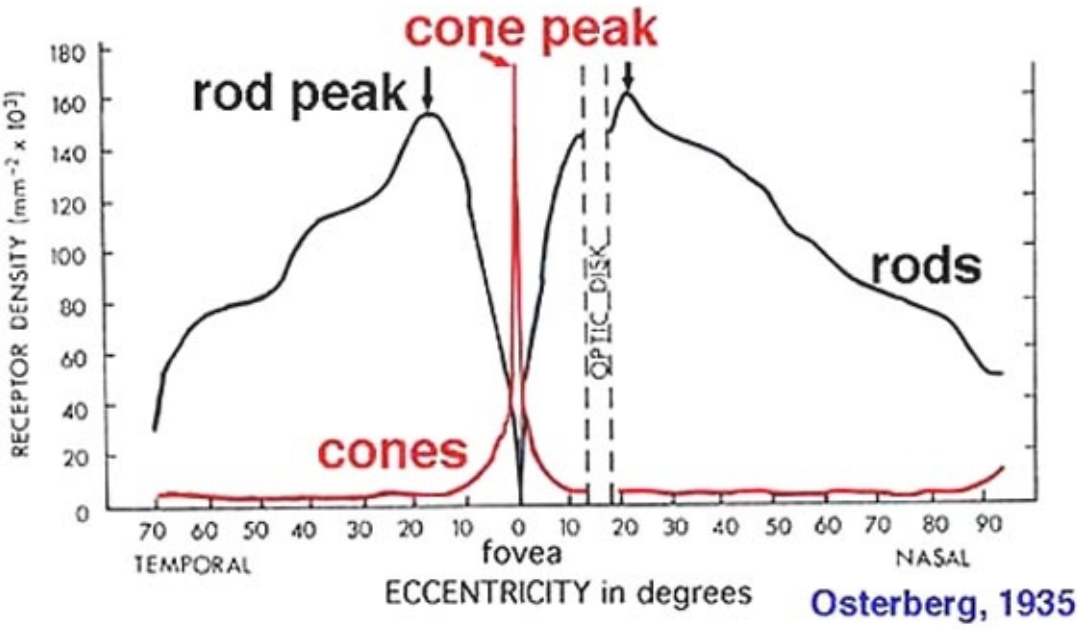

Figure 5. Graph to show rod and cone densities along the horizontal meridian.

Number of Neural and Glial Types in the Retina

The retina consists of many millions of cell types packed together in a tightly knit network spread over the surface of the back of the eye fundus as a thin film of tissue only 1/2 millimeter thick. The retina is like a three-layered cake with three layers containing cell bodies of neurons and two filling layers where synapses between the neurons occur. There are two basic kinds of photoreceptors—rods and cones. The cones are further subdivided into two types (long- and short-wavelength sensitive) in the majority of mammals, i.e., most mammals, which are dichromats and have divariant color vision. In primates, a third wavelength-sensitive cone has developed closely related to the long-wavelength cone type but a little more sensitive in the middle wavelength (i.e., green cone). Thus, primates including humans are trichromats and have trivariant color vision. Many reptiles, birds, and fish have four or even five types of cone, each sensitive to a slightly different peak wavelength.

The second-order neurons, postsynaptic to the photorecepors in the first synaptic (filling layer) (outer plexiform layer), are bipolar cells and horizontal cells. There are nine types of bipolar cell and two to four types of horizontal cell in species from mammals to fish. The third-order neurons are amacrine cells and ganglion cells that synapse in the inner synaptic filling layer (inner plexiform layer). There are two types of interplexiform cells stretching between both plexiform layers, in most vertebrate retinas. There are approximately 22 types of amacrine cell and 20 types of ganglion cell in the typical mammalian retina. There may be 30 or more amacrine cell types in fish and reptilian retinas and 22 or so ganglion cell types. The increased number of third-order neurons is attributable to the greater information processing taking place in the non-mammalian retinas than in mammalian retinas.

All vertebrate retinas also contain large numbers of glial cells. The radial Muller cells stretch from outer to inner limiting membranes and surround and isolate all neural cell types from each other except at synapses. Microglia arise in times of injury and are blood-borne cell types. Astrocytes surround ganglion cell axons and inner retinal blood vessels.

Fig. 6 shows a drawing of the human retina close to the fovea, where all of the cell types that have been studied in detail are depicted in their intricate and marvellous network.

Useful Units in Vision Science

From Wandell (18):

- Radiometric units represent a physical measurement, e.g., radiance is measured in watts sr^{-1} m^{-2}.
- Calorimetric units adjust radiometric units for visual wavelength sensitivity, e.g., luminance is measured in candela per square meter, cd/m^2.
- Lux are units of illumination. Thus, a light intensity of 1 candela produces an illumination of 1 lux at 1 meter.
  - Scotopic luminance units are proportional to the number of photons absorbed by rod photoreceptors to give a criterion psychophysical result.
  - Photopic luminance units are proportional to a weighted sum of the photons absorbed by L- and M-cones to give a criterion psychophysical result.
- Typical ambient luminance levels (cd/m^2):
  - Starlight: 0.001
  - Moonlight: 0.1
  - Indoor lighting: 100
  - Sunlight: 10.000
  - Maximum intensity of common CRT monitors: 100
- One Troland (Td) of retinal illumination is produced when an eye with a pupil size of 1 mm^2 looks at a surface whose luminance is 1 cd/m^2.
- Lens focal length: f (meters); lens power= 1/f (diopters).

Image Formation

From Wandell (18):

- The eyes are 6 cm apart and halfway down the head.
- Visual angle of common objects (degrees, deg)
  - The sun or moon = 0.5 deg
  - Thumbnail (at arm's length) = 1.5 deg
  - Fist (at arm's length) = 8-10 deg
- Visual field (measured from central fixation)
  - Monocular: 160 deg (w) × 175 deg (h)
  - Binocular: 200 deg (w) × 135 deg (h)
  - Region of binocular overlap: 120 deg (w) × 135 deg (h)
- Range of pupil diameters: 1-8 mm
- Refractive indices
  - Air: 1.000
  - Glass: 1.520
  - Water: 1.333
  - Cornea: 1.376
- Optical power (diopters)
  - Cornea: 43
  - Lens (relaxed): 20
  - Whole eye: 60
  - Change in power due to accomodation: 8

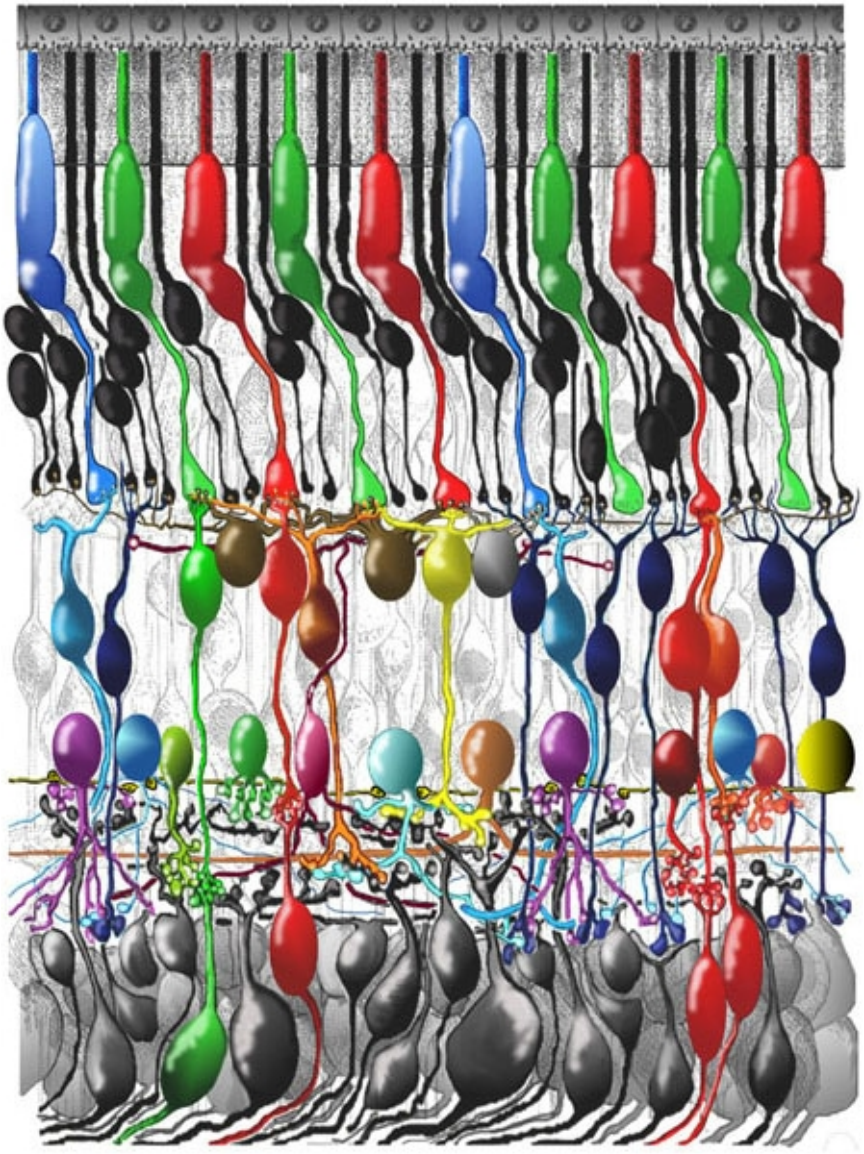

Figure 6. Drawing of a vertical section through the human retina to show the organization of the different neurons and glial cells constituting it.

- Axial chromatic aberration over the visible spectrum: 2 diopters
- Visible spectrum: 370-730 nanometers (nm)
- Peak wavelength sensitivity
  - Scotopic: 507 nm
  - Photopic: 555 nm
- Spectral equilibrium hues
  - Blue: 475 nm
  - Green: 500 nm
  - Yellow: 575 nm
  - No spectral equilibrium: red
